EDITED BY

GEORGE RIPLEY AND CHARLES A. DANA.

*WITH SUPPLEMENT.*

VOLUME XV.

SHOMER—TROLLOPE.

NEW YORK:
D. APPLETON AND COMPANY,
1, 3, AND 5 BOND STREET.
LONDON: 16 LITTLE BRITAIN.
1881.

*Among the Contributors to the Fifteenth Volume of the Revised Edition are the following:*

Prof. Cleveland Abbe, Washington, D. C.
Snow.
Storms.
Trade Winds.

Bvt. Brig. Gen. Henry L. Abbot, U. S. A., Willet's Point, N. Y.
Torpedo.

Hon. George Bancroft, Washington, D. C.
Southampton, Henry Wriothesley, Earl of.

Willard Bartlett.
Sinde.
Tanganyika.
Thibet.

Prof. C. W. Bennett, D. D., Syracuse University.
Soule, Joshua.
Strong, James.
Syracuse (University).

Julius Bing.
Sicilies,
Staël-Holstein, Baroness de,
Tasso, Torquato,
Thiers, Louis Adolphe,
and other articles in biography, geography, and history.

Hon. James Black, Lancaster, Pa.
Total Abstinence.

Francis C. Bowman.
Sivori, Ernesto Camillo.
Stradivari, Antonio.
Titjens, Therese.

Edward L. Burlingame, Ph. D.
Stuart, Arabella.

Rev. Charles P. Bush, D. D.
Smith, Eli.
Syria (in part).

C. H. Carter, Waterbury, Conn.
Town (in part).

Robert Carter.
Stevens, Thaddeus.
Story, Joseph.
Sumner, Charles.
Taylor, Zachary.

John D. Champlin, Jr.
Shomer, Jebel,
Siberia,
Slang,
Spain,
Sweden,
and other articles in biography and geography.

Prof. E. H. Clarke, M. D., Harvard University.
Squill,
Strychnia,
and other articles in materia medica.

Hon. T. M. Cooley, LL. D., University of Michigan, Ann Arbor.
Slavery (in part),
Taney, Roger Brooke,
Taxes,
and other legal articles.

Prof. E. Curtis, M. D., College of Physicians and Surgeons, New York.
Spectacles.

Rev. S. S. Cutting, D. D.
Slater, Samuel.

Prof. J. C. Dalton, M. D., College of Physicians and Surgeons, New York.
Smell,
Stomach,
Taste,
Thorax,
and other medical and physiological articles.

Rev. B. B. Drake.
Theophylact, Simocatta.
Theophylact, Archbishop.

Prof. M. J. Drennan.
Siemens, Ernst Werner.
Siemens, Karl Wilhelm.
South Sea Scheme.

Eaton S. Drone.
South Carolina,
Strauss, Family of,
Tennessee,
Trade Mark,
and other articles in American geography.

Prof. Thomas M. Drown, M. D., Lafayette College, Easton, Pa.
Steel.

Robert T. Edes, M. D., Harvard University.
Articles in materia medica.

W. M. Ferriss.
Targums,
Trigonometry,
and articles in biography and history.

Prof. Willard Fiske, Cornell University, Ithaca, N. Y.
Sweden, Language and Literature of (in part).

Joseph Fitzgerald.
Silk.
Stocking.
Straw.

Lieut. Com. Henry H. Gorringe, U. S. N., Washington, D. C.
Tarragona.
Teneriffe.
Tristan da Cunha.

Prof. W. E. Griffis, late of the Imperial College, Tokio, Japan.
Tokio.
Tomomi Iwakura.

Prof. James Morgan Hart.
Tell, William.

J. W. Hawes.
Springfield, Mass., Ohio, Ill., and Mo.,
Texas,
Trenton, N. J.,
and other articles in American geography.

Louis Heilprin.
States General.
Thirty Years' War.

M. Heilprin.
Slavonia.
Taurus.
Thrace.

Prof. Joseph Henry, LL. D.
Smithson, James.
Smithsonian Institution.

G. A. Hewlett, Shreveport, La.
Shreveport.

Prof. J. E. Hilgard, U. S. Coast Survey, Washington, D. C.
Tides.

Thomas Hitchcock.
Swedberg, Jesper.
Swedenborg, Emanuel.

Charles L. Hogeboom, M. D.
Sodium.
Sulphur.
Sulphuric Acid.

Prof. Thomas Henry Huxley, LL. D., Royal School of Mines, London.
Species.

Lieut. Henry Jackson, U. S. A., Office of Chief Signal Officer, Washington, D. C.
Signal Service.

Rossiter Johnson.
Tennyson, Alfred,
Thackeray, William Makepeace,
and other articles in literary biography.

Prof. C. A. Joy, Ph. D., Columbia College, New York.
Silicon,
and other chemical articles.

Joseph C. G. Kennedy, LL. D., Washington, D. C.
Shubrick, William Crawford.

Prof. S. Kneeland, M. D., Mass. Inst. of Technology, Boston.
Silkworm,
Stag,
Swallow,
Tortoise,
and other articles in zoölogy.

Prof. S. P. Langley, Allegheny Observatory, Allegheny, Pa.
Sun (in part).

Charles Lindsey, Toronto, Canada.
Toronto.

Prof. Joseph Lovering, Harvard University.
Telegraph (in part).

Capt. S. B. Luce, U. S. N., U. S. Navy Yard, Boston.
Signals, Naval.

Prof. Alfred M. Mayer, Stevens Inst. of Technology, Hoboken, N. J.
Sound.
Spectrum.
Stereoscope.

Rev. Andrew B. Morse, Danbury, Conn.
Siam (in part).

Rev. Franklin Noble.
Spurgeon, Charles Haddon,
Sunday Schools,
Thanksgiving Day,
Tract and Publication Societies,
and articles in biography and geography.

Rev. Bernard O'Reilly, D. D.
Sisterhoods, Roman Catholic,
Syllabus,
Trappists,
and other articles in ecclesiastical history.

Prof. S. F. Peckham, University of Minnesota, Minneapolis, Minn.
Tallow.
Tar (in part).

Edward T. Peters, Bureau of Statistics, Washington, D. C.
Trades Union.

Richard A. Proctor, A. M., London.
Spectrum Analysis,
Star,
Sun (in part),
Telescope (in part),
Transit (in part),
Transit Circle (in part),
and other astronomical articles.

Prof. Rossiter W. Raymond, Ph. D., Editor of the "Engineering and Mining Journal."

Spencer, Herbert.

# THE AMERICAN CYCLOPÆDIA.

**SHOMER, Jebel,** an inland division of Arabia, between lat. 25° 40′ and 32° N., and lon. 37° 20′ and 47° 20′ E., bounded N. by the Syrian desert, N. E. by Irak Arabi, S. E. and S. by the Wahabee sultanate, and W. by Turkish Arabia. It is divided into the provinces of Jebel Shomer, Jowf, Kheybar, Upper Kasim, and Teyma, with a total population estimated by Palgrave in 1862 at 440,000, including 166,000 nomadic Bedouins. Jebel Shomer in its general aspect is a flat table land, a large part of which is desert, with occasional oases. These are merely depressions in the desert surface, and take sometimes the form of a long valley covered with a thin soil, under which water may generally be found at the depth of a few feet. Fruits, bushes, herbs, and coarse grass grow in sufficient quantities to supply food for the Bedouins and their camels and flocks. The entire N. portion is covered by a rocky desert. On the E. border, about lat. 31°, is a long valley, called Wady Sirhan or Serhan (valley of the wolf), which extends from near Bozrah in Syria in a S. E. direction to about lat. 29° 20′ in Arabia, where its base rests on Wady Jowf, a deep valley lying E. and W., and which may be considered the porch or vestibule of central Arabia. (See Jowf.) The Wady Sirhan is the common route for caravans to and from Syria. S. and E. of Jowf lies a wide expanse of sandy desert. The caravan route to the province of Jebel Shomer lies across this waste in a S. E. direction through what is called the Nefud or Sand pass, consisting of parallel ridges of loose reddish sand 200 to 300 ft. high, where no water can be obtained for nearly 100 m. The route runs beside a small range of hills called Jebel Jobbah, a cluster of black granite rocks streaked with red, about 700 ft. high. Beyond them, on the south, is a barren plain, partly white and incrusted with salt, partly green and studded with palm groves, among which is the small village of Jobbah. From the heights overlooking Jobbah are visible in the southeast the main range of Jebel Shomer, and in the southwest the palm groves of Teyma, famed in Arab history, and supposed by some to be identical with the Teman of Scripture. Beyond Jobbah the undulations are not so deep, and the sand has occasional shrubs and tufts of grass. The plain gradually rises as it approaches the mountain ranges, which, stretching N. E. and S. W., cross two thirds of upper Arabia. These ranges, Jebel Adja on the north, the mountains of Upper Kasim on the south, and Jebel Solma between, lie nearly parallel, and are separated by broad plains covered with grass and shrubbery. Within their limits is the chief centre of population of Shomer. Hayel, the capital, lies in an extensive plain between Adja and Solma, girt on every side by a high mountain rampart. The only approach from the north is by a narrow winding defile through Jebel Adja, which 50 men could defend against thousands. The range of Jebel Adja, or Jebel Shomer as it is now more generally called, is a ragged granitic mass, piled up in fantastic disorder, attaining at times an elevation of 1,400 ft. above the plain, but Solma does not rise more than 700 or 800 ft. Good crops of grain, fruits, and vegetables are raised by a laborious system of artificial irrigation. The date is the principal fruit. There is a considerable trade by caravans between Hayel and Medina on the southwest, and Riyad, the capital of Nedjed, on the southeast. Many horses and asses are exported. Upper Kasim, the southernmost province of Shomer, is an elevated plateau, forming part of a long upland belt that crosses diagonally the northern half of the peninsula, one extremity reaching nearly to Zobeyr, near the head of the Persian gulf, and the other to the neighborhood of Medina. Its surface is covered with shrubs and brush-

wood, and in spring and summer with grass. This great plateau is intersected at intervals by long broad valleys, which contain villages built around wells, surrounded by palm groves, gardens, and fields, and varying in population from 500 to 3,000. Dates are exported in large quantities to Yemen and Hedjaz, and cotton is raised to a small extent.—The sultanate of Jebel Shomer originated in the present century. In 1818 Abdallah, an ambitious chief of the family Rashid, was driven out of Hayel by his rival Beyt Ali, who assumed the sovereignty. Abdallah took refuge at the court of the Wahabee monarch, who was then reconstructing his father's dominions, and for his services to him was made absolute governor of Shomer, with right of succession, and supplied with the means to establish his rule. Beyt Ali and his family were cut off, and Abdallah made himself master of the whole mountain district. He died about 1845, and was succeeded by his son Telal, who extended his dominions, subdued the Bedouins, invited trade from abroad, and established law and order. Under his rule the country has made rapid advances in civilization and prosperity, and has become virtually independent.

**SHOOTING STARS.** See METEOR.

**SHORE, Jane**, an English woman, the wife of Matthew or William Shore, a goldsmith in London, and mistress of King Edward IV. She was beautiful and amiable, and Sir Thomas More says that the king's favor "she never abused to any man's hurt, but to many a man's comfort and relief." After the death of the king she became attached to Lord Hastings; and when Richard III. had resolved on the destruction of that nobleman, he accused Jane Shore of witchcraft and of having withered his arm by sorcery. The king, though he sent her to prison and confiscated her goods, did not attempt to maintain his charge of witchcraft; but the bishop of London caused her to do public penance for impiety and adultery. After the death of Hastings, Thomas Lynom, the king's solicitor, desired to marry her, but was prevented by the king. She lived till the time of Henry VIII., and tradition represents her as dying of hunger in a ditch. A celebrated tragedy by Rowe is founded on her story.

**SHOSHONE**, the N. county of Idaho, bounded S. by the Clearwater river, and intersected in the north by Clarke's fork of the Columbia and the Kootenay river; area, about 12,000 sq. m.; pop. in 1870, 722, of whom 468 were Chinese. It is watered by tributaries of the Clearwater river and by the Spokane river, and contains Cœur d'Alène and Pend d'Oreille lakes. The surface is mountainous. There is fertile land around the lakes and along the streams. Timber is abundant, and there are extensive placer gold mines. Capital, Pierce City.

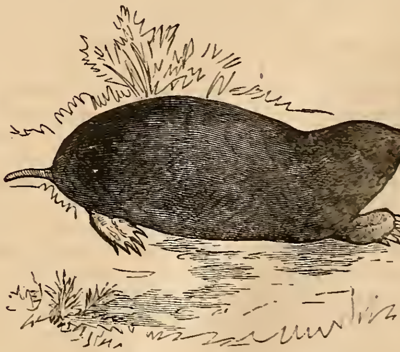
**SHOSHONES**, or **Snakes**, a family of North American Indians, embracing the Shoshones proper, the Utes, Comanches, Moquis, Chemehueves, Cahuillo, and the Kechi, Kizh, and Netela of California. The Shoshones proper are a large and widespread people. According to their tradition, they came from the south, and when met by Lewis and Clarke in 1805 they had been driven beyond the Rocky mountains. The various Shoshone bands have gone by numerous names. The most important were the Koolsatikara or Buffalo Eaters, who have long defended their homes on Wind river, and the Tookarika or Mountain Sheep Eaters, a fierce tribe in the Salmon river country and upper Snake river valley. The western Snakes near Fort Boisé were separated from the others by the kindred Bannacks. The Shoshocos (footmen), called also White Knives, from the fine white flint knives they formerly used, were digger tribes on Humboldt river and Goose creek, and included apparently most of those in the basin of Great Salt lake. These bands were generally mild and inoffensive, lurking in the mountains and barren parts, and having little intercourse with the whites. About 1849 they were in open war, and the peace made with some of the bands at Salt Lake, in September 1855, did not end it. In 1862 California volunteers, under Col. Connor, nearly exterminated the Hokandikah or Salt Lake Diggers in a battle on Bear river. Waushakee's and other bands of the Koolsatikara Shoshones made peace at Fort Bridger, July 2, 1863; Pokatello's and other bands of the Tookarika at Box Elder, July 30; the Shoshoco or Tosowitch at Ruby valley, Oct. 1; and the Shoshones and Bannacks at Soda Springs, Oct. 14. In 1864 the Yahooskin Snakes made peace, and with the Klamaths and Modocs ceded their lands; and on Aug. 12, 1865, the Wohlpapes also submitted. The government did not promptly carry out these treaties, and many of the bands renewed hostilities. In 1867, in the campaign of Gen. Steele, a number of Indians were killed, and immense stores of provisions laid up by the Shoshones were destroyed. Gen. Augur at last allowed them to come in and make peace at Fort Bridger. The government then attempted to collect the whole nation and restrict the Shoshone bands to certain reservations. The Yahooskin and Wohlpape Snakes had prospered on the Klamath reservation, although their crops frequently failed. The Fort Hall reservation in Idaho was begun in 1867 for the Bannacks, and several bands of Shoshones, about 1,200 in all. The Shoshone reservation in Wyoming, set apart under treaty of July 3, 1868, for Waushakee's and other bands of eastern Shoshones and Bannacks, is exposed to attacks from the Sioux, and only about 800 have united there. There are also the northwestern Shoshones in Nevada and Utah, estimated at from 2,000 to 3,000, and a band of 400 in the N. W. part of Idaho.—Vocabularies have been obtained from various bands of the Shoshones, but no critical study of their language has appeared. The Episcopalians have a mission on the reservation in Wyoming.

**SHOT.** See Lead, vol. x., p. 262.

**SHOVELLER.** See Duck, vol. vi., p. 289.

**SHREVEPORT,** a city and the capital of Caddo parish, Louisiana, in the N. W. corner of the state, on the W. bank of Red river, at the head of low-water navigation, 330 m. above its mouth according to Humphreys and Abbot, or 500 m. by local authorities; pop. in 1870, 4,607, of whom 2,168 were colored. It has since been enlarged, and the population in 1875 was locally estimated at 12,000. It contains many handsome residences and substantial business structures, is lighted with gas, and has a good fire department and several miles of street railroad. The principal public buildings are the new market, costing $50,000; the Presbyterian church, costing $35,000; and the synagogue, a fine specimen of architecture. The surrounding country is very productive, and the climate is mild and generally healthful. Shreveport is the E. terminus of the Texas and Pacific railroad, which affords an all-rail route to St. Louis *via* Marshall, Tex. Steamers run regularly to New Orleans and intermediate points on the Red and Mississippi rivers. The trade is extensive and increasing, the value of shipments amounting to about $7,500,000 a year, and the sales of merchandise to about $7,000,000. The shipments of cotton average 100,000 bales annually, including about 20,000 bales from the upper Red river reshipped at this point. The transactions in hides, wool, and tallow are also considerable. The principal manufactories are two of carriages, one each of cotton gins, cotton-seed oil, sash and blinds, and spokes and hubs, three founderies and machine shops, a planing mill, two saw mills, and three breweries. There are three private banks, two public schools (one for white and one for colored children), nine private and denominational schools and academies, two daily and weekly newspapers, and eleven churches (Baptist, Episcopal, Jewish, Methodist, Presbyterian, and Roman Catholic), of which five are for colored people. Shreveport was incorporated in 1839.

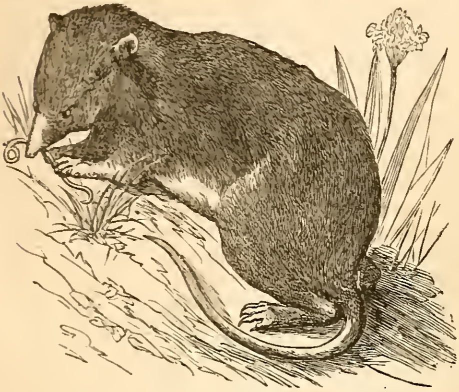
**SHREW, or Shrew Mouse,** the common name of the insectivorous mammals of the family *soricidæ*, characterized by a general rat-like or mouse-like appearance, elongated and pointed muzzle, and soft fur. The distinct auricle of the ears, and the normal size of the anterior feet, not usually employed in digging, distinguish them from the moles. The skull is long and narrow, compressed at the orbits, malar bone and zygomatic arch wanting; the ribs are 12 to 14 pairs, 6 to 8 vertebræ without ribs, 3 to 5 sacral, 14 to 28 caudal; tibia and fibula united, clavicles thin, and pubic arch closed; stomach simple; cæcum in some absent, in others very large; on the sides of the body, nearest the anterior limbs, and in some at the base of the tail, is a series of glands which secrete a strong musky fluid. The teeth vary from 28 to 32; there are two very large incisors in each jaw, nearly horizontal in the lower and much curved in the upper; canines absent; premolars $\frac{3-3}{2-2}$ to $\frac{4-4}{2-2}$, molars $\frac{3-3}{3-3}$; the posterior molars are many-pointed, and the anterior ones conical; the precise homologies of the cheek teeth have been the subject of much controversy. The snout ends in a naked muffle with the nostrils pierced on the sides; eyes very small, ears distinct, and feet nearly plantigrade and usually naked beneath; mammæ six to ten; feet five-toed, each with a claw. Their food consists of insects, worms, and mollusks, though they sometimes destroy small vertebrates and devour each other; they are nocturnal, more or less aquatic, do not hibernate, and the young are born blind and naked; most of the species live on the surface of the ground, and a few in burrows. They are spread over the northern hemisphere, sometimes going very far north, and the smaller species enduring severe cold. The subfamily *soricinæ* is the only one represented in North America; other subfamilies are found in south and central Africa, Asia, the East Indies, and Europe; none as yet have been detected in South America.—Of the American genera, *neosorex* (Baird) has rather short ears, partly furred on both surfaces; teeth 32; tail longer than body and head, and hairs of equal length except a tuft at the tip; feet very large, with a fringe of ciliated hairs; muzzle very slender. In the genus *sorex* (Linn.), which contains a great part of the species of the new and old worlds, the ears are large and valvular, the tail about as long as the body, and the feet moderate and not fringed; it is divided into two sections, one with 32 and the other with 30 teeth, most of the American species belonging in the former. Prof. Baird describes 12 species in vol. viii. of the Pacific railroad reports, varying in length from 3 to 4½ in., of which the tail is about one half, ranging from blackish and brownish to grayish above and lighter to whitish below. The *S. personatus* (Geoffr.) is the least of the American shrews, and among



Mole Shrew (Blarina talpoides).

the smallest of the quadrupeds of this country, being not quite 3 in. long; it belongs in the S. Atlantic states. Most of the species belong on the Pacific coast or in the N. W. territories.

In the genus *blarina* (Gray) the body is stout; the tail shorter than the head, with short bristly hairs and small brush at tip; the hands large in proportion to the feet, and the soles usually hairy at the heels; skull short and broad; ears very short, with the external surface densely furred. This genus, peculiar to America, is also divided into sections, one with 32, the other with 30 teeth. The mole shrew (*B. talpoides*, Gray), the largest of the American shrews, 4½ in. long, is found from Nova Scotia to Lake Superior, and south to Georgia; it is



Common European Shrew (Sorex araneus).

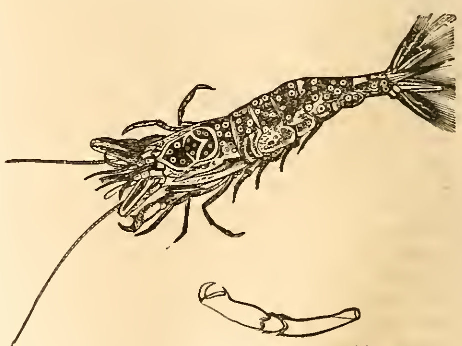
dark ashy gray above and paler below, with whitish feet. Several other species are described by Baird, of which two are in Mexico and Texas. In the old world, among the species of *sorex*, subdivided into several by Wagler, and called *musaraignes* by the French, is the common European shrew (*S. araneus*, Linn.), 4½ to 5 in. long, of which the tail is 1½ in.; the color is reddish mouse above and grayish below; it is found in dry places very generally over Europe.—The shrews appear during the miocene age in small numbers, and continue through the diluvial epoch to the present time, without material change.

**SHREW MOLE.** See MOLE.

**SHREWSBURY,** the shire town of Shropshire, England, on the river Severn, 140 m. N. W. of London; pop. in 1871, 23,406. The remains of the ancient castle are still standing, and also a portion of the ancient walls of the city. The Severn is crossed by two bridges; there is a canal, and railways connect it with all parts of the kingdom. Shrewsbury is the seat of a Roman Catholic bishop, and in 1872 had 32 places of worship. The principal manufactures consist of thread, linen yarn, and canvas; and there are extensive iron works at Coleham, a suburb. The salmon fishery of the Severn is valuable. There is a considerable trade in Welsh flannels.—Shrewsbury was important in the 5th century, and is prominent in English history as a royal residence for short periods. Its original name of Pengwern was changed by the Saxons to Scrobbesbyrig (Scrubsborough), of which Shrewsbury is a corruption. Parliaments were held here in 1283 and 1398; and a battle was fought here in 1403 between the royalist troops and the insurgents under Douglas and Hotspur, in which the latter was killed. (See PERCY.)

**SHRIKE.** See BUTCHER BIRD.

**SHRIMP,** a common decapod or ten-footed and long-tailed crustacean, of the genus *crangon* (Fabr.); with the prawn (*palæmon*) it is called *crevette* by the French. The integument is corneous, the carapace considerably flattened, the abdomen very large, and the tail powerful; the rostrum very short; eyes large and free; antennæ inserted about on the same transverse line, the internal pair the shortest and ending in two many-jointed filaments, the outer larger and longer; mandibles slender and without palpi; jaw feet moderate, with a terminal flattened joint and a short palpus on the inside; sternum very wide behind; first pair of feet strong, ending in a flattened hand having a movable hook opposed to an immovable tooth; second and third pairs of legs very slender, and the fourth and fifth much stronger; branchiæ seven on each side, consisting of horizontal lamellæ; false swimming feet on under side of abdomen large, and caudal plates wide. The common shrimp (*C. vulgaris*, Fabr.) is 1½ to 2½ in. long, greenish gray spotted with brown; the carapace is smooth, except a spine behind the rostrum, one on the sternum, and seven on each side of the thorax; abdomen without ridges or spines, and middle caudal plate pointed and not grooved below. It is common on the coasts of Europe, and in England and France it is much used as food. The shrimpers catch these animals in large nets with a semicircular mouth, which they push before them along the bottom during ebb tide; this fishery gives employment to many hundred people in Great Britain. Shrimps are used in the United States chiefly as bait. They spawn throughout most of the year, carrying the eggs



Common Shrimp (Crangon vulgaris).

attached to the swimming appendages, and cast their skins from March to June. They feed on such animals as they can seize with their claws, and on what may be killed by the

waves or other causes, and are themselves devoured by fishes, aquatic birds, echini, and star fishes. Other species are found in the Mediterranean. Though the American shrimp received from Say a different name from that of Europe, there seem to be no well marked specific differences.—The long-beaked, almost transparent crustacean, commonly called shrimp in New England, and used sometimes for bait, has been described by Mr. Stimpson as *palæmonopsis vulgaris*.

**SHROPSHIRE,** or **Salop,** a W. county of England, bordering on the counties of Chester, Stafford, Worcester, Hereford, Radnor, Montgomery, and Denbigh; area, 1,291 sq. m.; pop. in 1871, 248,064. The surface is greatly diversified. Toward the frontiers of Wales it becomes wild and mountainous, while the other parts are comparatively level. The Severn flows S. E. between the elevated and the level portions, and has a course within the county of nearly 70 m., all navigable. Its chief tributaries are the Tern and the Teme. There are several small lakes, of which Ellesmere, covering 116 acres, is the largest. There is communication by canals with all the important rivers of England. The soil varies much, and there are considerable tracts of moorland, but much of it is easily worked and yields good crops. Large numbers of cattle are reared. Lead mines are worked to a considerable extent. Iron, coal, and limestone are found, and the manufacture of iron is extensively carried on. There are manufactures of machinery, glass, stone-china ware, earthenware, and coarse linen and woollen goods. The principal towns are Shrewsbury, the capital, Bridgenorth, Wenlock, and Ludlow.

**SHROVE TIDE** (A. S. *scrifan*, to absolve in confession), the days immediately preceding Ash Wednesday. These days were so designated because on them, and especially on the last of them, people were wont to confess their sins as a preparation for Lent. Shrove tide or confession tide comprised a whole week in some countries. In most Roman Catholic countries it began on the Sunday before Lent. While the ancient penitential canons were in vigor, all adults were enjoined to present themselves to the bishops and priests, in order that private penitents might be shriven in private and assigned a day for receiving communion, and that public penitents might be instructed as to what they should do to be reconciled at Easter. This practice continued substantially long after public penance had fallen into disuse. It is mentioned in the homilies of Ælfric (died about 1005) as being in force in England in his time. Shrove tide soon became a season of feasting and merriment, especially Shrove Tuesday, the eve of the long Lenten fast. This day is still called *mardi gras* (fat Tuesday) by the French, and Shrove tide is known to them as *les jours gras*. Shrove Tuesday is also popularly called Pancake Tuesday in English-speaking countries, from the common practice of eating pancakes on that day, the use of eggs having been formerly forbidden during Lent.

**SHUBRICK. I. John Templar,** an American naval officer, born in South Carolina, Sept. 12, 1778, lost at sea in 1815. He entered the service as a midshipman in 1806, and was attached to the Chesapeake in her affair with the Leopard in 1807. In May, 1812, he was made a lieutenant, and served in the Constitution in her action with the Guerriere in August, 1812, and in the Hornet's with the Peacock in February, 1813. For his services in these engagements he received medals from congress. He was second lieutenant of the President when she was captured by a British squadron in January, 1815. In that year he was first lieutenant of the Guerriere, and was present in all the operations against Algiers. On the conclusion of peace, he was despatched with the treaty to the United States in the Epervier sloop of war, which was never heard from after she left the Mediterranean. **II. William Branford,** an American naval officer, brother of the preceding, born in South Carolina, Oct. 31, 1790, died in Washington, D. C., May 27, 1874. He was appointed midshipman in June, 1806, and in May, 1807, joined the sloop of war Wasp. At the beginning of the war of 1812 he was an acting lieutenant on board the Hornet, and was soon transferred to the frigate Constellation, which rendered important services in defence of Norfolk and the navy yard at Gosport. In 1813 he was transferred to the Constitution, in which he made two cruises, and aided in the capture of three ships of war, including the Cyane and Levant (1815). When the Levant surrendered he was ordered to her command. He returned to the United States in May, 1815, second in command of the Constitution, and was awarded a sword by his native state and a medal by congress. In December, 1815, he was made senior lieutenant of the Washington, 74 guns, under Creighton, the first ship of the line which made a full cruise under the United States flag, returning in 1818. He became commander in 1820 and captain in 1831, and on Feb. 3, 1844, was appointed chief of the naval bureau of provisions and clothing. On July 9, 1846, he was appointed to command the Pacific squadron; on July 8, 1853, the eastern coast squadron; and on Sept. 8, 1858, the Brazil squadron and Paraguay expedition, from which he returned May 11, 1859. On July 16, 1862, he was commissioned rear admiral.

**SHUMLA,** a walled and strongly fortified city of European Turkey, in Bulgaria, 48 m. W. of Varna and 185 m. N. W. of Constantinople; pop. about 20,000, exclusive of the garrison. It lies on the N. slope of the Balkan, about midway between its crest and the lower Danube, in a gorge, enclosed on three sides by mountains. The inhabitants of the higher portion of the town are principally Turks; of the lower, Jews, Armenians, and Greeks. There

is trade in grain, wine, silk goods, copper ware, morocco, soap, and candles.—This town, originally called Shumen or Shumna, was burned in 811 by the emperor Nicephorus, and in 1087 it was besieged by Alexis Comnenus. It was taken by the Turks in 1387, and embellished and fortified in 1689 and the 90 years that followed, mainly by the grand vizier Hassan, whose tomb is the most remarkable monument of the city. In all the wars between Turkey and Russia, it has formed the point of concentration of the Turkish army. The Russians attempted unsuccessfully to take it in 1774, in 1810, and in 1828.

**SHURTLEFF COLLEGE,** an institution of learning under the control of the Baptists, at Upper Alton, Madison co., Illinois, 1½ m. E. of the city of Alton. It was established in 1832 under the title of Alton seminary, and chartered in 1835 as Alton college. In 1836 its name was changed in honor of Benjamin Shurtleff, M. D., of Boston, who had given it $10,000. It was designed especially for the education of young men for the ministry, but a distinct theological department was not organized till 1863. The institution now consists of an academic and preparatory department, Kendall institute for young ladies, the college, and the theological department. Both sexes are admitted to the academic and preparatory department and to the college. The latter has a classical and a scientific course, on the completion of which the degrees of bachelor of arts and bachelor of philosophy respectively are conferred. Kendall institute, established in 1873, has a fine building and grounds, and is chiefly used as a home for young ladies attending the other departments. Tuition is free in the theological department, and several scholarships have been founded to provide for the tuition of needy students in the other departments. Additional aid is afforded to needy candidates for the ministry by the "Illinois Baptist Education Society." The libraries of the institution contain 7,300 volumes. The number of instructors in 1874–'5 was 14; of students, 204 (154 males and 50 females), viz.: theological department, 5; college, 53; academic and preparatory department, 146. The whole number of students has been 3,825; of graduates, 159. The property of the institution amounts to about $180,000; the debt to $30,000.

**SHUVALOFF, Peter Andreyevitch.** See p. 879.

**SIAM,** the chief kingdom of the peninsula styled Indo-China, or Further India. Siyam, from the dark color of the inhabitants or of the soil, is the ancient, and Muang T'hai, the kingdom of the free, the modern native appellation for the country; T'hai, the free, for the people. With its Laos, Cambodian, and Malay peninsular dependencies, it lies between lat. 4° and 22° N., and between lon. 97° and 106° E.; greatest length 1,350 m., breadth 450 m.; area estimated at about 300,000 sq. m.; pop. about 5,750,000. The capital is Bangkok. Siam proper lies mainly between lat. 13° and 18° and lon. 98° and 102°, being bounded by its dependencies, the gulf of Siam, and the British territory of Tenasserim. Two mountain ranges, extending mainly S. E. from the Himalaya, form general natural divisions from China on the north, and partly from Anam on the east and Burmah and the British possessions on the west. A third range, less continuous and direct, passes through the central regions; in this is situated the P'hra Bat, or mountain of "the sacred foot" (footprint) of Buddha, a Mecca for Buddhists. The gulf of Siam, between Siam proper and the Malay peninsula, forms a long coast line, and has numerous islands, much precipitous shore, and several ports, of which Bangkok is the chief. It is never visited by typhoons or heavy gales.—The country is watered by several rivers, bearing the generic name Menam, "mother of waters," and taking the specific name or names from cities or provinces. The Menam Kong, Mekong, or river of Cambodia, 1,800 m. long, traverses in its middle course the N. E. or Laos dependencies of Siam. (See MEKONG.) The Menam Chow P'ya, Menam Bangkok, or simply the Menam, rises in the north and flows S. through the centre of Siam proper into the gulf of Siam. Its length is about 600 m.; its principal tributary is the Meping from the west. Bangkok, Ayuthia, Angtong, and other towns are situated on the Menam. The Salwen flows on the border of British Burmah. These rivers, with the very numerous intersecting canals, for rowing, not tracking, are the great highways of traffic. The plains, irrigated and enriched by their annual overflow, are extensive and fertile; the valley of the Menam equals in richness that of the Nile, and in extent half of the state of New York.—The seasons are two, the wet or hot and the dry or cool. The former, opening near the middle of March, is not a succession of wholly rainy days, but resembles a New York April and August combined. The annual rainfall is about 60 inches. April, the hottest month, has at Bangkok a maximum of 97° F. and a mean of 84°. In October the S. W. monsoon gives place to the N. E., which ushers in the dry and cool season; this is very fine, with only a few light showers throughout. January is the coolest month; but the mercury rarely falls below 65°. The mean annual temperature is 82½°, and the mean range 13°. Vegetation is luxurious, fruitful, and beautiful beyond description, and the soil yields a rich return to rude and careless cultivation. Rice, sugar, pepper, cotton, and hemp are the staple products. In the abundance, variety, and excellence of fruits, vegetables, and spices, Siam is unsurpassed. Many fruits, as the durian, mangosteen, and custard apple, are cultivated in large gardens or orchards, trenched, and watered by the daily tide. In the forests are found gutta percha, lac, dammar, gamboge, catechu, gum benjamin, and the odoriferous agila or eagle wood; innumerable medicinal

plants, herbs, and roots; sapan, fustic, indigo, and other dyes; the lofty silk-cotton tree, with its soft silky floss for mattresses, but too brittle for the loom; the bamboo, the rattan, and the atap, together forming the material of three fourths of the houses; the teak, with other ship and house timbers; iron, red, and white woods, rose woods, and ebony; the banian, and the sacred fig tree. The animal kingdom is no less varied and interesting. Most celebrated is the white elephant, a dark-cream albino, prized and honored as very rare, and when captured belonging to the king. The national standard is a white elephant on a crimson ground, and the royal seal, medals, and money bear the same device. Albino deer, monkeys, and even tortoises are sometimes found, and the natives believe white animals to be the abode of transmigrating souls. The elephants of Siam attain a size and strength unsurpassed in other countries, and are much prized throughout India. Among other animals are the rhinoceros, tiger, leopard, bear, pangolin, otter, musk civet, wild hogs, ourang outangs and other apes, monkeys, and deer; dogs and cats, wild and domestic, are innumerable. The forests abound in peacocks, pheasants, pigeons, and other birds; aquatic birds of all kinds are numerous; the sea swallow which produces the edible nest is common. Among the reptiles are the crocodile, turtle, python, cobra de capello, numerous other snakes, and several varieties of lizards. Fish are plentiful, but of poor quality. The most noteworthy insect is the *coccus ficus*, which produces the lac of commerce by punctures in resinous trees. Gold, copper, iron, tin, and lead all abound, in great purity; but by reason of the rudeness of working, the jealousy toward foreigners, and the fevers and hardships of the jungle, their vast wealth is comparatively undeveloped. Antimony, zinc, sulphur, and arsenic also exist, and silver in combination. Salt is largely manufactured by solar evaporation, and saltpetre less so. Mining, previously under the strict surveillance of government, and carried on chiefly by Chinese, has recently excited some interest among Europeans. Rubies, spinel, corundum, sapphire, amethyst, garnet, topaz, and other precious stones are found.—According to the French consul Garnier at Bangkok (1874), the population of Siam proper and its Laos dependencies is composed of 1,800,000 Siamese, 1,500,000 Chinese, 1,000,000 Laos, 200,000 Malays, 50,000 Cambodians, 50,000 Peguans, and 50,000 Karens and others. The Siamese are of Mongolian origin and Laos or Shyan descent. They are olive-colored and of medium height. The head is large, face broad, forehead low, cheek bones prominent, jaw bones in retreat very divergent; mouth capacious, lips thick, nose heavy, and eyes black and without the Chinese turn of the lid. The teeth are stained black, and sometimes serrated. The hair is all plucked from the face in youth, and the most of the head is shaved bi-monthly. A black bristling tuft 4 or 5 in. broad and 2 in. high is left on the top; that of the women, whose hair is only closely cut, is often encircled by a thread of bare skin whence two or three hairs' breadths have been uprooted. The dress consists of a cotton waist cloth (to which women add a silk shoulder scarf), a jacket for the cold, and a straw hat for the sun. Children under seven or eight years old are clad only in jewels, fig leaves, flowers, and turmeric. Priests, with head entirely shaven and uncovered, wear several yellow robes of cotton and silk. Kings and nobles on state occasions wear silk and gold brocades and high conical hats. The Siamese are indolent, greedy, and untruthful, intemperate, servile, and superstitious. At the same time they are peaceable and polite, decorous in public, and affectionate to kindred and kind to the poor and imbecile. The dwellings are of one story, partly to prevent the indignity of another's walking over the head. They consist of huts, built on piles, of bamboo, roofed and sided with atap leaf; boats, serving also as peddling stalls or vehicles; floating houses, of panelled teak, rising and falling with the tide on bamboo rafts; and palaces, of white stuccoed brick, adorned with gilding, carving, painting, foreign furniture, pictures, gold, silver, china, and glass. These palaces are not of Chinese, but rather of Indian architecture, and they often occupy several acres, with the dwellings of the wives, the quarters of the servants, and the grounds, which are paved, shaded, adorned with flowers, and enclosed by high walls Marriage takes place as early as 18 for males and 14 for females, without the aid of magistrates or priests, though the latter may be present to make prayers, and especially to feast and to receive presents. The number of wives, ordinarily one, in the palaces reaches scores and hundreds; but the first is the wife proper, to whom the rest are subject. Social distinctions are very numerous, and in the law are represented numerically, from 100,000 for the second king down to 5 for the lowest slave. Before "the lord of life" on the throne, far above numerical representation, all crawl and crouch, or, with head bowed to the ground, lie "dust at the sacred feet." Prince is approached by noble, noble by lord, lord by master, &c., each with body bent, eyes prone, and hands folded and raised to the forehead or above the head, giving and receiving homage. An annual service of three months is paid to the king by all, save the Chinese triennially taxed. One third of the common people, it is largely estimated, are slaves by birth, by gambling or other debts, by redemption from the penalty of crime, by capture, &c. Men sell their children, their wives, or themselves; convicts in scores clank their chains about the streets; villages of thousands are made up of foreign captives. Yet Siamese life is in the main comfortable, and is moreover gladdened by many

sports, amusements, and holidays. On all great occasions the coffers of kings and nobles are opened widely for merrymaking for the people, and merit-making for themselves. The only honorable disposal of the dead is by burning. The badges of mourning are white robes and an entire shaving of the head. A limited and superficial education is afforded gratuitously at the temples, to the males, 80 or 90 per cent. of whom read. The drama is much cultivated, and dramatic companies are attached to the palaces and gaming houses. The music is unwritten, simple, plaintive, and pleasing. Bands of 10 or 12 instruments, most resembling Javanese, are a part of every wealthy establishment. Gaudy and incongruous paintings, of rude perspective, chiefly adorn the temples. The medical art is in a barbarous state. Nowhere else does Buddhism hold so pure and absolute a sway as in Siam. It is of the Ceylonese rather than Chinese type. The wats or temples, resembling not the Chinese, but distantly the Egyptian architecture, are among the most beautiful and splendid in the East. They are in vast, choicely situated, paved parks, with white walls gleaming through the leaves, serrate roofs and spacious domes and lofty *prachadi* spires, all painted and gilded and glazed, vocal with air-rung bells, and resplendent in the sunlight. One is estimated to have cost, with all its paraphernalia, over $800,000. (See Bangkok.) Missions have been carried on by the Roman Catholics, under the greatest vicissitudes, since the middle of the 16th century. The missionaries are French, and their converts were reckoned in 1872 at 10,000 in 16 congregations. At the head of the mission is a vicar apostolic. Protestant missions date from the visits of Gützlaff, Tomlin, and Abeel in 1828–'31, and properly from the settlement of Jones in 1833. Representatives of the American Baptist missionary union, of the Presbyterian board of foreign missions, and of the American missionary association have established several Protestant congregations, schools, and religious papers. The number of the Baptist congregations in 1874 was 154, and of Presbyterian 38.—In commerce Bangkok once ranked second only to Calcutta and Canton in the far East; but monopolies, exorbitant duties, and numberless restrictions had well nigh stifled production and banished trade till in 1855–'6 new treaties were negotiated for Great Britain, the United States, and France, by Sir John Bowring, Townsend Harris, and Count de Montigny. The purchase of land is now allowed; the monopolies and tonnage duties are abolished; imports pay 3 per cent. in money or kind, and exports one duty only, according to tariff. In 1873 the number of Siamese vessels entering the port was 157, tonnage 55,049; British 84, tonnage 32,406; German 15, tonnage 4,731; French 14, tonnage 5,198; American 1, tonnage 388. The total arrivals in 1873 were 386, tonnage 102,454; clearances 265, tonnage 97,212. The principal exports are rice, sugar, pepper, sesamum, sapan wood, hides, and cardamoms. Their total value in 1873 was about $4,600,000; that of the imports, $4,000,000. The most important trade is that with China, carried on in junks built and navigated by Chinese. The junks leave the Menam generally in June, returning in December. The tical, a silver coin bearing the device of an elephant and weighing 236 grains troy, with bars of silver cut into pieces, stamped, and bent into an irregular oval, in value 7½, 15, and 60 cents, with cowries, form the currency. Dollars are also current, though usually exchanged for silver ticals at the rate of three dollars for five ticals. The rate of interest is about 30 per cent. The inland trade is conducted chiefly by boats. Foreign steamers ply between Bangkok and Singapore. The United States and European treaty powers are represented by resident consuls at Bangkok. —The government of Siam is theoretically a duarchy, practically a monarchy. While there is a second or vice king, the first or senior king is actual sovereign. The crown is hereditary, but without primogeniture, being bequeathed, with the sanction of princes and nobles, to any son of the queen; but intrigue and violence have often diverted the succession from the high royal line. A royal decree of May 8, 1874, announced that in future the king would give important laws only after consulting the council of state and the ministry. The council of state comprises the first king as president, the ministers, who have no vote, from 10 to 20 councillors, who have to draft new laws and from their own number elect a vice president, and six princes of the royal house. Any two members of the council may submit a new law to the king. The ministry (*senabodi*) consists of an honorary president, three ministers of the interior (of the west, the north, and the east), and the ministers of agriculture, justice, the royal house, and finance. The minister of finance may be dismissed at any time; the dismissal of any other minister requires a sentence of the court. The country is divided into 41 provinces, each of which is governed by a *phraya* or council of the first class. There are also several territories which have their own princes, tributary to the king. The king is by title "sacred lord of heads," "possessor of all," and property and life are at his will, to be taken at governmental necessity or caprice; but many considerations conspire to render a violent and arbitrary exercise of this absolute power comparatively unfrequent. The queen consort, the wife supreme among hundreds, must be of native and royal blood, and she is rigidly kept from all possible intercourse with an inferior of the other sex. She never becomes regent, or takes any part in political affairs, but is treated with the highest deference. She has a separate court, in which appear the princesses, who, not allowed to marry beneath them, rarely marry at all. She has her fe-

male guards in uniform and arms. The number of females within the palace is, on royal authority, 5,000, and of males about the same. The second king has also a separate palace, seraglio, officers, retainers, and soldiers, only second to those of the first. Though never appearing at the audiences of the nobles with the senior king, his opinion and sanction are sought on important state policy, and his name is associated in treaties. His position seems to be that of counsellor, not of co-ruler or successor. The larger portion of the public revenue is embezzled by the numerous officers, who receive only a nominal salary. The revenue of the king is estimated at about $4,000-000. There is a very ancient written code of laws, the acts and decisions of the kings, and an unwritten code, scarcely less authoritative, of traditional usages; both are often absurd, unjust, and cruel, and both liable to be disregarded at the royal will. More than 25 classes are excluded from testifying, many for the most trivial reasons. The penalties are various, from bambooing to beheading. Capital crimes are now very few. Treason, very comprehensive, is punished by beating the convict, enclosed in a large sack, nearly to death, and then casting him loaded into the river. The military force is small, and is disciplined by European officers. In time of war all male inhabitants are liable to service. The fleet consists of seven men-of-war carrying 40 guns. —The history of Siam dates back some centuries before Christ, but only the annals subsequent to the founding of Ayuthia, the former capital, A. D. 1350, can be deemed authentic. In the 16th century the dominion extended to Singapore, and the first western connection was made with the Portuguese and Spanish. In 1604 the Dutch established relations; in 1662 an English ship arrived; and the latter part of the century is remarkable for the grand embassies from and to Louis XIV. of France, and the later bloody and almost utter overthrow of French influence. In 1782 the present dynasty ascended the throne, and transferred the seat of government from Ayuthia (sacked by the Burmese) to Bangkok. In 1822 and 1825 treaties were made with Great Britain, or rather with the East India company, through Mr. Crawfurd and Capt. Burney. In 1833 a treaty was made with the United States through Edmund Roberts. The first embassy from the country for nearly two centuries was sent to England in 1857; and another was sent to France in 1861. In 1868, on the death of his father, the reigning king ascended the throne, with the title Phrabat Somdetya Chula Lankarana, and during his minority a regent carried on the government; he became of age Nov. 16, 1873. The name of the present second king (1875) is Kroma Phraratcha. The recent kings of Siam have been among the most remarkable characters of the East by their attainments in languages and general information, adoption of foreign ideas and improvements, wise and humane government, and liberal and enlightened intercourse with foreigners and foreign powers. In January, 1875, a conflict arose between the first and second kings, the latter for a time taking refuge with the British consul; but a reconciliation was soon effected.—The best books on Siam are Crawfurd's "Embassy to Siam and Cochin-China" (London, 1828); Pallegoix's *Description du royaume Thai ou Siam* (Paris, 1854); Bowring's "Kingdom and People of Siam" (London, 1857); Bastian's *Reisen in Siam* (Berlin, 1867); Mrs. Leonowens's "English Governess at the Siamese Court" (Boston, 1870); McDonald's "Siam, its Government, Manners, Customs," &c. (Philadelphia, 1871); "Siam, or the Land of the White Elephant," compiled by the Rev. George B. Bacon (New York, 1873); and "The Land of the White Elephant," by Frank Vincent, jr. (New York, 1874).

**SIAM, Language and Literature of.** Siamese is spoken from Burmah and British Burmah on the west to Anam and Cambodia on the east, and from the Malay state of Keddah on the south to the confines of China on the north. The dialectical variations are numerous, and the language is spoken well only in Bangkok and by persons educated there. (See INDO-CHINESE RACES AND LANGUAGES.) The Siamese alphabet, supposed to be derived from the ancient Cambodian letters still used in Siamese sacred books, and ultimately from the original Pali alphabet, consists of 44 consonants and 20 vowels, including diphthongs and semi-vowels. The gradation of the vowel sounds is very delicate, and some of the consonants are but slightly changed forms of the same letter, indicating the tone in which they are to be uttered in certain syllables. The English *g*, *j*, *v*, *x*, and *z* are wanting. The *th* sound, though frequent in Burmese, is entirely unknown in Siamese, the *th* used in transcriptions of the latter representing an aspirated *t*, or a combined utterance of the two sounds *t* and *h*. According to the tone in which it is uttered, a word has several distinct meanings, by means of which the otherwise very meagre vocabulary is considerably increased. Thus *hkai*, *hkai*, *hkai*, pronounced in the same tone, would mean who? who? who?; but enunciating each with a different tone, it may be made to mean "Who sells eggs?" This same word *hkai* may further be made to signify a fever, to open, rough, fortress, or camp, by other intonations. Besides the parts of speech distinguished in English grammar, there is in Siamese a peculiar class of numeral or classifying nouns. Such a word is *lam*, which is used in conjunction with objects having the quality of length, as ships and palm trees; others of this class are *an*, *toa*, *luk*, *ton*, and *met*, all of which must be used when speaking of one or another class of objects. Three genders, masculine, feminine, and common, are distinguished by the grammarians, but in common speech and in poetry gender is

commonly disregarded, except in distinctions of sex, which is indicated by the addition of special words. The plural is expressed by adding some word like *hlai*, many, or *mak*, much. There are no inflections, and case is indicated by the use of a preposition, or by the position of the word in the sentence. There is a great variety of pronouns, or pronominal expressions, and the proper use of one or another depends on the relative rank of those writing or speaking. Moods and tenses are indicated by prefixes and suffixes, or by auxiliary verbs; thus *hka bok*, I say; *hka dai bok*, I have said; *hka cha bok*, I shall say, &c. The Siamese are very fond of using words in pairs, for euphony, distinctness, or figurativeness.—Siamese literature is not of a very high order. The works on history and medicine contain little else but fables and quackery. The law books are very elaborate, but wanting in legal acumen and precision. The religious and philosophical productions are based upon the Pali scriptures and Chinese learning, and exhibit nothing of an original growth. The books of Siamese proverbs, however, have been praised as containing much social wisdom sharply put. The best productions of Siamese literature are works of fiction, poems, and dramas, though a large portion of them are borrowed from or imitations and adaptations of Hindoo works.—See Pallegoix, *Grammatica Linguæ Thai* (Bangkok, 1850), and *Dictionarium Linguæ Thai* (Paris, 1854); Bastian, *Reisen in Siam* (Berlin, 1867), which contains learned disquisitions on the language and literature of the country; Alabaster, "Wheel of the Law" (London, 1871); and the "Siam Repository," a journal published at Bangkok in English.

**SIAMESE TWINS.** See MONSTER.

**SIBERIA**, a part of the Russian dominions occupying the whole of northern Asia, bounded N. by the Arctic ocean, E. and S. E. by Behring strait, Behring sea or the sea of Kamtchatka, and the seas of Okhotsk and Japan (inlets of the North Pacific), S. by China and the Russian provinces of central Asia, and W. by European Russia, from which it is separated by the Ural mountains. As officially bounded, it extends from lat. 41° 30′ to 77° 50′ N., and from lon. 59° 30′ to 190° E.; length about 3,600 m., breadth 2,000 m.; area, 4,826,-329 sq. m.; pop. in 1870, 3,428,867. It is divided for administrative purposes into the four governments of Tobolsk, Tomsk, Yeniseisk, and Irkutsk, and the four provinces of Transbaikal, Yakutsk, Amoor, and the Littoral or Primorsk. In a geographical sense, however, the four northern provinces of Russian Central Asia, Semipolatinsk, Akmolinsk, Turgai, and Uralsk, and portions of the governments of Perm and Orenburg, also belong to Siberia, and will be included in parts of this description. Tobolsk comprises the western end of Siberia, as officially constituted, and extends from the Arctic ocean to the Central Asian province of Akmolinsk. Tomsk lies E. of it on the borders of the Central Asian province of Semirietchensk. Yeniseisk includes the Arctic coast from the gulf of Obi to the river Anabara, and extends S. to the borders of Mongolia. Irkutsk lies between Yeniseisk and Lake Baikal, and the Transbaikal province east of Lake Baikal. Yakutsk comprises the Arctic coast from the Anabara river to Cape Shelagski, extending S. to the Amoor province, which includes the country on the left bank of the Amoor from the Stanovoi mountains to the N. E. extremity of Mantchooria. The Littoral province covers the entire E. coast from Cape Shelagski in the Arctic ocean to the sea of Japan, including the Tchuktchi peninsula, Kamtchatka, the district of Okhotsk, the lower course of the Amoor, and the island of Saghalien.—The coasts of Siberia, both along the Arctic ocean and the seas on the east and south, are indented by many bays and inlets. On the N. coast the first large inlet, beginning at the W. extremity, is Kara bay, an offshoot of the Kara sea lying between Siberia and Nova Zembla. Next is the gulf of Obi, an inlet of the same sea, which forms between it and Kara bay the Yelmert or Samoyed peninsula. It receives the Obi or Ob at its S. W. extremity. A branch on its E. side is called the Taz gulf. The gulf of Yenisei, the outlet of the river of the same name, forms with Khatanga gulf, the outlet of the Khatanga river, the Taimyr peninsula. On the W. side of Taimyr bay is Cape Taimyr or Northwest cape, and on its E. side, at the extremity of a long peninsula, is Tcheliuskin or Northeast cape, the northernmost point of Asia, in lat. 77° 50′ N. Between Khatanga gulf and Behring strait are many smaller bays, most of which are the outlets of some of the numerous rivers which empty into the Arctic ocean. The principal islands off the N. coast are the Liakhoff or New Siberia group, extending 205 m. opposite the shore between the mouths of the Yana and the Indigirka; the largest, Kotelnoi, is 100 m. long by 60 m. broad; the next in size is called Fadeyeff, and the next New Siberia. Between the main group and the coast are smaller islands called Liakhoff and Maloi. The surface of the islands is covered with alternate layers of sand and ice, and in their hills are immense alluvial deposits filled with wood and the fossil bones of animals. Great quantities of fossil ivory have been obtained from them and the neighboring coasts of the mainland. N. of the coast, about the 180th meridian, and separated from it by Long strait, is Wrangel's, Plover, or Kellett land, of unknown extent. Along the whole Arctic coast of Siberia the sea is frozen for more than half the year; and in the warmer seasons the ice floats in such masses as to render navigation always dangerous and often impossible. A large part of the coast is unexplored, and all efforts to double Cape Tcheliuskin have been unsuccessful; but Lieut. Tcheliuskin, from whom it is named, reached its north-

ernmost point in 1742 in a sledge. The easternmost point of Siberia is Cape East at the end of the Tchuktchi peninsula, which juts into Behring strait, opposite Cape Prince of Wales in Alaska, the westernmost point of the American continent. On the S. side of this peninsula is the bay of Anadyr, an inlet of Behring sea. The coast follows thence a general southwesterly direction to the end of the peninsula of Kamtchatka, W. of which lies the Okhotsk sea, separated from the Pacific by the chain of the Kurile islands stretching from Kamtchatka to Yezo. Of the islands of Behring sea, only Behring and Copper islands and those lying close to the coast belong to Russia.—The surface of Siberia is in its general form a vast diluvial plain, slightly undulating, and sloping gradually from the Altai mountains on the south to the Arctic ocean. In the W. part are the steppes of Ishim and Baraba, broad tracts of lowland in which grassy prairies alternate with reed marshes, fresh lakes with salt, and tracts of rich arable land with extensive forests. Parts of this region present in summer fine park scenery, in which beautiful wooded hills rise from grassy plains covered with flowers. Here the birches often attain a diameter of 4 ft. and a height of 150 ft., and the pines much greater dimensions. S. and E. of the steppes the spurs of the Altai mountains jut into the plain like the headlands of a seacoast. Many of the great rivers rise here, the upper part of their courses being through dense forests. In eastern Siberia the plain is more broken by hills, and has but little land fit for agriculture. In the S. part of Irkutsk and in Yakutsk the hills and mountains are covered for most of the year with good pasture, and in favorable places all the grains of temperate climates are grown. The greater part of the country is covered with open forests, in which there is tolerable pasturage at certain seasons. Between the Kolyma river and Behring sea the country is traversed by several mountain ranges having a general elevation of 2,000 to 3,000 ft. above the sea. The entire N. coast of Siberia is a dreary region of salt steppes and frozen swamps, called the *tundra*, where the soil is perpetually frozen to the depth of hundreds of feet. The surface is never thawed before the end of June, and is again ice-bound by the middle of September, and deep snow covers the ground nine or ten months in the year. The banks of the rivers are lined with vast numbers of uprooted trees brought down by floods, which eventually find their way into the Arctic ocean, to be drifted away by the current flowing from E. to W. along the Siberian coast.—The principal mountain range of Siberia is that which forms in the west its S. boundary with China, and which is called by various names in different parts. Its E. extremity is at East cape in Behring strait, whence it extends in a general S. W. direction, forming the boundary between the Littoral, the Amoor, and Yakutsk provinces, until it reaches the Chinese frontier, when its course is first S., then W., and then N. W. to the boundary between Irkutsk and Yeniseisk, from which it again runs S. W. to the borders of Turkistan. In the east and along the shores of the sea of Okhotsk this range is called the Stanovoi mountains, W. of the Amoor province the Yablonnoi, further W. the Daurian and Sayanian mountains, and finally the Altai mountains in the narrower sense. The general height of the chain (the Altai in its widest sense) is about 3,000 ft., but the highest summits of the Altai proper reach an elevation of upward of 10,000 ft., and the Yablonnoi mountains are little more than an undulating plateau. There are many spurs from the main range, as well as several smaller ranges in the interior. (See ALTAI, AMOOR COUNTRY, and KAMTCHATKA.)—With the exception of the Amoor and a few streams of less importance, the rivers of Siberia all flow into the Arctic ocean. The Obi ranks among the largest rivers in the world, and many of its tributaries are of great size; the most important of these are the Irtish, Ishim, Tobol, and Tom. The Yenisei is by some authorities said to drain a greater extent of surface and to have a longer course than the Obi; its chief affluents are the Lower Tunguska, Stony Tunguska, and Upper Tunguska or Angara. The Lena is nearly as large, and the principal streams which join it are the Viliui, Vitim, Olekma, and Aldan. The other rivers of most importance which flow into the Arctic ocean are the Nadym, Pur, Taz, Piasina, Khatanga, Anabara, Olem, Olenek, Yana, Indigirka, Alazeya, Kolyma, and Tchaun. The chief rivers flowing into the seas which bound Siberia S. E. are the Amoor or Saghalien, which forms part of the southern boundary and receives several considerable tributaries from the north; the Anadyr, flowing into the gulf of the same name; and the Okhota, which has its mouth on the W. shore of the sea of Okhotsk. Few of these rivers present any obstacles to navigation except ice. Frozen inundations are frequent. As the rivers flow from warm to cold latitudes, their lower and middle courses freeze while their head waters are still open. Near their mouths they freeze to the bottom, while above for hundreds of miles only the surface is frozen. The waters accumulating under the ice finally burst from confinement and flood the valleys with many thicknesses of ice. At the close of winter these accumulations are sometimes 20 ft. in depth. There are many lakes, but they are all small, with the exception of Baikal, between the Transbaikal province and the government of Irkutsk. (See BAIKAL.)—The geology of Siberia is but little known, excepting in a few parts. Granite and crystalline schists are found in the Ural mountains, and also in the Altai and its E. continuations, between lon. 85° and 120° and as far N. as lat. 57°, and again in the E. extremity of the country between lon. 165° and Behring strait. Volcanic

rocks occur chiefly in the south, and are found along with the granite and crystalline schists; and there are a few active volcanoes. Other rocks, belonging to the Silurian, Devonian, and carboniferous systems, are found in the south and extending toward the interior of the country. The tertiary formation is the most extensively developed, and is found throughout the whole of Siberia. The shores of the Arctic ocean are covered for a considerable distance inland, and for a great part of their extent, by a deep alluvial deposit which contains immense numbers of fossil remains of extinct species of elephants and other animals, from which large quantities of ivory are procured. (See MAMMOTH.) Mining operations in Siberia are confined to three parts of the country. The westernmost district is on the E. face of the Ural mountains, and occupies a tract about 40 m. broad, extending between lat. 56° and 60°; gold, silver, platinum, copper and iron ores, and precious stones, are all found in this territory. This region is, however, not officially included in Siberia. (See YEKATERINBURG.) The second district lies on the N. side of the Altai mountains, in the neighborhood of the head streams of the river Irtish; silver and copper are found here, and gold and lead in smaller quantities. The third district lies in the Yablonnoi mountains, E. of lon. 120°; in this gold, silver, lead, zinc, antimony, iron, and arsenic are all found, and there are emerald and topaz mines of great value. Diamonds are occasionally found on the E. slopes of the Ural mountains. Porphyry, jasper, and malachite, for ornamental uses, and mica, used as a substitute for window glass, are common. Salt is found in great abundance on the steppes, and on the surface of some of the lakes, where the summer heat rapidly evaporates the water and leaves masses of crystallized salt, sometimes 8 or 9 in. thick, and so solid that beasts of burden pass over in safety.—The climate of Siberia is much colder than in corresponding latitudes in Europe. At Ustyansk, at the mouth of the river Yana, in lat. 70° 55′, the mean annual temperature is 4·39° F., while at North cape in Europe, a few minutes further north, it is 32°. At Irkutsk, in lat. 52° 17′, 1,240 ft. above the sea, the mean temperature is 31°; in winter quicksilver freezes, and remains so for about two months. In 1864 Pumpelly saw the thermometer indicate 70° below zero at a station near Irkutsk. The severity of the climate increases toward the east. At Nizhni Kolymsk, at the mouth of the Kolyma, in lat. 68° 31′, lon. 160° 56′, and nearly on a level with the sea, the river freezes over in the beginning of September, and is not again free from ice till the beginning of June. The sea begins to freeze in October, but the cold at this time is somewhat diminished by vapors which rise from it before the ice forms. In January the thermometer falls to 60° below zero, and respiration becomes difficult. The cold is almost as great in February, but in March it begins to decrease perceptibly; the wind blows from E. S. E., and the temperature rises to 29°. In June it is sometimes 72° at noon; and in July the heat is very great, and the atmosphere is filled with swarms of gnats, which compel the reindeer to migrate from the forests to the open country on the shores of the sea. In August frosts begin at night and the temperature rapidly decreases.—Forests cover a large part of southern and central Siberia, but the tundra on the N. coast is bare of trees. The birch, larch, fir, pine, willow, poplar, elm, and Tartar maple are the principal trees. The silver poplar is found as far north as lat. 60°; the silver fir ceases at about 60° 50′; the polar limit of birch is about 63°, although dwarf specimens are sometimes seen further north; the pine is found on arid slopes and heights in lat. 64°, and the red fir (*pinus abies*) disappears about the same parallel. Larch trees with twisted trunks and many branches are found in the southern part of the tundra. On the most desolate steppes and mountain sides, from the Okhotsk sea to the Arctic ocean, grows the trailing cedar, called *kedrevnik* by the Russians. It has needles and cones like the common white pine; it never stands erect, but covers the ground under the snow with a network of gnarled, twisted, and interlocking trunks. It furnishes almost the only firewood of the wandering natives, and without it N. E. Siberia would be nearly uninhabitable. With the opening of summer the melting snows are rapidly followed by foliage and flowers, and the whole region is converted for a short time into a blooming garden. The flora of Irkutsk is richer than that of Berlin, exhibiting the plants of warmer countries beside those of the arctic regions. Turtchaninoff discovered 1,000 phanerogamous plants in its neighborhood, many of them of unknown species.—Along the banks of the rivers, particularly in S. W. Siberia, is much land well suited for agricultural purposes. Wheat, barley, rye, buckwheat, oats, and hemp are grown, and some inferior tobacco. Grain is cultivated as far north as lat. 61°, and turnips and other vegetables of temperate climates thrive in favorable places. Reindeer and wild sheep are found on the mountains which separate Siberia from Mongolia, and the former roam in vast herds throughout the N. part of the country. The Bengal tiger and a species of panther (*felis irbis*) also inhabit these mountains, and are sometimes seen much further north. The Caspian antelope is found in the southwest, and the black and arctic or stone fox in the north. Sables, ermines, marmots, martens, and squirrels abound in the south. The white bear, the lynx, the wolf, the wild hog, and the glutton are common everywhere. The dog of the country, which bears a strong resemblance to the wolf, is used to drag sledges. The animals belonging to central Asia are nearly all found in the S. part of Siberia. Camels are kept by the Calmucks and some other tribes, but do not

live N. of lat. 55°. The domestic sheep are of two species, the Russian and the broad-tailed Kirghiz; the latter are chiefly kept by the nomadic tribes, single herdsmen of whom sometimes possess flocks of 10,000 head. The horned cattle of Russia degenerate in size in Siberia. The horses are good, and generally white, but sometimes they are singularly marked. Fish are very numerous. Ducks, geese, swans, woodcocks, partridges, and other fowl abound in the S. part of the country.—The population of Siberia is composed of various tribes and races. More than half are Russians or their descendants, some of whom came to the country as volunteer immigrants, but the greater part were sent as exiles. These exiles consist of three classes, criminals and political and religious offenders. The worst class are condemned to the mines, and those whose offences have not been so great are employed at less laborious work, while the rest are formed into settlements under the supervision of the police, and receive grants of land for cultivation. None except the worst criminals are sent to Siberia without their families. In 1874, from May to October, 16,889 persons were banished to Siberia. Of these 1,700 were sentenced to hard labor, and 1,624 were drunkards and vagrants. They were accompanied voluntarily by 1,080 women and children over 15 years of age, and 1,269 younger children. Among the native tribes are the Samoyeds in the N. W., and the Ostiaks, who occupy the country S. of them as far E. as the river Yenisei; these people live by fishing and hunting, and but few of them have been converted to Christianity. In the S. W., besides some hordes of Bashkirs, are the Kirghiz, occupying the steppes of the Ishim and Irtish, commonly called from them the Kirghiz steppes; they are still in a barbarous state. Among the inhabitants of the W. parts of the Altai mountains the most numerous are the Calmucks, who have become partially civilized and have laid aside many of their national peculiarities; they manufacture iron and gunpowder, and cultivate some grain and tobacco, but their chief subsistence is drawn from their flocks and herds. Their religion is made up of various superstitions. On the slopes of the E. part of the Altai chain are several tribes known as Beruisses, Beltirs, Sagai, and Katchins. The Buriats are of Mongol origin, bear a strong resemblance to the people of N. China, and are the most numerous native tribe in Siberia; they are found chiefly about Lake Baikal and E. to the river Onon, a tributary of the Amoor. Most of the nations of N. E. Siberia may be referred to one or the other of three classes, the Yakuts, the Tunguses, and the Tchuktchis and Koriaks. The Yakuts, settled chiefly along the Lena, from its source to its mouth, are of Tartar origin, speaking a language said to resemble closely the Turkish. They are all more or less civilized by Russian contact, many having adopted the Greek faith, and are the most thrifty and industrious of the nations of N. Asia. The Tunguses, and the allied tribes, the Lamuts, the Monzhurs, and the Gilyaks of the Amoor river, all of Mongol origin, are found as far W. as the Yenisei and as far E. as Anadyrsk in lon. 169°. They are amiable, and easily governed and influenced. Their original religion was Shamanism, but they now profess almost universally the Greek faith. They train reindeer for riding and pack-carrying (the other nations using them only in sledges), and pay a regular tribute in furs to the government. The Tchuktchis and Koriaks, inhabiting the extreme E. part of Siberia, between the 160th meridian and Behring strait, strongly resemble the North American Indians in general appearance, and are tall, vigorous, and athletic. A part of them are settled along the seashore, but most are nomadic. The latter own large herds of reindeer, numbering frequently several thousand, and their wandering life is a necessity to provide food for them. The Tchuktchis and Koriaks are independent of civilization, impatient of restraint, and bold and self-reliant. They are the only Siberian tribes that ever made a successful stand against Russian invasion. Nearly all the Siberian nations eat a species of toadstool, called by them *muk-a-mur*, which in small doses produces all the effects of alcoholic liquor, but when eaten in large quantities is a violent narcotic poison. Its habitual use shatters the nervous system, and its sale to the natives by traders is made a penal offence by Russian law. In respect to religious belief the inhabitants are divided as follows: Orthodox Greeks, 2,875,533; Raskolniks, 65,505; Armenian Greeks, 9; Roman Catholics, 24,754; Protestants, 5,722; Jews, 11,400; Mohammedans, 61,083; pagans, 283,621. The population in towns numbers 113,236.—Although the manufactures of Siberia are not extensive, a remarkable spirit of enterprise among the people is rapidly developing the industrial resources of the country. In most of the chief towns there are manufactories of cotton and woollen cloths, linen, glass, iron, earthenware, and leather; and others are springing up all over the country. The internal commerce is of great importance, consisting principally of skins, furs, cattle, fish, both dry and salted, caviare, soap, and tallow. The transit trade between China and European Russia is also largely carried on across Siberia. The sole entrepot of this commerce was formerly at Kiakhta, S. E. of Lake Baikal, but trade is not now restricted to it. The principal exports to China are cotton and woollen cloths, linen, furs, gold and silver articles, and leather; the imports, tea, both leaf and compressed in cakes, sugar, silks, cottons, wool, cattle, leather, furs, grain, dried fruit, and colors. This trade has been chiefly carried on by means of the rivers which flow into Lake Baikal, thence through the Upper Tunguska to Yeniseisk, thence after a land carriage of about 40 m. passing through

the Ket, the Obi, and the Irtish to Tobolsk, whence there is again a land conveyance of about 500 m. across the Ural mountains to Perm. In winter it is maintained by means of sledges. But recently the tendency of the trade has appeared to be to take the sea route by the coast of China to Nikolayevsk, and thence up the Amoor by steamboat. There is also a considerable caravan trade with Ili, Tashkend, Khokan, &c. A great deal of the trade of the country is transacted at fairs held at stated periods. The most important fairs are at Obdorsk near the mouth of the Obi, Turukhansk on the Yenisei, Ustyansk on the Yana, Ostrovnoye on a tributary of the Kolyma, Tiumen on a W. tributary of the Irtish, and Irbit in the E. part of the government of Perm. During the summer steamers ply on all the large streams of central and southern Siberia and on Lake Baikal, so that there is less than 1,000 m. of wagon transit between St. Petersburg and the mouth of the Amoor. A great railway across the continent is projected, to connect European Russia with Peking. The proposed western terminus is Yekaterinburg on the E. slope of the Ural mountains, whence the line will pass through Shadrinsk, Omsk, Tomsk, and Krasnoyarsk to Irkutsk.—Siberia is divided into two military circumscriptions, East and West Siberia: the former comprises the governments of Irkutsk and Yeniseisk, and the provinces of Transbaikal, Yakutsk, Amoor, and the Littoral; the latter the governments of Tobolsk and Tomsk, together with the Kirghiz territories of central Asia. The respective capitals are Irkutsk and Omsk. Each of these two great divisions, which were formed on the present basis in 1865, has a military governor general, who is also commander-in-chief of the troops, and has control of all affairs, civil and military. Each of the governments and provinces has also a civil governor, subordinate to the governor general, who is assisted by a council of regency. A vice governor fills his place in case of his absence or sickness.—Genghis Khan conquered a part of Siberia, and his successors reduced the country lying on both sides of the Irtish. About 1580 the Russian family of Strogonoff, to whom the czar had granted lands on both sides of the Ural mountains, applied to a Cossack chief, Yermak Timofeyeff, for assistance against the khan Kutchum, who ruled the country on the Tobol and Irtish rivers. Yermak invaded the country and made extensive conquests. Other adventurers followed up his successes, which resulted in 1587 in the subjection to Russia of the khanate of Sibir (called after a town of that name, whence the name Siberia). Tobolsk, Tiumen, Pelymsk, and Berezov were soon after founded and settled by Europeans. In 1604 Tomsk was founded, and the Cossacks, pushing eastward, founded successively Kuznetsk, Yeniseisk, Irkutsk, Selenginsk, and Nertchinsk, and at last reached the shores of Behring strait. The conquest of the entire country was effected in about 80 years. The Amoor region was soon after visited by a Pole and some other exiles escaped from Yeniseisk, who built a small fort on the river; but having quarrelled with the Tunguses, they offered the conquest to the emperor of Russia, and begged forgiveness for their former offences, while the Tunguses about the same time applied to the emperor of China for assistance. This led to disputes between the two governments, but war was prevented, and the boundary between China and Siberia established, by a treaty concluded at Peking in 1689. A second treaty was made in 1727, confirming the former and confining commercial intercourse to Kiakhta and Maimatchin. The Amoor country was finally ceded to Russia in 1858, and in 1860 a treaty was concluded by which the whole line of the frontier was thrown open for traffic. The transportation of criminals to Siberia was begun by Peter the Great in 1710. A well organized insurrection of Polish exiles was promptly suppressed in 1866. In 1871 the Russians took possession of the whole of the island of Saghalien, which by a treaty concluded in 1867 had been divided between Russia and Japan, and in 1875 the Japanese government resigned all claims to it.—See Atkinson, "Oriental and Western Siberia" (London, 1858); Pumpelly, "Across America and Asia" (New York, 1870); and Kennan, "Tent Life in Siberia" (New York, 1870).

**SIBLEY**, a S. county of Minnesota, bounded S. E. by the Minnesota river; area, about 500 sq. m.; pop. in 1870, 6,725. The surface is undulating and the soil fertile. Lake Minnetonka, 30 m. long, is in this county. The chief productions in 1870 were 237,706 bushels of wheat, 142,060 of Indian corn, 221,416 of oats, 34,545 of barley, 32,659 tons of hay, 19,600 lbs. of wool, and 310,217 of butter. There were 1,726 horses, 3,531 milch cows, 5,952 other cattle, 3,666 sheep, and 3,990 swine. Capital, Henderson.

**SIBOUR, Marie Dominique Auguste**, a French prelate, born at St. Paul-Trois-Châteaux, Drôme, April 4, 1792, assassinated in Paris, Jan. 3, 1857. He was educated at Avignon and at Paris, was for a time professor in the seminary of St. Nicholas du Chardonnet in Paris, was next vicar to the parish of St. Sulpice and to the chapel of the *missions étrangères*, in 1822 became canon of the church of Nîmes, in 1838 vicar general of that diocese, in 1840 bishop of Digne, in 1848 archbishop of Paris, as successor to Affre, and in 1852 a senator. In 1857, while opening the yearly nine days' devotion in honor of St. Geneviève in the church of St. Étienne du Mont, he was stabbed to the heart by a priest named Verger, whom he had recently suspended. He was distinguished for religious and charitable activity, and published *Institutions diocésains* (2 vols., 1845).

**SIBYL** (Gr. σίβυλλα), a name applied to several women reputed prophetic in the ancient mythical period. Some authors say there

were four, others ten, viz.: the Babylonian, the Libyan, the Delphian, the Cimmerian, the Erythræan, the Samian, the Cumæan (sometimes identified with the Erythræan), the Hellespontian or Trojan, the Phrygian, and the Tiburtine. Counsel and help were sought from them under the belief that they were able to predict, to avert calamities, and to appease the gods. The most famous of all was the Cumæan sibyl, so called from Cumæ, her residence in Campania. According to an ancient Roman legend, she offered to sell Tarquinius Priscus nine books, which the king refused. Burning three, she offered the remaining six for the same price that she had asked for the nine; refused again, she burned three more, and still demanded the same price for the remaining three. The king purchased these, and the sibyl vanished. They were the famous sibylline books, and were preserved in the temple of Jupiter Capitolinus, in care of two officers (*duumviri*), afterward 10 (*decemviri*), and finally 15 (*quindecemviri*), who alone, directed by the senate, might inspect their contents. Of these nothing definite is known. The sibylline books having perished when the temple of Jupiter Capitolinus was burned in 83 B. C., a new collection was compiled by ambassadors sent to the various sibylline oracles in Italy, Greece, and Asia Minor, and was deposited in the new temple of Jupiter. In the reign of Augustus spurious prophetic books multiplied in private hands, and the emperor ordered 2,000 of them to be burned. Those volumes in custody of the state, revised by Tiberius, were preserved in two gilt chests in the temple of Apollo. Eight books of apocryphal Christian literature, collected after the 2d century, entitled "Sibylline Oracles," and still extant, consist of a heterogeneous mixture of heathen, Jewish, and Christian poems. An edition of these books was published by Gallæus in 1689 (4to, Amsterdam), and fragments have been edited by Angelo Mai (Milan, 1817) and Struve (Königsberg, 1818).

**SICARD, Roch Ambroise Cucurron**, abbé, a French philanthropist, born at Fousseret, near Toulouse, Sept. 20, 1742, died in Paris, May 10, 1822. He was educated at the university of Toulouse, entered holy orders, received instruction from the abbé de l'Épée, opened the school for deaf mutes at Bordeaux in 1786, and became vicar general of Condom and canon of Bordeaux. In 1789, on the death of De l'Épée, he was appointed his successor in the institution at Paris. His former church preferments caused him to be suspected, and on Aug. 26, 1792, he was imprisoned, and barely escaped death at the September massacre. His lectures attracted many of the more eminent literary men of Paris; but he incurred the wrath of the directory, and was banished for his strictures upon the government. He improved De l'Épée's method by the addition of signs for metaphysical ideas. In 1815 he visited England, taking with him his pupils Massieu and Clerc. He published several works on deaf-mute instruction. (See Deaf and Dumb, vol. v., p. 733.)

**SICILIES, The Two** (It., *Regno delle Due Sicilie*), formerly a kingdom of southern Italy, including the island of Sicily, with various smaller islands, and the kingdom of Naples. At the time of its incorporation with the dominions of Victor Emanuel in 1860, the area was 43,225 sq. m., and the population 8,703,130. It now forms six main divisions of the kingdom of Italy, viz.: the island of Sicily, with seven provinces (see Sicily), and the continental divisions of Abruzzo and Molise, Campania (with Naples), Apulia, Basilicata, and Calabria, with an aggregate of 16 provinces (including Benevento, which formerly belonged to the papal dominions) and somewhat over one third of the population of all Italy. (See Italy.)—The early history of the peninsular part of the country, which in ancient times comprised the divisions of Bruttium, Lucania, Calabria, Apulia, Samnium, Campania, and a part of Latium, is closely connected with the history of Rome, and, through the Magna Græcian cities of Tarentum, Croton, Sybaris, Thurii, Rhegium, Neapolis, and others, partly also with that of Greece. After the fall of the western empire the country was successively under the power of the Goths, the Byzantine exarchate of Ravenna, and the Saracens; but several small republics or duchies, as Naples, Salerno, Amalfi, Gaëta, and Benevento, ultimately rose to independence. During the first half of the 11th century great numbers of Norman adventurers served these small states as mercenaries, but soon began to wage war on their own account; and under the leadership of William Bras de Fer, Drogo, and Robert Guiscard, they conquered the greater part of Apulia, which they divided into 12 counties, forming together a feudal confederation. In 1053 Pope Leo IX., at the head of German and Italian troops, tried to expel the new conquerors; but he was defeated at Civitella and taken prisoner, and his captors obliged him to recognize their conquests by formally holding them as vassals of the holy see. Robert Guiscard established his power paramount over his companions in arms, assumed the title of duke of Apulia, and subdued Calabria, while his youngest brother Roger made himself master of the island of Sicily, previously occupied by the Saracens. In 1127 the whole of the Norman acquisitions were united under Roger II., son of Roger I., the conqueror of Sicily, who received in 1130, from the antipope Anacletus II., the title of king of Sicily and Apulia. The bull which conferred that dignity clearly established the paramount lordship of the pope, and stipulated the annual tribute to be paid by the new kingdom. Roger conquered Capua and Naples. He was succeeded in 1154 by his son William I. the Bad, who left his crown to William II. the Good (1166-'89);

the latter promoted public prosperity, and was a stanch supporter of Pope Alexander III. and the cities of Lombardy against the emperor Frederick Barbarossa. William II. died without issue, and his kingdom was claimed by his aunt Constantia, who had married the son of Frederick Barbarossa. Her husband, Henry VI., upheld her rights against the usurper Tancred, and finally in 1194 united the kingdom of Naples and Sicily to the empire. On his premature death in 1197, his Italian crown passed to his son, afterward the emperor Frederick II. The exertions of this prince to annihilate the Lombard league and to strengthen his dominion over Italy drew upon himself and his descendants the persecution of the papal court; and during the minority of Conradin, his grandson, the Roman see took the kingdom. Manfred, a natural son of Frederick II., at first regent for his nephew Conradin, then king on the pretended death of this young prince (1258), was finally defeated and slain at the battle of Benevento (Feb. 26, 1266), by Charles of Anjou, who had been crowned as his successor by Pope Clement IV., and who now usurped the power in the two kingdoms. Conradin, the last of the Hohenstaufen, was utterly defeated at Tagliacozzo, Aug. 23, 1268, and beheaded at Naples, Oct. 29. The exasperation produced by Charles's despotism finally culminated (March 30, 1282, at the hour of vespers) in the revolt and massacre at Palermo provoked by the licentious brutality of a Frenchman, and the expulsion of the French from Sicily, an event known as "the Sicilian vespers," and Pedro III. of Aragon, the husband of Constantia, Manfred's daughter, became king. Charles strove in vain to regain possession of Sicily. For more than a century and a half the island (mainly ruled by a younger branch of the house of Aragon) and the continental kingdom were separated from each other, and the sovereigns of both parts styled themselves kings of Sicily. The destinies of the house of Anjou at Naples, obscured during the later years of Charles I. and the reign of his son Charles II. the Lame, brightened again under Robert the Wise (1309–'43), the patron of Petrarch; but the reign of his granddaughter, Joanna I., was marked by all sorts of domestic crimes and disorders. After her execution by order of the king of Hungary (see JOANNA) in 1382, a bloody contest raged between Louis I., the head of the second house of Anjou, her adopted son, and Charles of Durazzo, her lawful heir. The latter finally triumphed, but was called to Hungary by discontented nobles in 1385, crowned king, and murdered soon after. His son Ladislas, scarcely 10 years old, was overthrown by the Angevine party, who called in Louis II. of Anjou in 1389; but in 1399 he reascended his throne, and crushed the adherents of his rival. He was succeeded in 1414 by his sister Joanna II., whose reign of 21 years was as shameful and disastrous as that of Joanna I. After adopting in succession Alfonso V. of Aragon and Louis III. of Anjou, she finally, on the latter's death, bequeathed the crown to his brother René. After a few years' war René was expelled by Alfonso V., who received the investiture of his new kingdom from Pope Eugenius IV., and thus reunited the two parts of the old monarchy. On his death in 1458 he left the kingdom of Naples to his natural son Ferdinand I., who finally maintained his rights against John of Calabria, son of King René, while Sicily as well as Aragon fell to his brother John II. In 1494 the kingdom of Naples was suddenly conquered by Charles VIII. of France, and its possession was disputed by the French and Spaniards until Ferdinand the Catholic became master of it in 1503, and was successively known as Ferdinand III. of Naples and Ferdinand II. of Sicily. The oppressive rule of the Spanish viceroys resulted in 1647 in the rising under Masaniello at Naples, and in other commotions; the disturbances created by the former lasted for years, though Masaniello was speedily assassinated (July 16, 1647). During the war for the Spanish succession the people sided with Philip V., the Bourbon king; but in 1707 they accepted his competitor Charles of Austria, afterward emperor of Germany as Charles VI., whose title to Naples was confirmed by the treaty of Utrecht in 1713, while Sicily was given to Victor Amadeus of Savoy. The latter exchanged Sicily in 1720 for Sardinia, and the two kingdoms remained under the rule of Charles VI. till 1734, when they were conquered by Don Carlos, son of Philip V. of Spain, who was crowned at Palermo in 1735 as Charles III., and acknowledged as king of the Two Sicilies. In 1759, on his succession to the throne of Spain, his son Ferdinand IV. became king of Naples and Sicily. Under the influence of his wife Queen Caroline and her favorite the prime minister Acton, he joined the first coalition against France, and in 1799 the French established the Parthenopean republic in the Neapolitan territory. This was overthrown after a few months, and Ferdinand restored. He retained the island of Sicily with the assistance of England, but after his violation of the treaty of Paris which in 1801 he had concluded with France, Napoleon deposed the Bourbons, and in 1806 gave the throne of Naples to his brother Joseph, and in 1808 to Murat. In 1815, after the overthrow of Murat, Ferdinand was restored; and on Dec. 12, 1816, he assumed power over the two countries as Ferdinand I. of the (united) kingdom of the Two Sicilies. He abrogated the constitution which he had granted while in Sicily. The rising under Pepe in 1820 obliged him to adopt the Spanish liberal constitution of 1812, but with the aid of Austria he soon suppressed it. On his death, Jan. 4, 1825, he was succeeded by his son Francis I., who had become popular by his liberalism, but whose reign was notorious for his subserviency to Austria. He died in 1830.

His son and successor, Ferdinand II. (1830–'59), was the most odious of all the Bourbon rulers from his sanguinary repression of insurrections in Sicily and Naples. His excesses aroused the national spirit and paved the way for liberty. His son Francis II. adhered to his despotic system. In 1860 Garibaldi invaded Sicily, conquered it, and crossed the strait of Messina. On his approach in September toward Naples Francis fled to Capua. There he rallied an army, which was however compelled to surrender with the fortress, Nov. 2, the court retiring to Gaëta. The two kingdoms were merged with Victor Emanuel's possessions, and the flight of Francis from Gaëta and the surrender of that stronghold to Gen. Cialdini, Feb. 13, 1861, removed the last obstacles to national unity, and Victor Emanuel received on Feb. 26 the title of king of Italy.—See Giannone, *Storia civile del regno di Napoli* (4 vols., Naples, 1723; new ed., 13 vols., Milan, 1823 *et seq.*); Colletta, *Storia del reame di Napoli dal* 1734 *sino al* 1825 (2 vols., Capolago, 1834; English translation, 1858); and Reuchlin, *Geschichte Neapels während der letzten siebzig Jahre* (Nördlingen, 1862).

**SICILY** (anc. *Trinacria*, from its triangular shape, *Sicania*, and *Sicilia*), the largest island of the Mediterranean, forming part of the kingdom of Italy, separated from Calabria by the strait of Messina, between lat. 36° 38′ and 38° 18′ N., and lon. 12° 25′ and 15° 40′ E. The northern side is 180, the southwestern 171, and the eastern 113 m. long; area, 11,291 sq. m.; pop. in 1872, 2,584,099. The extreme points of the island are Capo di Faro or Cape Peloro (anc. *Pelorus*) at the northeast, Cape Passaro (*Pachynus*) at the southeast, and Cape Boeo (*Lilybæum*) at the northwest. It is divided into the provinces of Caltanisetta, Catania, Girgenti, Messina, Palermo, Syracuse, and Trapani. Capital, Palermo. The coast has numerous indentations, the largest of which are the gulf of Castellamare on the northwest, the gulf of Patti on the northeast, and the bay of Catania on the east; the best harbors are those of Palermo, Messina, Agosta, and Syracuse. The tides on the coast are slight and irregular. Of the two principal currents of the Mediterranean, that from the Atlantic and that from the Black sea, only the first is felt upon the shores of Sicily, and in its set through the strait of Messina it causes the whirlpool at the N. end called by the ancients Charybdis. Most of the mountains of Sicily are regarded as part of the system of the Apennines. The northern part of the island is generally high, the mountains in several places coming close to the sea; but in the opposite direction they recede to a considerable distance, and the coasts are of moderate elevation. The celebrated volcano Mt. Etna rises in solitary grandeur (upward of 10,800 ft.) from the E. coast, midway between the N. and S. extremities of the island. (See Etna.) A range of mountains runs from Cape Peloro, on the strait of Messina, to the S. W., following the E. coast to near Taormina, 30 m. from Messina, where it is joined by a chain from the west which keeps much nearer the N. than the S. W. shore, and sends off spurs to the coast in the former direction. The first chain, now called Pelorian, was anciently known as Neptunius Mons; the second is now called Madonian, and was anciently known as the Nebrodian. No part of this chain rises above 6,300 ft., and in the west it becomes much broken. About half way across the island a chain of great hills breaks off from the Madonian mountains, runs W. of the high plateau of Etna to the southeast, and is cut up by numerous and precipitous ravines, but sinks into a flat country as it approaches the S. E. point of Sicily. The island is watered by numerous streams, the most important of which are the Alcantara (anc. *Taurominius*) and Giaretta or Simeto (*Symæthus*) on the E. coast, the Salso (S. *Himera*), Platani (*Halycus*), and Belici (*Hypsas*) on the S. W., and the Termini (N. *Himera*) on the N. They are nearly all mere torrents, dry or nearly so in summer, but swelling into floods during the seasons of heavy rains; and few of them are navigable even at their mouths. The largest lake is that of Lentini, near the E. coast, between Catania and Syracuse; it is about 12 m. in circumference, but shallow and stagnant.—Sicily contains no strata corresponding to those of the Silurian, the old red sandstone, the carboniferous, or the new red sandstone formation; granite and limestone are found in some places, and near Etna a large tract is covered with volcanic products. Different kinds of fine stone abound, and amber is procured near Catania. Small quantities of argentiferous lead, quicksilver, iron, copper, and antimony are found, but they are seldom worked. The other minerals include marble, petroleum, emery, alum, rock salt, agates, and sulphur, the most important of all. The climate is temperate and agreeable. The thermometer rarely rises higher than 92° F. and seldom sinks below 36°, and the mean annual temperature at Palermo is about 64°. The annual fall of rain is about 26 inches, nearly all during the winter months. In summer the weather is settled, but after the autumnal equinox it becomes for a time hazy and boisterous. Thunder storms are violent and frequent; and the sirocco, or S. E. wind, blowing for three or four days at a time, is very distressing in some parts of the island. There are two kinds of level ground in Sicily. Of the first an example is found in the dreary wastes along the S. shore, where the limestone rock coming near the surface supports a scanty vegetation; and of the second in the fertile plains of Palermo, Catania, and Castellamare, filling up the curves of the mountains which recede from the sea. The hilly regions are varied with undulating slopes and bold crags, the former of which are clothed with forests of fine timber, or covered with excellent pastures. In the fertile plains cultivation is general, and

although the mode is rude and careless, the crops are often remarkable for their luxuriance; the most important are wheat, maize, barley, and pulse. Artificial grasses are grown to a small extent, and hemp is raised in the deeper and lower grounds. The vine and olive are extensively cultivated, and often intermixed. The other productions include sugar, barilla, cotton, sumach, saffron, manna obtained from a species of ash (*fraxinus ornus*), and the mulberry, which is extensively applied to rearing silkworms. Various kinds of fruit abound. The most valuable kinds of timber are ash, oak, pine, elm, and chestnut. Cattle are not numerous, and are generally neglected. Sheep are extensively reared, but the breed is inferior, and in many places goats are preferred to them. Snakes are common in the plains, and wolves in the mountains.—The population is a mixture of many races, but the Sicanians or Siculians seem to have been the aborigines. Greeks, Carthaginians, Romans, Vandals, Goths, Herulians, Arabs, and Normans afterward settled among them. The Sicilians are of light olive complexion, middle stature, and well made. The dialect differs considerably from the Italian, being much mixed with Arabic and other languages. They are all Roman Catholics, excepting a number of descendants of modern Greek settlers, who adhere to the Greek church. The unequal distribution of landed property, the fatal rule of the Bourbons, the total neglect of education, and other untoward circumstances have produced great misery in Sicily; but the island is gradually improving under Victor Emanuel, although brigandage still prevails, especially under a wide-spread organization known as the *Mafia*. There are now elementary schools in the villages and higher schools in the towns, and Palermo has a celebrated university. Industry is not much developed, and the manufactures are limited chiefly to the larger towns. The wines of the country are largely exported, along with fruit, grain, oil, sulphur, silk, wool, sumach, &c. The fisheries are among the most productive in the Mediterranean.—The first inhabitants of Sicily are supposed to have come from the continent of Italy. The Phœnicians early founded colonies there, including Panormus (now Palermo) and Eryx. In the 8th century B. C. the Greeks drove them into the interior, and in that and the following two centuries established several colonies on the coasts, such as Zancle or Messana (Messina), Syracuse, Leontini (Lentini), Catana (Catania), several towns called Hybla, Gela, Selinus, and Agrigentum (Girgenti), of which Syracuse and Messana became the most celebrated. The Carthaginians invaded the island early in the 5th century and also established colonies, which, after long contests with the Greeks, finally fell under the power of Syracuse. (See SYRACUSE.) During the first Punic war Agrigentum was the principal stronghold of the Carthaginians, but was conquered by the Romans, who subsequently obtained possession of the whole island, afterward their principal granary. On the decline of the Roman empire Sicily was overrun by barbarians. The Ostrogoths, who conquered it at the close of the 5th century, were expelled in 535 by the Byzantine general Belisarius. The Saracens occupied it about 830, and made Palermo their capital. In the 11th century they were driven out by the Normans, who established the feudal system, and united Sicily to Naples, with which its subsequent history is identified. (See SICILIES, THE TWO.)—Among recent works on Sicily are: *L'Histoire de la Sicile sous la domination des Normands*, by Bazancourt (2 vols., Paris, 1846); *Storia dei Musulmani di Sicilia*, by Amari (Florence, 1853); *Compendio della storia di Sicilia*, by San Filippo (7th ed., Palermo, 1859); *Neapel und Sicilien*, by Löher (2 vols., Munich, 1864); *Siciliana*, by Gregorovius, included in his *Wanderjahre in Italien* (4 vols., Leipsic, 1874); "History of Sicily to the Athenian War," by W. Watkiss Lloyd (London, 1874); and *Geschichte Siciliens im Alterthum*, by Ad. Holms (3 vols., Leipsic, 1874 *et seq.*).

**SICKINGEN, Franz von**, a German soldier, born in the castle of Sickingen, Baden, March 1, 1481, died May 7, 1523. He was rich and distinguished for valor and generosity. He encouraged the reformation, protected Reuchlin and Ulrich von Hutten, and offered an asylum to Luther. In 1513 he declared war against the city of Worms, and subsequently fought against the duke of Lorraine, levied large amounts of money upon Metz and other cities, and laid siege to Mentz, when the quarrel was adjusted by the emperor. In 1521 he invaded Picardy with the count of Nassau, but was forced by a stratagem of the chevalier Bayard, and by sickness in his army, to abandon the expedition. In 1522 a private dispute brought him into war with the archbishop of Treves, and he raised an army of 12,000 men and desolated his territories. In 1523 he was besieged in his castle Landstuhl near Kaiserslautern, and surrendered after receiving a mortal wound. He was one of the last nobles who maintained in Germany the right of private warfare. His descendants became counts of the empire; only one branch of them now survives.—See *Ritter Franz von Sickingen und seine Nachkommen*, by Schneegans (Creuznach, 1867).

**SICKLE.** See SCYTHE.

**SICKLE-BILL.** See CURLEW.

**SICKLES, Daniel Ephraim**, an American general, born in New York, Oct. 20, 1822. He studied at the university of New York, but did not graduate, and was admitted to the bar in 1844. In 1847 he was elected to the state legislature, and in 1853 was appointed corporation attorney in New York city. In the latter year he accompanied Mr. Buchanan to England as secretary of legation. He was elected to the state senate in 1855 and to congress in 1856, and re-elected to the latter in 1858 and 1860. In 1859 he shot Philip Barton Key in Washington for

an intrigue with his wife, and was tried for murder, but acquitted. On the outbreak of the civil war in 1861 he raised the Excelsior brigade in New York, and was commissioned colonel. In September his nomination as a brigadier general of volunteers was rejected by the senate, but on its renewal was confirmed; and in the battles of the Chickahominy campaign he commanded a brigade of Hooker's division of the 3d corps. He succeeded Hooker in the command of his division, which he led in the battles of Antietam and Fredericksburg. He was commissioned a major general of volunteers Nov. 29, 1862, and commanded the 3d corps at Chancellorsville, May 2–4, 1863, and at Gettysburg, July 2, where he lost a leg. He was appointed colonel of the 42d infantry regiment of the regular army, July 28, 1866, and was commander of the second military district (North and South Carolina) till Aug. 26, 1867. In 1869 he was appointed minister to Spain, which office he resigned in 1874. He married a Spanish lady as his second wife.

**SICYON** (now *Vasilika*), one of the most ancient cities of Greece, in the Peloponnesus, originally on a plain near the Corinthian gulf. Having been destroyed, it was rebuilt by Demetrius Poliorcetes on a hill between the Asopus and Helisson, about 10 m. N. W. of Corinth. The streets, laid out at right angles, are still traceable. Its territory was called Sicyonia. It was one of the Dorian states, and was ruled by tyrants for about a century after 676 B. C. It joined the Persians in their wars, was repeatedly assailed by the Athenians, and favored the Spartans in the Peloponnesian conflict. Aratus, its general, united it to the Achæan league in 251. It was long a chief seat of Grecian art, and had an eminent school, founded by Eupompus and including Apelles and Pamphilus, and was the model of taste and fashion in dress for all Greece.

**SIDDONS, Sarah,** an English actress, born in Brecknock, South Wales, July 5, 1755, died in London, June 8, 1831. The eldest of the children of Roger Kemble (see KEMBLE), at 13 years of age she took principal parts in English operas. At 18 she married Mr. Siddons, a young actor in the Kemble company. She first appeared at Drury Lane theatre Dec. 29, 1775, as Portia in the "Merchant of Venice," but failed to produce a decided impression, apparently in great part from timidity, and at the close of the season was dismissed. She devoted herself anew to study, and, after great successes at various provincial theatres, was solicited to reappear at Drury Lane. On Oct. 10, 1782, she began this second engagement as Isabella in "The Fatal Marriage," producing a profound sensation. At once she stood at the head of the British stage, and so continued till her retirement from professional life, June 29, 1812. On this occasion she played Lady Macbeth, and the moment the night scene was over the audience rose and demanded that the play should close. Mrs. Siddons was of medium height, symmetrical and majestic, with corresponding voice and expression. Her countenance was of extraordinary flexibility. Her genius at first inclined to pathetic characters, as Isabella, Ophelia, Jane Shore, Belvidera, or Euphrasia, but later to those of power and majesty. In some other rôles she was but moderately successful. Her private character was highly esteemed.

**SIDEREAL TIME.** See DAY.

**SIDI MOHAMMED,** emperor of Morocco, born in 1803, died Sept. 20, 1873. He succeeded to the throne in 1859, as the elder son of Abderrahman, and soon afterward was engaged in difficulties with France and in a serious war with Spain, on account of the depredations of the Rif pirates. The Spanish forces under Prim and O'Donnell achieved signal victories, and the final treaty of April 27, 1860, bound the emperor to pay an indemnity to Spain of 20,000,000 piasters, and to cede her some territory, besides granting her other concessions. He afterward strove to secure the good will of Christian powers by introducing reforms and making concessions to foreigners, which produced such discontent among his subjects that they nearly drove him from the throne in 1862. Yet in 1864 he granted liberty of commerce to all European traders in his dominions, and the result was repeated insurrections. That of 1867, the most formidable, he quelled by attacking the insurgents in person at the head of a powerful army. He was succeeded by his son Muley Hassan.

**SIDMOUTH, Lord.** See ADDINGTON.

**SIDNEY, Algernon,** an English statesman, born about 1622, executed on Tower hill, London, Dec. 7, 1683. He was the second surviving son of the second earl of Leicester of that creation, by the eldest daughter of the earl of Northumberland, and grandnephew of Sir Philip Sidney. In 1632 he accompanied his father to Denmark, where the latter was accredited as ambassador, and four years later to France. In 1641 he served in Ireland as captain of a troop of horse in a regiment commanded by his father; and at the outbreak of the civil war, while on his way with his brother to join the king's forces, he was detained at Liverpool by order of parliament. The king believed this had been done through the connivance of the young men, who, resenting his distrust, at once declared for the parliament. Algernon Sidney was commissioned a captain in May, 1644, and fought with gallantry at Marston Moor, where he was severely wounded. In 1646 he was appointed lieutenant general of horse in Ireland, and governor of Dublin. In the same year he entered parliament for Cardiff, and in May, 1647, received the thanks of parliament for his services in Ireland, and was made governor of Dover castle. He acted as one of the judges of the king, but refrained from signing the warrant for his execution, although he subsequently characterized it as "the justest and bravest action that ever was

done in England or anywhere else." His opposition to the protectorship of Cromwell compelled him to relinquish his legislative duties; and in April, 1653, he retired to his father's residence at Penshurst. He resumed his seat at the first meeting of the restored parliament in 1659, and on May 13 was nominated one of the council of state. On June 5 he was sent as one of the commissioners to negotiate a peace between Sweden and Denmark, and was absent from England at the time of the restoration. Unwilling to return to his native country while it remained under "the government of a single person, kingship, or house of lords," he remained a voluntary exile for nearly 18 years. Intent upon establishing an English republic, in 1665 he sought the assistance of the Dutch government and the influence of the French ministers toward that end. Failing in both instances, he retired to the south of France, where he lived till 1677, when, at the solicitation of his father (a centenarian), a permission for him to return home was obtained from the king. He soon became an active opponent of the court, but was defeated in two attempts to obtain a seat in parliament. He is charged with accepting 500 guineas for favoring the intrigues of Barillon, the French ambassador, who about this time was in clandestine correspondence with prominent members of the popular party seeking to crush the duke of York and the Roman Catholics, the parliament, and the ministry. But it has been alleged that, if true, the act was not criminal, as it required no betrayal of his principles, and as he needed the money and its acceptance was not repugnant to the practice of the age. The discovery of the Rye House plot, in June, 1683, gave the king an opportunity to exact vengeance for years of restraint and humiliation; and Sidney, with his illustrious companion in misfortune, William Lord Russell, was arrested on a charge of complicity with the conspirators, and imprisoned in the tower. At his trial, over which Jeffreys presided, but a single living legal witness to the conspiracy for an insurrection, the infamous Lord Howard, could be produced; but garbled extracts from a theoretical work on government in manuscript, which had been found among Sidney's papers, were read in evidence against him. These, though containing assertions of the right of a people to depose an unworthy sovereign, were unconnected by other evidence with the conspiracy itself; under the ruling of the court, they were nevertheless deemed sufficient to convict. Sidney met his death "with the fortitude of a stoic." His attainder was reversed by the first parliament of William and Mary. His "Discourses concerning Government" were published in 1698, and a fourth edition, with additions by Thomas Hollis, including his "Apology," dated on the day of his death, and a number of letters and miscellaneous pieces, in 1772. His "Essay on Virtuous Love" was published in vol. viii. of the Somers collection of tracts (1742). The fragmentary distich,

> . . . manus hæc inimica tyrannis
> Ense petit placidam sub libertate quietem,

which he wrote in the university album at Copenhagen, is perhaps the best remembered extract from his writings. The report of his trial, after Jeffreys had struck out whatever he pleased, was published in 1684; it is also given in "Howell's State Trials."—His life has been written by George Wilson Meadley (8vo, London, 1813), and by G. Van Santvoord (12mo, New York, 1851). See also Arthur Collins, "Memoirs of the Lives and Actions of the Sidneys," prefixed to his "Letters and Memorials of State," &c. (2 vols. fol., London, 1746), and Blencowe, "Sydney Papers" (8vo, 1825).

**SIDNEY**, or **Sydney**, Sir **Philip**, an English author, born at Penshurst, Kent, Nov. 29, 1554, died in Arnhem, Holland, Oct. 7, 1586. His father, a descendant of Sir William Sidney, chamberlain to Henry II., was in his youth the bosom friend of Edward VI., and during the reign of Elizabeth held for many years the office of lord deputy of Ireland. His mother was the eldest daughter of the ambitious and unfortunate John Dudley, duke of Northumberland, and sister of Robert Dudley, earl of Leicester. At the age of 12 Sidney was sent to the grammar school of Shrewsbury, and in 1569 entered Christ Church college, Oxford. He subsequently studied at Cambridge, and at both universities was distinguished not less for preëminence in manly exercises than in mental accomplishments. In May, 1572, he obtained a license from the queen "to go out of England into parts beyond the seas," in order to perfect his knowledge of the continental tongues. At the court of Charles IX. of France he attracted the attention of the king, who appointed him gentleman in ordinary of his chamber; but the spectacle of the St. Bartholomew massacre induced him to depart abruptly from Paris, and he travelled through Germany, Italy, Hungary, Poland (where he took some part in the skirmishes with the Russians), and the Low Countries. Returning to England at the expiration of three years, he at once took his place among the foremost of the accomplished Englishmen of the time. The queen showed him special favor, and called him "her Philip," in opposition, it is supposed, to Philip of Spain, her sister Mary's husband. In 1576 he was nominated ambassador to Vienna, ostensibly to condole with the emperor Rudolph on the demise of his father, Maximilian II., but with the secret instruction to cement an alliance of the Protestant states against Spain; a mission which he discharged successfully, gaining the esteem and high praise of the prince of Orange. He returned in 1577, and for the next few years was employed in no important public capacity, partly from his reluctance to give up his literary

occupations, and partly, it has been suggested, through the machinations of Lord Burleigh. But he defended successfully the character of his father, whose administration in Ireland had been misrepresented by enemies at court. When admonished by the queen, in consequence of a dispute between himself and the earl of Oxford, of the difference in degree between earls and gentlemen, he replied that, "although Oxford was a great lord by birth, alliance, and grace, yet he was no lord over him; and therefore the difference of degrees between freemen could not challenge any other homage than precedency." Although the answer was taken in good part by the queen, Sidney deemed it prudent to retire for a while from court; and while residing at the seat of his sister, the countess of Pembroke, he wrote his pastoral romance of "Arcadia," which is in prose, interspersed with short poems. It never received the finishing touches and corrections of the author, and was moreover left incomplete. After circulating in manuscript for several years, it was published by the countess of Pembroke in 1590; and such was its popularity, that previous to the middle of the 17th century upward of ten editions had appeared, and a French translation was published in 1624. To this period also probably belong the "Defence of Poesie," published in 1595, and originally designed as an answer to the attacks of the Puritans, and the series of amatory poems entitled "Astrophel and Stella" (1591), which recount the author's passion for Lady Rich, sister of Lord Essex, to whom he was at one time betrothed. In the intervals of his literary occupations he participated in courtly pageants and jousts, the most conspicuous of all the brilliant circle who surrounded the throne; and in 1583 he married the daughter of Sir Francis Walsingham, and was knighted. In 1585 he was nominated governor of Flushing, and in the latter part of the year appointed general of horse under his uncle the earl of Leicester, who was sent with a body of English troops to aid the Dutch in their war of independence. Sidney was fast building up a reputation as a skilful general when his career was brought to an untimely close. On Sept. 22, 1586, a small detachment of English troops under his command unexpectedly encountered 3,000 Spaniards who were marching to the relief of Zutphen, and a desperate engagement was fought under the walls of the fortress, in which the enemy were signally defeated. Sidney, seeing the Spanish leader going into battle lightly armed, was induced by a chivalric spirit of emulation to imitate his example; and after a series of gallant charges, in which he had a horse killed under him, he received a musket ball in his left thigh. While leaving the field, "being thirsty with excess of bleeding," says Lord Brooke, "he called for drink, which was presently brought him; but as he was putting the bottle to his mouth, he saw a poor soldier carried along, who had eaten his last at the same feast, ghastly casting up his eyes at the bottle. Which Sir Philip perceiving, took it from his head before he drank, and delivered it to the poor man, with these words: 'Thy necessity is yet greater than mine.'" He lingered several weeks in great agony, and met his death with Christian serenity, solacing even his last hours with literary composition. His body was taken to London, and after lying in state was interred in St. Paul's cathedral, Feb. 16, 1587; and a general mourning, the first on record in England, was observed. Spenser has embalmed their mutual friendship in a pastoral ode entitled "Astrophel." Sidney left an only daughter, who became fifth countess of Rutland, but died without issue; and his name is now represented in the English peerage by Lord De l'Isle, a descendant of his brother Robert. His "Complete Works" were published in 3 vols. 8vo (London, 1725), and his "Miscellaneous Works" were edited with a memoir by W. Gray (Oxford, 1829; reprinted, Boston, 1860). The latest edition of his works is "The Complete Poems of Sir Philip Sidney," edited by the Rev. A. Grosart, in the "Fuller Worthies' Library," printed for private circulation (2 vols., 1873).—His sister MARY, countess of Pembroke (died Sept. 25, 1621), is intimately connected with his private history. He joined with her in a translation of the Psalter "into sundry kinds of verse," first printed in London in 1823. She wrote an elegy on her brother, a pastoral poem in praise of Astræa (Elizabeth), and a poem "On our Saviour's Passion," preserved in manuscript in the British museum, and published in 1862, besides translating from the French the "Tragedy of Antonie."

**SIDON**, or **Zidon** (Heb. *Tzidon*, fishery; now *Saida*), an ancient city of Phœnicia, on the coast, 23 m. N. of Tyre. According to Josephus, it was called Sidon after the first born of Canaan, but the name probably has reference to the first occupation of its inhabitants. From its antiquity it was termed the metropolis of Phœnicia. It seems to have been divided into Great Sidon, on the sea, and Little Sidon, some distance inland. The Phœnicians as a nation often designated themselves as Sidonians, and were generally called so by neighboring peoples. The period of the greatest prosperity of Sidon, according to the classical historians, was from about 1600 to 1200 B. C., during which time, as appears from the Egyptian inscriptions, it was more or less under the supremacy of Egypt. At the time of the Hebrew conquest of Palestine, the rule of Sidon extended over the N. W. part of that country. The ancient history of the town is in a measure that of the whole of Phœnicia, at least until the commencement of the supremacy of Tyre. (See PHŒNICIA, and TYRE.) It flourished under the Persians, but was destroyed in 351 B. C., as a punishment for rebelling against Artaxerxes III. Ochus. It was thenceforth a provincial capital, but retained its own

local government until the time of Roman supremacy. Christianity early found an asylum here (Acts xxvii. 3), and a Sidonian bishop is mentioned as present at the Nicæan council of 325. On the rise of Moslem power it readily submitted to it. In 1108 it was invested by the crusaders, and in 1110 it was taken by Baldwin I. The Saracens captured it in 1187, but the Christians recovered it in 1197. They abandoned it in 1291, and Sultan Malek Ashraf ordered it to be razed. (See SAIDA.)

**SIDONIUS APOLLINARIS, Caius Sollius Modestus,** a Latin author and saint, born probably in Lyons about A. D. 431, died at Clermont in Auvergne, in 482 or 484. He was a diligent student, and early acquired a high reputation. He married a daughter of Flavius Avitus, afterward emperor, accompanied him to Rome in 456, and pronounced his panegyric in verse before the senate, for which that body erected a bronze statue in his honor. He was prefect of Rome when Avitus was dethroned by Majorian. Sidonius pronounced at Lyons a public panegyric on the latter, by whom he was created a count and sent to govern the Gallic province of Arles. In 467 he went to Rome as ambassador of the Arverni, delivered a panegyric on the reigning emperor Anthemius, was made a patrician, and governor of the city a second time, and was honored with a second statue. In 472 he was elected bishop of Clermont (Arvernum), though only a layman, accepted the office reluctantly, fulfilled its duties faithfully, and strenuously opposed the spread of Arianism. He left nine books of epistles of considerable historical interest, which, with his poems and panegyrics, were published in Milan in 1498 by Sirmond (Paris, 1614; republished by Labbe in 1652, the best edition), and by Migne in vol. lviii. of his *Patrologie latine.*—See *Saint Sidoine Appollinaire et son siècle,* by Chaix (2 vols., Clermont-Ferrand, 1867–'8).

**SIDRA, Gulf of.** See SYRTIS.

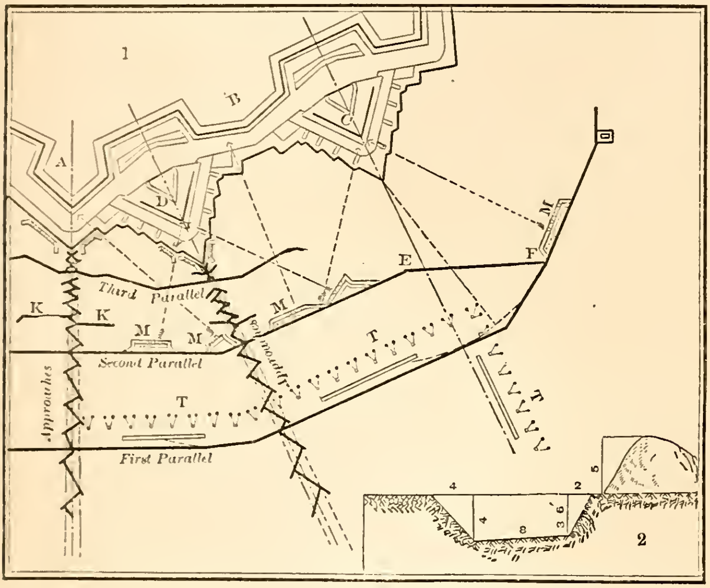
**SIEBOLD. I. Philipp Franz von,** a German traveller, born in Würzburg, Feb. 17, 1796, died in Munich, Oct. 18, 1866. He studied medicine, natural sciences, and geography, and in 1822 went to Batavia as a physician and naturalist in the Dutch service, and in 1823 to Japan as a member of the Dutch embassy. In 1826 he went to Yedo, and was involved in difficulties with the Japanese for procuring an official map of their country. Finally acquitted, he returned to Europe in 1830, but from 1859 to 1862 resided again in Japan. He published *Nippon, Archiv zur Beschreibung von Japan* (20 vols., Leyden, 1832–'57); *Fauna Japonica* (jointly with Temminck and others, 1833 *et seq.*); *Flora Japonica* (1835 *et seq.*); *Bibliotheca Japonica* (jointly with J. Hoffmann, 6 vols., 1833–'41); and several other works on Japan. **II. Karl Theodor Ernst von,** a German physiologist, brother of the preceding, born in Würzburg, Feb. 16, 1804. After teaching in various places, he became in 1853 professor of physiology, comparative anatomy, and afterward also of zoölogy, at Munich. His principal works are *Lehrbuch der vergleichenden Anatomie der wirbellosen Thiere* (Berlin, 1848; English translation, London, 1854), and *Beiträge zur Parthenogenesis der Arthropoden* (1871).

**SIEDLCE. I.** A W. government of Russia, in the kingdom of Poland, bordering on the governments of Lomza, Warsaw, Radom, Lublin, Volhynia, and Grodno; area, 5,534 sq. m.; pop. in 1872, 543,392. It is level and fertile. The chief river is the Bug, which forms the E. and N. E. frontier. The principal towns are Siedlce, Miendzyrzecz, and Wlodawa. The government embraces the principal portions of the former palatinate of Podlachia. The more ancient Polish territory of the same name, however, lay mainly between the middle Bug and the Niemen. **II.** A town, capital of the government, 51 m. E. S. E. of Warsaw, with which it is connected by rail; pop. in 1867, 10,013. It has a fine palace and town hall, distilleries, sugar refineries, and manufactories of agricultural implements. During the wars between the Russians and Poles it was repeatedly taken and retaken.

**SIEGE** (Fr. *siége*, seat), a protracted military attack upon a fortified place. Such a place may sometimes be taken by throwing in heavy projectiles, explosive shells, incendiary balls, &c.; or by completely surrounding it, preventing reception of supplies, the defenders may be compelled to surrender; or, advancing by regular approaches, the besiegers may breach the walls, and carry the place by assault. The first is called a bombardment, the second a blockade, and the third a siege, which term is often also applied to the other two. In a strict sense, the term siege signifies the process of advancing toward a fortified place under cover of earth thrown up from trenches, silencing the fire from the work by a superior one, and breaching the ramparts, compelling a surrender or carrying the place by assault. Sieges are divided into ancient and modern, or those carried on before and after the application of gunpowder to military purposes.—*Ancient Sieges.* The ancients fortified a place by surrounding it with a wall of brick or stone, forming a continuous line around the city or town, high enough to render escalade difficult, and thick enough to offer considerable resistance to the battering ram. Sometimes there were two and even three of these walls, often connected by others to give them greater solidity. Outside of the wall was a ditch, always filled with water if circumstances permitted. The inhabitants were the defenders; and as their lives, liberty, and property were involved, the resistance in ancient sieges was more obstinate and persevering than that usually made in modern times. The modes of attack were by surprise, aided by treason or particular knowledge of unguarded points; by escalade, having surprised the place; by escalade in an assault, having outnumbered and overpowered the defenders; by blockade, having deprived

them of supplies; and by regular siege operations. When the siege seemed likely to last some time, the ancients were in the habit, if they expected sorties from the place or an attempt to relieve it from without, of securing their position by a double line of works, of circumvallation and countervallation. These were generally continuous lines constructed of earth, wood, and sometimes of masonry, flanked by towers. Annoying the besieged with missiles thrown from all the artillery known in that day, they pushed forward covered approaches on the points of attack. These were wooden frames, 7 ft. high, 8 ft. wide, and 16 ft. long, mounted on wheels, with a roof strong enough to resist the projectiles thrown by the besieged. They were covered with raw hides or turf, or protected by other expedients from being set on fire. The ditch when reached was filled with earth, logs, and stones, upon which the battering ram could be placed in position to breach the wall; or a descent was made into it for the purpose of undermining the wall. The battering ram was ordinarily placed in the lower story of a tower and suspended by chains or other mechanism. The tower was high enough to command those of the place, and was filled with armed men, who drove the defenders away from that part of the wall in its front. They were frequently aided by other towers pushed along on the ground or on inclined planes. The besieged, besides shooting lighted arrows and throwing incendiary compositions against the approaches, made sorties, which were usually bloody in their results, for want of covered ways or other exterior works beyond the ditch. The battering ram being in position, the besieged suspended beams of wood, stuffed contrivances like huge mattresses, and other devices, between the head of the ram and the wall, to deaden its blows. They sometimes used machines on the principle of the crane, by means of which they caught the head of the ram, or even the whole engine, and lifted it from the ground or overturned it. Archimedes devised such machines for the defence of Syracuse when it was besieged by the Romans, in 214–212 B. C. The wall being breached by the ram, or thrown down by undermining, preparations were made to assault the place through the opening. Often, while the besiegers were engaged in removing the ruins from the breaches, so that an assault could be made, the besieged were building a new wall in rear of the breach enclosing the part attacked, and the whole operation of moving forward the battering rams and breaching the wall had to be renewed. The surrender or capture was generally due to the exhausted condition of the besieged, rather than to the assaults. It was the custom for the besieging army to demand a surrender before they began the siege; and usually the besieged offered to capitulate before the final assault was made, as a hopeless resistance entailed death or slavery on all the defenders. Even in modern times the lives of the garrison are jeoparded if the besieged delay making terms until the final assault is successful.—*Transition Period.* The introduction of gunpowder in military operations led to the substitution of earthen trenches for the wooden covers and other ancient expedients, and also replaced the battering ram by heavy cannon. In this period, owing to the imperfection of the artillery, the want of connection between the approaches, and other deficiencies in the measures of attack, the besieged were often able to make a vigorous and prolonged defence, and sieges became the most important military operations of the time. Before 1741 there were more sieges than battles; from 1741 to 1783 the proportion was 67 sieges to 100 battles; during the French revolution the proportion was about 25 to 100; and during the first empire there were only 16 sieges to 100 battles. In recent wars these proportions have still further diminished. But the necessity for sieges still exists, and the rules and practice of taking a fortified place still hold a prominent position in the military art. The present method of attacking a fortified place by regular approaches is practically that organized by Vauban. Previous to his time, the middle of the 17th century, although many sieges had terminated successfully, there was no uniform system in the modes of attack. Vauban is especially credited with the invention of ricochet firing, the concentration of enfilading batteries, and the systematic arrangement of the parallels.—*Modern Sieges.* Let it be supposed that siege operations are to be conducted against a fortified place immediately upon the theatre of war. As the operations against a place fortified by any of the modern systems are governed by the same general conditions, and are practically the same until the besiegers reach the counterscarp of the ditch, the methods used will be fully explained by considering the mode of conducting an attack on a place fortified by the bastioned system. (See FORTIFICATION.) To simplify the explanation, it is supposed that the front to be attacked has the usual outworks and occupies a horizontal site, and that the cannon used by both the besiegers and besieged are the ordinary smooth-bore siege artillery. Irregularity of site and the use of heavier calibre or rifled cannon will only have the effect of increasing certain distances and adding to the difficulties of the siege, without affecting the principles common to them all. As the scarp walls are hidden from the besiegers' view by masks of earth, the object of the siege works is to reach, under cover, positions where openings in the walls can be made either by breaching batteries or mines; and under the shelter of these approaches troops can be brought up to make assaults through the openings. In this front, in order to make a breach in the scarp by artillery fire that will be practicable for the

assaulting column, the cannon must be placed on the crest of the covered way, and to make it accessible a descent into and passage of the ditch are necessary. If it is proposed to make an opening by mining, all the preliminary operations as far as the glacis of the work are identical. If the main work has outworks from which a reverse fire can be had on that part of the covered way where the breaching batteries are to be placed, they must first be taken. The accompanying plan will aid in explaining practical siege operations. The attack is made on bastion A, and as the adjacent demilunes D, D, those on the right and left of A, place the covered way of this point



1. Half of Plan of regular Approaches against a Front of Attack.

A. Point of attack. B. Adjacent bastion. D. Demilune of front of attack. C. Collateral demilune. E, F. Trench connecting first and second parallels. K, K. Demi-parallels. M, M, M. Enfilading, counter, and mortar batteries. T, T. Troops, called guards of the trenches, protecting the workmen on opening the first parallel.

2. Section showing Slopes and Dimensions of Profile of Approach by simple Trench.

A bastion corresponding to B, demilunes to C and D, and approaches on the left of A, are supposed to be indicated and to form the whole front of attack.

in a reëntrant angle, these demilunes must be taken before the bastion can be breached. This bastion and the adjacent demilunes with their outworks must be taken by breach or assault, and the fire from the collateral demilune C and bastion B shown in the plan, and the corresponding ones on the left not shown, must be kept under by opposing batteries during these operations, to enable the besiegers to carry on their work successfully. Approaches are made on the three salients, A, D, D, and these connected by parallels to hold large bodies of troops to protect the workmen and repel sorties. The siege operations may be divided into two general parts, one including all the measures taken to prevent ingress and egress, the other those required to gain possession of the place; but for convenience they are ordinarily classed into three parts, called the first, second, and third periods. The first period comprises the investment and the encampment of the besieging army around the place; the second, all the works from the opening of the trenches until the completion of the third parallel; and the third, all subsequent measures until the place is taken. The investment is performed by detaching a strong corps, who, moving quickly and secretly, suddenly surround the place, seize all avenues of approach, cut off all communications, and secure everything that may be of service to the defence. The main army follows and intrenches in positions around the place outside of cannon range. The intrenchments ordinarily form two lines, between which the besieging army places its camps, and are called lines of circumvallation and countervallation. They may be continuous or with intervals, the outer line being used to prevent succors, and the inner to resist the attacks of the garrison. This method of constructing lines and enclosing the army between them was used by the ancients, and fell into disuse during the middle ages. It was revived in the 16th century by the princes of Nassau, and has been practised more or less ever since. These lines not only enable the besieging army to repulse detachments that try to reënforce the place, but are also useful where the besieging army is forced to take up weak positions to complete the investment. The strength of the besieged work, the nature of the ground, and the facilities for transporting troops and supplies from the depots are governing considerations in selecting the front of attack. Salients are usually the weakest points of a fortification; low, marshy soil and rocky ground present the greatest difficulties in constructing siege works.—The second period begins with the opening of the trenches, which is done by digging a ditch or trench, between 600 and 700 yards from the most

advanced point of the fortification, from 3 to 4 ft. deep and 10 to 12 yards wide, and throwing up the earth in the form of a parapet on the side toward the work. This trench and all similar ones are constructed according to the general rules for throwing up field works; that is, they must afford a shelter from the enemy's fire, and permit those occupying them to use their arms with effect. The trench is extended far enough on each side of the point of attack to embrace all the positions required for batteries to keep down the fire of the collateral works. From its being parallel to or concentric with a line connecting the most salient points of the work, it is called the first parallel. At this distance, the fire of the besieged upon the workmen in the obscurity of twilight and darkness will not be troublesome; but the distance will be materially affected by irregularity of site and the size and kind of cannon used. At Sebastopol in 1854 the French established their first parallels, one at nearly 1,000 and the other at 1,800 yards, and the English at 1,800 yards, from the defences in their front. At Fort Wagner, Charleston harbor, in 1863, Gen. Gillmore opened his first parallel at 1,360 yards from the works. Accidents of the ground may enable the besieger to place it much closer. Communications are opened from the parallel to the depots in the rear, by trenches of the same general form, so arranged as to avoid an enfilading fire from the fortifications. As the besiegers desire to get as near as they can to the point of attack with as little sacrifice of life as possible, they make their advances by means of trenches similar in form to the parallel. These are pushed forward toward the point of attack, running in zigzag directions, crossing and recrossing the lines of the capitals of the salients, and avoiding enfilading fires from any point of the defences within cannon range. The approaches, called by many writers *boyaux* or branches, are as a general rule not longer than 100 yards, and, starting at the first parallel with a front of 60 yards, are narrowed to 30 yards at the third parallel. In this position along the capitals of the salients, they are less in the way and less exposed. These are shown in the plan, one to each salient, or three in this particular case, but there should be more if the circumstances require them. When advanced not quite half way between the first parallel and the fortification, they are connected by a second parallel, which in all essential particulars except in extent is like the first. Being constructed within destructive range of case shot, the flying sap is used instead of the simple trench, as more speedy cover for the workmen is obtained by it, and differs from it only in having the interior slope revetted with gabions. Being nearer to the first parallel than to the fortification, it is protected from sorties made against it in its unfinished condition, and its object is to protect the approaches as they are pushed forward from it. Vauban prescribes that there shall be at least three of these parallels. They serve as places of arms in which troops are stationed to protect the workmen and to resist sorties, as communications between the approaches, and to keep these free for the workmen and clear of troops. Only three, and the demi-parallels K, K, are shown in the plan, but there are often many more. At Sebastopol the French constructed seven, and at Fort Wagner Gen. Gillmore used five. Whatever the number, they should be placed in good tactical relations with each other, not so far in advance that the troops occupying the one in the rear cannot come to their support before they are reached by a sortie from the fortification. The besiegers place in front of the second parallel mortar, ricochet, and counter batteries, which, firing upon the work, break down the palisades, dismount the guns, and drive away the defenders. The use of rifled guns will cause these batteries to be placed further away from the work than is here represented, probably from 2,000 to 3,000 yards, in which case they should be enclosed in small works with a sufficient number of men in each to defend them. From the nearness to the work, the advance from the second parallel can only be made by means of saps. These are the flying, single or full, the double and half double saps, according to the direction and amount of fire to which the approach is exposed, and are constructed by engineer soldiers called sappers. When the foot of the glacis is reached, from 60 to 30 yards from the salient, the third parallel is constructed, demi-parallels which are long enough to contain troops to protect the workmen, and short enough not to hinder the fire from the batteries, having been made between it and the second parallel. The second period ends with the construction of the third parallel.—Thus far the advance and progress of the siege have been made without any great degree of difficulty or danger. This is now changed, and if the defence is vigorous future progress must be made under a murderous fire from the besieged, accompanied by many difficulties in the construction of the necessary works for protection. The advance on the nearest point of the covered way from the third parallel is by assault or by regular approach. The former is more rapid and more brilliant, but is seldom successful, and ought never to succeed if the besieged are not entirely exhausted and make even an ordinary resistance. It has been shown in recent wars that a single trench, defended by two ranks of infantry armed with the improved weapons of the present day, is almost unassailable by main force. In an attack by two divisions of infantry on a continuous trench before Petersburg, Va., defended by a single line of infantry, the number of the attacking force killed exceeded the total effective strength of the defenders. If it be decided to make the assault, the third parallel is arranged

with steps on the inner side to allow a detachment of picked men to sally out at a given signal with a front equal to that of the assaulting column. They are preceded by engineer officers, who mark out the lines for a trench four or five yards from the crest of the glacis, and extending around the salient place of arms, and are followed by a detachment of engineer troops to construct it. When everything is in readiness, all the batteries open fire on the place. At a given signal they cease, and the column of assault rushes forward and takes possession of the covered way. The engineers immediately make the sap, into which the troops retire if successful, and afterward connect it by suitable communications with the third parallel. The execution of this trench around the salient place of arms is called crowning the covered way. In 1708, at the siege of Lille, the covered ways of two of the salients of the front of attack were crowned by assault. The attack was made at nightfall by 10,450 men, not counting the troops in the trenches; they lost 2,000 killed and 4,000 wounded. The best engineering authorities are opposed to an assault except in case of urgent necessity, when a day gained may decide the fate of the besiegers themselves, or the time saved by it compensates for the immense loss of life that must accompany it. If the advance is to be made by regular approaches, they are started from the third parallel by saps, which when within 30 yards of the salient are spread out in a circular form to enclose it, and high mounds of earth, called trench cavaliers, are thrown up, by which a command over the covered way is obtained. Protected by them, the engineers advance their saps to the salients and extend them to the right and left along the faces, at least as far as the traverses, as in the case when the assault was made. As soon as this is done, they proceed to establish counter and breaching batteries to fire against the demilune and bastion. The former are placed around the salients so as to fire in the direction of the ditches against the portion of the work by which they are swept, while the latter are placed near the counter batteries and nearly opposite to the points where the breaches are to be made. Underground galleries are also constructed, by means of which a descent into the ditch can be effected. A breach is considered practicable for assault when the interior of the work is exposed for a width equal to the front of the column of attack and the débris forms a slope of easy ascent. If breaches are to be made at several points, the operations should be carried on and the assaults made simultaneously. The breach in the demilune will be carried by assault or by regular approach, and in all essential things there will be no difference in the mode of taking it from that described for the covered way. As soon as the breach is gained, it is crowned, or a lodgment made by encircling it with a trench in which troops are placed to prevent the besieged from regaining possession of the work. The demilune being taken, advances are made against the reëntrant places of arms and salient of the covered way of the bastion, if they have not already been crowned. Other batteries are established against the faces and flanks of the bastion, and operations similar to those already described are carried on against the main work. A capitulation will ordinarily follow the crowning of the breach in the bastion, unless there are interior retrenchments, in which case the same method of attack will be followed until there is no longer any defence between the besieger and besieged. The breaches are supposed to have been made by battering the ramparts with artillery fire. The other method is by means of mines, which are rarely used because of the slowness of the operation and the uncertainty of the result. The explosion of the mine gives no practicable slope for the use of the assaulting column, and this must be made by workmen before it can be used, which is very difficult and dangerous. To resist the approach of the besiegers, the defence make use of mines; to destroy these, and to advance their works, the besiegers also employ them. They will be most largely used between the third parallel and the main work. The passage of the ditch is a difficult and dangerous operation, rendered doubly so when the besieged have a wet ditch, or can make use of water in their defence. In an actual siege, a daily record is made by the engineers of the amount of work done and the time required, which is transmitted to headquarters and preserved. By comparisons of these records and the results obtained in engineering schools, the time necessary to complete all these works has been calculated. This time has been used in comparing the relative value of different systems or methods of fortification, by submitting them to a fictitious siege. It is of no value in practice, for the duration of sieges depends on laws which no method of calculation can determine. In order that the besiegers should be successful, their numbers and their armament should be in excess of those brought to resist them, and no fixed rules can be stated for this excess. As a general rule, supposing the investment to be complete, the besiegers should be about six times as numerous as the besieged, and should be kept so by sending the wounded and sick to the rear and replacing them by fresh troops. As the defence have not this resource, their numbers constantly dwindle until they are exhausted or overpowered.—Among the most celebrated sieges in history are those of Babylon, Tyre, Syracuse, Carthage, Numantia, and Jerusalem in ancient times, and of Constantinople, Antwerp, Bergen-op-Zoom, Stralsund, Candia, Lille, Buda, Schweidnitz, Saragossa, Sebastopol, Vicksburg, Strasburg, Metz, and Paris since the introduction of gunpowder.

**SIEGEN**, a town of Prussia, in the province of Westphalia, on the Sieg, 37 m. S. of Arns-

berg; pop. in 1871, 11,070. It is the chief seat of the tanning and leather industry of Westphalia, and has large manufactories of iron and steel ware, and of linen, cotton, and woollen goods. It is rapidly increasing in population. Rubens was born here.

**SIEGERT, Karl August,** a German painter, born in Neuwied in 1820. He studied at Düsseldorf under Hildebrandt from 1837 to 1841, and subsequently at the academy till 1846, travelled in various countries, and in 1851 became a professor of painting at Düsseldorf. He excels in genre pictures. His recent works include "Dinner Hour," "A Welcome Pause," "Sunday Morning," and "A Lay Brother distributing Alms."

**SIEMENS. I. Ernst Werner,** a German inventor, born at Lenthe, near Hanover, Dec. 13, 1816. He entered the Prussian army in 1834, became an artillery officer in 1838, busied himself with researches in electro-metallurgy, and took out in 1841 a patent for electro-plating and gilding. From 1844 he had charge of the government artillery works at Berlin, and also devoted himself to perfecting the electric telegraph. In 1848 he laid at Kiel the first submarine mines exploded by electricity. In 1849 he left the army and founded in Berlin the telegraph-building establishment of Siemens and Halske. Among the more important of Siemens's inventions are: the method of determining the position of injuries in subterranean and submarine lines; of examining insulated wires; of charging subterraneous and submarine conductors, in order to lessen the disturbing influences of induced currents in the cables. **II. Karl Wilhelm,** brother of the preceding, born at Lenthe, April 4, 1823. He studied at Göttingen, entered the Stolberg machine works, and in 1843 settled in London as a civil engineer. In 1858 he undertook the management of a London branch of the firm of Siemens and Halske of which he had become a partner. With his brother Werner he carried on investigations in electro-magnetism, and several important improvements in the manufacture of submarine cables and the mode of insulating with caoutchouc were made by them jointly. Assisted by his younger brother Friedrich (born Dec. 8, 1826), he instituted in 1846 experiments looking to the discovery of a more perfect combustion of fuel. The result was the regenerating gas furnace. (See Furnace, vol. vii., p. 543.) In perfecting this invention all the brothers took part, although the chief merit belongs to Wilhelm. In 1869 the Siemens steel works were erected at Landore in Wales, in which nearly 1,000 tons of cast steel are produced weekly, partly by the Siemens method directly from the ore, and partly from cast and wrought iron. Other inventions of Wilhelm Siemens are: the bathometer, a hydrostatic instrument for measuring depths at sea; the hydraulic brake to prevent the recoil of artillery on ships of war; a pyrometer (see Pyrometer), &c. He has published dissertations "On a Regenerative Condenser" (1850); "On the Conversion of Heat into Mechanical Effects" (1853); "On a Regenerative Steam Engine" (1856); and "On the Increase of Electrical Resistance in Conductors with Rise of Temperature, and its Application to the Measure of ordinary and Furnace Temperatures" (1871).

**SIENA, or Sienna. I.** A central province of Italy, in Tuscany, bordering on Florence, Arezzo, Perugia, Rome, Grosseto, and Pisa; area, 1,465 sq. m.; pop. in 1872, 206,446. It is watered by the Ombrone, Orcia, and other rivers. The N. E. portion is very mountainous. There are several lakes. A portion of the soil is fertile, producing wheat, olive oil, and wine; a larger portion comprises forests, prairies, and pasture grounds; much of it is uncultivated. Cattle raising is a chief occupation. It comprises the districts of Siena and Montepulciano. **II.** A city, capital of the province, on two hills in a dreary plain, 31 m. S. by E. of Florence; pop. in 1872, 22,965. The streets are narrow, and many of them too steep for vehicles. The cathedral, built in the 13th century, is a fine specimen of Italian Gothic, and there are several other churches which are rich in works of art. The university, which was flourishing in the middle ages, has a library of 50,000 volumes and 5,000 manuscripts. Siena is an archbishop's see, and has numerous academies of literature, science, and the fine arts. The hospital of Santa Maria della Scala is one of the oldest in Europe. The piazza del Campo, celebrated in Dante's *Purgatorio*, contains the loggia di San Paolo, the seat of a commercial tribunal in the middle ages.—Siena is a very ancient place, as the remains of Etruscan walls still visible testify. It was a bishop's see in the 6th century. In the middle ages it was a powerful republic, and rivalled Florence, with which it was often at war. In the struggle between the popes and emperors it sided with the Ghibelline party, and its soldiers defeated the Guelphs at Monte Aperto or Montaperti in 1260. The council of Pavia, transferred to Siena, lasted from June 22, 1423, to Feb. 26, 1424. A long period of civil war ended in its capture by the troops of Charles V. in 1555, and it was united with Tuscany in 1557.

**SIERRA,** a N. E. county of California, bounded E. by Nevada, and drained by the North and Middle forks of the Yuba river; area, 830 sq. m.; pop. in 1870, 5,619, of whom 810 were Chinese. It is situated among the Sierra Nevada mountains, and but little of it is less than 3,000 ft. above the sea. There are several isolated peaks, the most conspicuous of which are Table mountain, more than 6,500 ft. high; Saddle mountain, a little lower; and the Sierra buttes, 8,300 ft. high. Nearly the whole county is underlaid by auriferous slates, generally covered by volcanic accumulations. It is one of the chief gold-producing counties in the state. The surface is covered with a heavy growth

of coniferous trees. The land suited to agriculture or grazing is mostly confined to a few small valleys and mountain flats. The climate in winter is rigorous. The chief productions in 1870 were 7,794 bushels of wheat, 8,250 of oats, 10,415 of barley, 8,451 of potatoes, 39,200 lbs. of butter, and 7,466 tons of hay. There were 464 horses, 887 milch cows, 2,257 other cattle, 402 sheep, and 437 swine; 13 saw mills, 1 machine shop, and 6 quartz mills. Capital, Downieville.

**SIERRA LEONE,** a British colony on the W. coast of Africa, forming one of the West African settlements. It occupies a small peninsula terminating in Cape Sierra Leone, lat. 8° 30′ N., lon. 13° 18′ E., and extending N. to the estuary of the same name. Along the N. bank of this estuary is a narrow strip of territory belonging to the colony, which also includes the district around the mouth of the Sherbro river, about 70 m. down the coast; area, 468 sq. m.; pop. in 1872, 38,936, of whom 107 were Europeans and 1,741 were native Christians. The peninsula is mountainous, some of the peaks rising to the height of 3,000 ft. above the sea; but there are tracts of level ground, and several small valleys, the whole being well watered and for the most part densely wooded. The lower districts are purely alluvial, but in the more elevated parts the geological formation is volcanic, and iron ore occurs. Free Town is the capital, in addition to which the colony contains several considerable villages. The climate is deadly to Europeans. The wet season extends from May to November inclusive; the average annual rainfall is 160 inches, and the mean temperature not far from 82° F. From February to December, 1871, of the 98 Europeans resident at Free Town, 24 died, a death rate far exceeding any other in the British dominions. This excessive mortality, however, is confined to the coast; the mountain villages, only 3 or 4 m. inland from Free Town, are described as quite salubrious. The land breeze, which begins to blow in the evening, comes over swampy ground laden with malaria, and the unwholesome mists cling to the lower terraces. The soil is not naturally very productive, but cassada, cacao, maize, ginger, ground nuts, Guinea corn, yams, plantains, sugar cane, and fruits are all successfully grown. The principal exports are palm oil, nuts, hides, and timber; the total value of the exports in 1871 was £467,755, against imports to the amount of £305,849. In the same year 411 vessels of 110,646 tons were entered in the colony, and 409 of 110,919 tons were cleared. The established educational system is inefficient. The colony has two bishops of the church of England, and there are 100 Christian ministers of all denominations, many of the most intelligent being natives; but the Mohammedan priests from the interior have achieved tenfold the success of the Christian missionaries in making converts. The colonial governor, who is appointed by the crown and is officially known as the chief administrator, is the executive of all the West African settlements. He is assisted by a legislative council, of which some of the members are pure negroes. The revenue in 1871 was £80,486, collected partly by import duties on spirits, tobacco, and gunpowder, while the expenditure amounted to £76,130.—The settlement was originally formed in 1787 by Granville Sharp and other British philanthropists, with the view of providing a suitable home for destitute negroes from different parts of the world, as well as promoting African civilization. The first foreign inhabitants were destitute negroes from London, nearly 500 in number. These were followed in 1790 by more than 1,000 freed slaves who had been collected in Nova Scotia, in 1800 by about 500 maroons from Jamaica, and in 1819 by a disbanded West India negro regiment. In 1807 the Sierra Leone company, which was organized by Sharp, Wilberforce, and others, and had previously controlled the colony, transferred all its rights to the British government. From that time until recent years the population was largely augmented by the introduction of the negroes taken from slave ships by vessels of the British navy.

**SIEYÈS, Emmanuel Joseph,** count, better known as abbé, a French statesman, born in Fréjus, May 3, 1748, died in Paris, June 20, 1836. After completing his studies in the university of Paris, he took orders, received in 1775 a canonship in Brittany, and became in 1784 vicar general and chancellor of the bishop of Chartres. The ministry having invited French writers to present their views upon the summoning of the states general, he almost simultaneously published three pamphlets: *Vues sur les moyens d'exécution dont les représentants de la France pourront disposer en* 1789; *Essai sur les privilèges*, a vindication of the rights of the people; and *Qu'est ce que le tiers état?* The answer to this question, which he summed up in "the nation," made him famous as the oracle of the revolution. He was elected deputy to the states general, where he moved that the three orders should immediately meet in general assembly to verify their powers in common; and the privileged orders refusing to comply with this motion, he insisted that the third should declare itself the "national assembly." He drew up the oath taken by the deputies, June 20, 1789, and originated the organization of the national guards and the division of France into departments. In his *Aperçu d'une nouvelle organisation de la justice et de la police en France*, he proposed jury trial in civil as well as criminal cases. He was elected president of the assembly in 1790. After the flight of the king to Varennes, he vigorously opposed the establishment of a re-

public. In September, 1792, he took his seat in the convention, being elected by three departments at once. On the trial of the king, he at first protested against the unlawful assumption of powers by the convention; but yielding to the majority, he sat as one of the judges, and silently voted for death without appeal to the people. During the reign of terror he gave up his priesthood and pension, and skilfully avoided attention, but after the fall of Robespierre regained influence among the moderate party. He moved the restoration of the surviving Girondists to their seats in the assembly, and had a large share in the direction of foreign policy. On the establishment of the directorial government he was elected one of the five directors, but declined, contenting himself with being a member of the council of 500. An unsuccessful attempt was made to assassinate him in 1797. In 1798 he went as minister to Berlin, and secured the neutrality of Prussia. In May, 1799, he succeeded Rewbell as a member of the directory, of which he soon became president. After the *coup d'état* of the 18th Brumaire, of which he was one of the originators, the liberal constitution prepared by him was altered so as to suit the aspirations of the first consul; and while Bonaparte seized upon absolute power, Sieyès, after having been one of the provisional consuls, had to content himself with a seat in the senate, the presidency of which he held for a while. He also received as a compensation the princely estate of Crosne, with a large income. Although he figured among those opponents whom Bonaparte styled ideologists, he was afterward made a count. In 1814, while absent from the senate, he, through Talleyrand's advice, adhered by letter to such measures as were taken by that body against the emperor, but was nevertheless made a peer during the hundred days. He however stood aloof, censured the "Additional Act to the Constitution of the Empire," and appeared neither at the meeting in the Champ de Mai nor at the opening of the chambers. On the second return of the Bourbons, he sought a refuge at Brussels. After the revolution of July, 1830, he returned to Paris. One volume of his collected works, edited by Cramer, appeared in 1796.—See *Étude sur Sieyès*, by E. de Beauverger (Paris, 1851).

**SIGISMUND**, emperor of Germany, the last of the Luxemburg line, born in 1368, died Dec. 9, 1437. He was the second son of the emperor Charles IV., and became elector of Brandenburg, while his elder brother Wenceslas succeeded to the empire in 1378. He was affianced to Mary, daughter of Louis the Great of Hungary and Poland, and was designated as successor in both kingdoms. But on the death of Louis, in 1382, the Poles rejected him, while an adverse party in Hungary raised Charles the Little of Naples to the throne. Charles was assassinated, and Sigismund, having espoused Mary, was crowned king of Hungary (1387). He fought the Turks, was routed by Bajazet at Nicopolis in 1396, and fled to Greece; and when after several years he returned to Hungary, he had to contend against a new rival, Ladislas of Naples, who finally withdrew in 1403. In 1400 the incapable emperor Wenceslas had been deposed and succeeded by Rupert of the Palatinate, and on the death of the latter in 1410 Sigismund and his cousin Jodocus of Moravia contested the imperial crown. The electors were at first divided, but on the death of Jodocus in 1411 Sigismund was elected. He called a general council at Constance, violated the safe-conduct accorded to Huss, and provoked the great Hussite war. He succeeded Wenceslas in Bohemia, received the Lombard crown in 1431, and was crowned at Rome in 1433. He was succeeded by his son-in-law, Albert II. of Hapsburg.

**SIGMARINGEN.** See Hohenzollern.

**SIGNAL SERVICE.** Organized signal services existed in armies from very early periods. Polybius (about 200 B. C.) mentions the wonderful skill acquired by the signal corps of his day. In later years semaphores were used with armies, and codes of flag signals became common for fleets. The invention of the electric telegraph greatly developed organizations of this description. Telegraphic corps are now attached to many armies, and field signals are widely used. Messages of any description, and in words or characters of any language, can be sent by signals, by day or night, as far as one man can by telescopes or other means be made visible to another. The apparatus can easily be carried in the hand on horseback or on foot. To transmit any message by the use of portable signal apparatus, a distance of 10 m. would be now considered easy. Ranges of from 16 to 20 m. are often reached in ordinarily clear weather; and on the western prairies messages have been transmitted 30 m. by flags. In time of war systems of reports are sometimes organized to cover extensive sections of territory. In some instances communication can be had from stations on elevated points over the heads of an enemy.—The signal service of the United States army is equipped to maintain communication by signals, by telegraph, or by semaphores, between officers or the different portions of an army or armies, or between armies and fleets. In time of peace it transmits intelligence in reference to storms or approaching weather changes by the display of signals of warning, and by reports at the different cities and ports of the United States. Maps showing the weather conditions are exhibited at board of trade rooms, chambers of commerce, and other places of resort. Bulletins of data are also prominently displayed, and are furnished without expense to leading newspapers. Signal stations are established also in connection with

life-saving stations, which are connected by telegraph, and, in addition to displaying storm signals and making the regular meteorological reports, are required to make special reports upon tempests at sea, the sea swell, currents, temperatures, &c. They also summon assistance to vessels in distress, either from neighboring life-saving stations or from the nearest port. Stations for river reports, to give notice of dangerous floods or conditions of the rivers affecting navigation, are established upon the courses of the great interior rivers. The officers and men of the signal service are instructed for the different branches of the service at the signal school of instruction at Fort Whipple, Va., and at the central office in Washington. They are taught the use of meteorological instruments, the modes of observing, and the forms and duties required at stations of observation, and for the display of storm signals. The force is also drilled with arms and in the usual duties of soldiers. The field telegraph trains of the signal service are organized for use with armies, and are managed by soldiers who are drilled to march with, manœuvre, work, and protect them. The trains carry light or field telegraph lines, which can be very quickly erected or run out at the rate of two or three miles an hour. They can be put in use for any distance, and as rapidly taken down, repacked, and marched off with the detachment to be used elsewhere.—For the duties of the observation of storms, and for the display of storm signals, all stations communicate directly with the signal office in Washington over telegraphic circuits arranged with the different telegraph companies, or connecting with the office at fixed hours each day and night. Each station is supplied with the following instruments: barometer, thermometer, maximum thermometer, minimum thermometer, Robinson's anemometer with electrical attachment and self-registering apparatus, hygrometer, wind vane, rain gauge, and, on stations located on rivers, lakes, or seacoast, thermometers designed for taking the temperature of water at different depths. The readings of these instruments, made three times a day at fixed hours, are reported to the central office in cipher. The stations at which cautionary signals are displayed are equipped with flags and apparatus for exhibiting the cautionary day or night signal. These stations are established (with the exception of those in the principal cities) solely with reference to the importance of their position for meteoric observations. Three graphic charts are prepared at the central office on the receipt of each report, as follows: 1. A chart of barometric pressures, temperatures, and winds, together with the wind velocities at the different stations, and the precipitation occurring; it exhibits the barometric pressures and the temperatures in their relation to districts and to each other by a system of isobaric and isothermal lines, and the wind directions by arrows at the different stations. 2. A chart of the cloud conditions prevailing over the United States, on which the different varieties and amount of clouds visible at the different stations appear by symbols; on this chart is also indicated the weather as reported at each station, the direction and movement of upper and lower clouds, and each morning the minimum temperature of the preceding night, in relation to districts of territory. 3. A chart showing the relative humidities over territorial districts, with the temperature at the several stations; this enables studies to be made for territorial sections, the difficulties attending the study of observations of this character being obviated to a very considerable degree by the intercorrections of the stations among themselves, and by the great extent of the regions over which the readings are simultaneously made. In the study of the charts for the reports, the well known rules and generalizations established by the experience of meteorologists are used. The published office report, based upon each general report of observations, consists of a synopsis of the meteoric conditions existing over the territory of the United States at the time of the report, and a statement of the changes likely to occur within the next 24 hours. For the purposes of convenient study and of condensed description, the territory of the United States is arbitrarily divided into districts. The reports from the stations, extending over territory reaching from the Atlantic to the Pacific, and from the capes of Florida into British America, are not unfrequently concentrated at the central office in the space of 45 minutes. In military lines connecting frontier posts and lines connecting life-saving stations upon the seacoast, the telegraphic duties are performed by the men of the signal service. The reports are those of readings of the different meteorological instruments made as nearly simultaneously as possible. The reports, made simultaneously from all the stations and received at the central office thrice daily, at intervals of about eight hours, are at once entered graphically upon synoptic charts (the weather maps), and from the study of these charts a deduction is had as to probable weather changes within the ensuing 24 hours. This deduction is furnished to the press and is telegraphed to 21 centres of distribution, to be there published and distributed in bulletin form for the use of farmers. The bulletins are displayed at post offices in numerous villages in the agricultural districts. In the case of serious storms noticed as approaching the lakes, or threatening any part of the seacoast, cautionary signals are ordered from the central office to be displayed at the different lake and sea ports and upon the coasts, as a warning to mariners. The fortunate position of the territory of the United States and its great extent enable a service of this kind to be conducted with especial advantage. The movements of the storms over the continent can be

traced upon the charts from report to report, and the direction and rate of their progress together with their intensity be noted in time to give warning of their approach. Floods occurring upon the western rivers can be traced sometimes from the fall of rain within the respective watersheds, and along the courses of the different confluent streams, until culminating in the dangerous flood of the principal river. In nearly the same manner that storms can be traced upon the charts, approaching changes of temperature and rainfall are foreseen, and notice is frequently given in time to prevent injury to agricultural and other interests. In the analyses of the official deductions of the office, or the "probabilities," the percentage of verifications is found to have been as follows: 1872, 76·8 per cent.; 1873, 77·6 per cent.; 1874, 84·4 per cent. The cautionary signal is a red flag with a black centre by day, and a red light by night. This signal indicates a probability of stormy or dangerous weather for the port or place at which it is displayed, or in that vicinity. While storms of limited extent, such as squalls, tornadoes, &c., may spring up suddenly or pass between stations in such a way that their coming or courses cannot be foreseen, extensive and well defined disturbances can as a rule be readily traced in time to forewarn the coasts or districts threatened. Arrangements have been made with the chiefs of meteorological services in Europe, in accordance with the recommendation of the Vienna conference of meteorologists (1873), providing for the exchange daily of one report taken at the same instant over all the territories of the United States, nearly all Europe, extending through Russian Asia to the Pacific coast, and in the northern portion of Africa. These exchanges are made every 15 days by mail. Besides the daily bulletins and weather maps, the signal office publishes a weekly review of the weather which is furnished to the press, and a monthly review, accompanied with charts showing the isobaric and isothermal lines, the prevailing winds, the tracks of low barometer, and a precipitation chart for the month.

**SIGNALS, Fog.** See Lighthouse, vol. x., p. 457.

**SIGNALS, Naval.** Naval signals are frequently mentioned by the classical writers, and recent investigation has discovered the fact that the system which prevailed during the naval supremacy of Greece and Carthage bore a striking resemblance to our present army code, invented by Gen. A. J. Myer, U. S. A. Signal flags began to be used in the English navy in the time of Elizabeth, or perhaps a little earlier. In the reign of James II. their use was somewhat systematized, and in 1790 or thereabouts, under Earl Howe and Kempenfelt, a regular code of day and night signals was perfected. Besides flags during the last century, arbitrary signs were used as signals, which were well known to all seafaring people. The signal to unmoor ship, for example, was the loosing of the maintopsail; that to prepare for sailing was loosing the foretopsail and firing one gun. In general there are three classes of signals: those for the day, made by square flags and triangular pennants variously colored of red, blue, white, and yellow; night signals, made with colored lights, rockets, &c.; and fog signals made by steam whistles, fog horns, bells, or guns. By means of the "International Code of Signals for the use of all Nations," all maritime countries use the same kind of signal flags, and having the signal book of each country printed in its own language, ships of different nationalities communicate as readily with each other as ships sailing under the same flag. In most systems the signal flags represent the numerals from 1 to 10, and in the signal book, corresponding to the numbers from 1 up to several thousand, are words and phrases most likely to be used by ships. But in the code just referred to the consonants of the alphabet were used in preference to numerals, by which means it was found that with 18 flags more than 78,000 distinct signals could be made without displaying more than four flags at a time. The number of flags and their position are also significant. Thus, when but two flags are shown, "danger" or "urgency" is implied. If in a signal consisting of two flags a burgee (a swallow-tail flag) is uppermost, it is known at once to be an "attention" signal. If a pennant is uppermost, it is a compass signal. A square flag above indicates an "urgent" signal. Three flags in one hoist express "latitude, longitude, time," and all ordinary signals required for communications. Four flags indicate geographical signals. The flags representing the alphabet are for spelling out words not found in the vocabulary. With a pennant above, the name of a ship of war is indicated; with a square flag uppermost, that of a merchant vessel. Observing, then, the colors of each flag, we seek in the signal book the same combination of letters and the corresponding message. Let us suppose, for example, that on the meeting of two ships at sea one is observed to hoist two flags. We know at once it is an urgent signal, and on closer examination find the upper one divided vertically, in white and red, the lower one a red burgee. The upper flag represents the letter H, the lower one the letter B. The combination H B in the signal book stands opposite the sentence, "Want immediate assistance." Thereupon the second ship hoists a white and red vertical flag (H), and beneath a red pennant with white ball in centre (F). H F in the signal book corresponds to the sentence, "We are coming to your assistance." As each ship has a signal book printed in the language of its country, this code furnishes a kind of universal language. If the ship first mentioned had found herself on a strange coast, she might have made the same signal to a shore station, and received

the friendly aid of a life boat. Should the distance between two points be too great to distinguish colors, the shape alone indicates the value of the signal, for which purpose a ball, a long pennant, and a square flag are used, known as "distance signals." In addition to the above, each national marine has a system of signals adapted to its own particular wants, not only for holding free communication among the ships of a fleet, the transmitting of orders, conveying of intelligence, &c., but to enable the commander-in-chief of a naval force to signal orders to his ships for the various evolutions of naval tactics. A complete naval signal book comprehends therefore a system of evolutionary tactics. For night signals, red, green, and white lights are used to represent those colors in the flags of the day signals, the green light taking the place of the blue bunting. The night signals known as the "Coston lights" are the best in use.—The greatest improvement of recent times in signalling is that made by Gen. A. J. Myer, already referred to. For its perfect simplicity and comprehensiveness it is now considered indispensable to both branches of the public service. The letters of the alphabet are represented by combinations of the numerals 1 and 2 for spelling the words of a message. Each word is punctuated by a comma represented by the numeral 3; 1, 2, and 3 being represented by arbitrary signs. A, for instance, is represented by 2-2, B by 2-1-1-2, C by 1-2-1, &c.; 3 indicates the end of a word, 3-3 the end of a sentence, and 3-3-3 the end of the message. There are also abbreviations. The signals commonly used to represent these numbers are as follows: The signalman, facing his correspondent, waves a flag (at night a lighted torch) to his right to indicate 1, bringing his flag to a rest in a vertical position; to the left to denote 2; and to his front for 3. By waving his flag or torch to his right and left he spells out the words of his message, using frequent abbreviations, so that two expert signalmen may transmit long communications with great rapidity and exactness.

**SIGOURNEY, Lydia Huntley**, an American authoress, born in Norwich, Conn., Sept. 1, 1791, died in Hartford, June 10, 1865. In 1814 she opened a private school in Hartford, and in 1815 published "Moral Pieces in Prose and Verse." In 1819 she married Charles Sigourney, a merchant of Hartford. In 1840 she visited Europe, and recorded her reminiscences in "Pleasant Memories of Pleasant Lands" (1842). She published nearly 60 volumes of poems, prose, and selections. Among her works are: "Letters to Young Ladies" (1833); "Pocahontas, and other Poems" (1841); "Past Meridian" (1854); "The Man of Uz, and other Poems" (1862); and her autobiography, posthumously published under the title "Letters of Life" (New York, 1866).

**SIGÜENZA Y GONGORA, Carlos de**, a Mexican scholar, born in Mexico in 1645, died there, Aug. 22, 1700. He was chaplain to the archbishop of Mexico, and taught astronomy and mathematics in the university of that city for 20 years. King Charles II. of Spain created him royal cosmographer and mathematician. He had several discussions on the nature of comets with Father Kuhn, the colonizer of California, and wrote histories of Texas and the Chichimecas, an account of the recovery of New Mexico after the revolt of 1680, and a history of the university of Mexico. With Juan de Alva Ixtlixochitl he prepared several treatises on Mexican antiquities and early American history, which perished with his library in the great fire of June, 1692. He was director of the military school of Mexico for several years, and in 1693 was appointed to accompany the expedition of Andrés de Pés against the French settlements in the gulf of Mexico. He planned the fortifications of Pensacola, and soon afterward published maps of the bays of Pensacola (Santa Maria de Galve) and Mobile, and of the Rio de la Palizada or Mississippi. His name was subsequently given to one extremity of Santa Rosa island and to the fort erected there. He entered the society of Jesus in 1693. His principal works are: *Ver Indicum, Poema sacro-epicum* (8vo, Mexico, 1668; 4to, 1680); *Expositio Philosophica adversus Cometas* (1681); *Triumphus Parthenicus* (4to, 1684); *Libra Astronomica et Philosophica* (1690); *Infortunia Alfonsi Ramirez circum per Orbem euntis* (1693); *Mercurius volans et Novum Mexicum restauratum præ se ferens* (1693); *Descriptio Sinus Sanctæ Mariæ de Galve* (1693); and a topography of Mexico and its neighborhood, enlarged and republished by Alzate in 1786.

**SIHON**, a name applied by some geographers to the Sir Darya or Jaxartes. (See JAXARTES.)

**SIKHS** (Hind. *sikh*, a disciple), a people of India, chiefly inhabiting the Punjaub. They were originally a religious sect, the founder of which was Nanak, a Hindoo of the warrior caste, born in 1469 near Lahore, who was a deist, advocating the worship of God without regard to form as an essential, universal toleration, and a fusion of Brahmanism and Mohammedanism, on the basis of a pure monotheism and of human brotherhood. He died in 1539, and was succeeded by his son Angad, who wrote commentaries upon his father's system, which underwent considerable change at the hands of his successors Amardas and Ramdas. Arjoon, the son of Ramdas, compiled the Sikh doctrines in a volume called *Adi-Granth*, established himself at Amritsir in 1581, and organized his followers, who had hitherto been only a religious community, into a confederation possessing also a political character, of which he became the sole chief. As the Sikhs rejected alike the Koran and the Vedas, they drew down upon themselves the hatred both of Moslems and Brahmans; and notwithstanding the peaceable increase of the sect up to that period, Arjoon was imprisoned by the

Mussulman government, tortured, and put to death in 1606. His son, Har Govind, to avenge his death, led the Sikhs against their Mohammedan foes; but they were driven from the region which they occupied about Lahore, and forced to find refuge in the mountains in the north. In 1675 Guru Govind, a grandson of Har Govind, became their tenth theocratic chief, gave them a code of laws, and organized them as a state. He added to their sacred books by writing the biographies of his nine predecessors. He abolished caste, established absolute equality, and introduced a peculiar dress, such as the wearing of blue, peculiar customs, such as allowing the hair and beard to grow long and uncut, and peculiar requirements, such as that every man should be a soldier and always carry steel. He recommenced the struggle against the Mogul emperors, but without avail, and was defeated and finally murdered by a private enemy. His successor, a chief named Banda, renewed the contest early in the 18th century, devastating the eastern Punjaub and Sirhind with such success that Bahadoor Shah himself took the field against the Sikhs, and partially repressed their rising power. In 1716 they were overwhelmingly defeated and almost annihilated. Their religious fervor decreased, and for many years they did not recover from this blow; but they finally united their roving bands and drove the Afghans from the Punjaub in 1764. For the following 30 years they were divided into 12 small confederations, called *misals*, which were governed by *sirdars* or petty chiefs, of whom Maha Singh was the most powerful. After his death in 1794, his son Runjeet Singh brought the other sirdars into subjection, and reduced the Punjaub to his sway. (See Runjeet Singh.) When this distinguished Sikh chieftan died, in 1839, his dominions, known as the kingdom of Lahore, included all the principal Sikh states except those E. of the Sutlej. They soon fell into anarchy, the power of the army became supreme, and war with the English broke out in 1845. Battles were fought and victories won by the British, under Sir Hugh Gough, at Moodkee, Dec. 18; at Ferozeshah, Dec. 21 and 22; at Aliwal, Jan. 28, 1846; and finally at Sobraon, Feb. 10, where the Sikhs lost 10,000 men. The contest then terminated in a treaty by which the greater part of their territory and almost their entire government was ceded to the East India company. This treaty soon led to new complications, and to a second war between the British and the Sikhs, beginning in 1848. Mooltan was invested in the autumn of that year, and taken in January, 1849; but the British, under Gough, were repulsed and narrowly escaped disastrous defeat at the battle of Chillianwallah, Jan. 13, when they lost 2,446 killed and wounded. A subsequent victory at Guzerat, in February, concluded the war; the Sikh army surrendered, and the Punjaub was incorporated into the British dominions. The only portion of the Sikh territories remaining independent is comprised in the nine small states of Sirhind. The Sikhs were faithful troops during the sepoy mutiny of 1857, and aided materially in its suppression.—In 1868 the number of Sikhs in British India was officially stated at 1,129,319. Their ethnological affinities are with the Jats. In spite of the destruction of their commonwealth, they maintain their national characteristics, being tall, thin, dark, and active, excellent soldiers and horsemen, frank, sociable, and pleasure-loving. Amritsir is their spiritual capital.

**SIKKIM,** a native state of British India, on the S. slope of the Himalaya range, bounded N. by Thibet, E. by Bhotan, S. by Bengal, and W. by Nepaul, between lat. 27° and 28° 10′ N., and lon. 88° and 89° E.; area, 2,544 sq. m.; pop. about 7,000, principally mountaineers. The surface consists of a series of ranges of the Himalaya mountains, which on the south rise abruptly from the plains to the height of from 6,000 to 10,000 ft., and increase toward the north and northwest, where Kintchinjunga, long believed to be the loftiest point on the surface of the globe, attains a height of more than 28,000 ft. above the sea. The mountains are separated by precipitous ravines, nowhere wide enough to form plains. The drainage belongs to the basin of the Ganges, toward which it flows by the Teesta, which rises in Thibet, and pursues a winding course through Sikkim. The mountains are covered with vegetation to the height of 12,000 ft., and at the lower levels it is often very luxuriant. Sikkim abounds in fine timber, producing oak, walnut, chestnut, and cherry at elevations of from 6,000 to 8,000 ft., and saul and sissoo further down. Copper is the chief mineral product. The soil consists mostly of a rich black mould; and the principal crops are millet, maize, and rice, the last of which has been cultivated to the height of 8,000 ft. above the sea. The aboriginal inhabitants have Mongolian features, and speak a Thibetan dialect.—The Gorkhas conquered Sikkim in 1789, and it became tributary to them; but during the Nepaul war of 1814 the rajah coöperated with the British, and in 1817, after peace was concluded, his independence was guaranteed, and his dominions were increased by the grant of certain tracts of Nepaulese territory. In 1836 the rajah ceded Darjeeling to the British, for an annual grant of £300, subsequently increased to £600. In 1849 he countenanced some outrages on British subjects, which led to a temporary forfeiture of this allowance, and a further loss of territory. In 1861 he opened his dominions to British trade without restriction, and in 1872 his allowance was increased to £1,200. His capital is Tumloong.

**SILENUS,** in Greek and Roman mythology, a satyr prominent in the retinue of Bacchus. He is differently called the son of Mercury and of Pan, and is represented as a jovial old man with a bald head, a pair of goat's ears,

and a fat, sensual face, always intoxicated, and either mounted upon an ass or carried by satyrs. In the contest with the giants Bacchus was assisted by Silenus, who slew Enceladus. Silenus is also represented as an inspired prophet, and a sage who despised the gifts of fortune. When he was drunk and asleep, any one could compel him to prophesy by surrounding him with a garland or chain of flowers. There was a temple sacred to him at Elis. Several poems and works of plastic art introduced more than one Silenus at a time, representing the older satyrs.

**SILESIA** (Ger. *Schlesien*), **Austrian**, a duchy comprising that part of Silesia which remained to the house of Austria after the peace of 1763, bounded by Prussian Silesia, Galicia, Hungary, and Moravia; area, 1,988 sq. m.; pop. in 1874, 544,459, of whom about 14 per cent. were Protestants, 1 per cent. Jews, and the remainder Roman Catholics. Fully one half of the population are Germans, 29 per cent. Poles, and over 19 per cent. Czechs. The Carpathian mountains pass through it in the southeast, and the Moravian in the northwest, and it is watered by the upper Oder, the Vistula, which rises in the province, and other rivers. About one third of the territory is covered with forests. It is one of the most important grazing provinces of Austria. The mining and weaving industries are important. Before 1849 it formed with Moravia a single administrative province, and then became a separate crown land under the name of the duchy of Upper and Lower Silesia. Until 1866 it was one of the 11 Austrian states belonging to the German confederation, and since 1867 it has been one of the 14 Cisleithan provinces represented in the Reichsrath. The principal towns are Troppau, the capital, Teschen, Bielitz, and Jägerndorf.

**SILESIA, Prussian**, the S. E. province of Prussia, bounded N. by Brandenburg and Posen, E. by Russian Poland and Austrian Galicia, S. by Austrian Silesia and Moravia, and S. W. and W. by Bohemia, the kingdom of Saxony, and the Prussian province of Saxony; area, 15,556 sq. m.; pop. in 1871, 3,707,167, of whom 1,760,341 belonged to the Evangelical church, 1,896,136 were Roman Catholics, and 46,629 Jews. It is divided into the districts of Breslau, Liegnitz, and Oppeln. It is separated from the Austrian dominions by the Sudetic chain of mountains, which consist of long well wooded ridges with isolated peaks. There are two principal groups, the Riesengebirge in the N. W. part of the range and the Glatz mountains in the opposite direction; the most elevated peak of the former, the Schneekoppe, is upward of 5,000 ft. high, and of the latter, the Great Schneeberg, nearly 5,000 ft. There are fertile valleys of considerable extent. The Oder flows through the province in a general N. W. direction, and divides it into two nearly equal portions, that on the left of the river being mountainous, and that on the right flat. This level portion is sandy, with extensive tracts of heath and stagnant pools. A small portion of the S. E. corner is drained by the upper course of the Vistula. The mineral wealth of Silesia is confined principally to the upper or S. E. part of the province. Gold and silver are procured in small quantities; copper, lead, and zinc are found; and coal and iron are abundant. Quarries of limestone, marble, and sandstone are worked. Large numbers of cattle and sheep are raised, the wool of Silesia being of superior quality, and forming next to linen the chief export. The principal manufactures are of linen, cotton, and woollens, iron, paper, leather, glass, porcelain, castings, and sheet iron. Among the principal towns, besides Breslau, the capital, are Glogau, Liegnitz, Oppeln, and the fortresses Schweidnitz, Neisse, Glatz, and Kosel.—Silesia became subject to Poland in the 10th century, and in 1163 it was ruled by three independent Polish princes. It was afterward subdivided into numerous petty states, which in detail became tributary to the king of Bohemia, and fell to Austria in 1526. The claims of Frederick the Great upon the former duchies of Liegnitz, Brieg, Wohlau, and Jägerndorf, founded on an old treaty of inheritance, gave rise to three wars for the possession of Silesia, the first in the years 1740–'42, the second in 1744–'5, and the last in 1756–'63 (the seven years' war). By the treaty of Hubertsburg in 1763 the province was finally secured to Prussia, except the part now known as Austrian Silesia. A part of Lusatia was added to it by the treaties of 1815.

**SILICA.** See SILICON.

**SILICATES, Soluble.** See GLASS, SOLUBLE.

**SILICON**, or **Silicium**, the essential constituent of silex or flint. It is obtained in a dull brown amorphous powder by passing the vapor of chloride of silicon over heated potassium or sodium contained in a glass tube. It may also be obtained from the aqueous solution of the gaseous fluoride of silicon. Neutralized with solution of potash, this affords a silico-fluoride of potassium, which when well dried is mixed in a glass or iron tube with $\frac{8}{10}$ or $\frac{9}{10}$ of its weight of potassium or sodium and heated. The silicon set free partially combines with the excess of the alkali, from which it is finally removed by washing in water. When heated in air or oxygen, it burns vividly, and with such intense heat as to fuse the external crust of silica. In its chemical properties silicon exhibits striking analogies with carbon and boron. When strongly heated in a close platinum crucible, it becomes darker and of greater specific gravity; it loses its affinity for oxygen, so that it will not ignite even if heated by the blowpipe and immersed in oxygen, and is not attacked by pure hydrofluoric acid. If aluminum be substituted for the sodium of the above experiment, silicon is obtained in a crystalline condition. Two methods are employed to prepare crystalline silicon: 1,

fuse a mixture of 5 parts pulverized glass, 10 parts cryolite, 1 part aluminum, and wash the product with hydrochloric and hydrofluoric acids; 2, fuse 15 parts silico-fluoride of sodium, 20 parts granulated zinc, 4 parts sodium, and wash with hydrochloric and nitric acids. Amorphous silicon was discovered by Berzelius in 1824, crystalline by Deville in 1855. Crystalline silicon forms brilliant black scales having a lustre like that of specular iron ore, sometimes prismatic, at others octahedral, foliated, graphitic, with a specific gravity of 2·49. The symbol of silicon is Si; atomic weight, 28. It is a poor conductor of electricity, fuses at a temperature between that of cast iron and steel, is harder than glass, and is insoluble in all acids excepting hydrofluoric and nitric. There were at one time supposed to be three modifications of silicon, the amorphous, graphitoid, and crystalline, but the graphitoid is now regarded as somewhat problematical. Silicon belongs to the class of tetrads, being equivalent in its most usual combinations to four atoms of hydrogen.—There is but one anhydrous oxide of silicon, commonly known as silicic acid or silica; its formula is $SiO_2$. Silica, or silicic anhydride, occurs in nature dimorphous: 1, in hexagonal prisms with terminated pyramids, as quartz, rock crystal, smoky quartz, amethyst, &c.; 2, in wedge-shaped crystals, with sharp angles, or hexagonal tables, or in twins (called tridymite), colorless and clear as water. The former has the specific gravity of 2·6, the latter of 2·3. Its only solvent among the acids is the hydrofluoric, by means of which it is decomposed, and a gaseous compound is obtained of its base with the acid. When passed into water this combination is broken up, and silica is reproduced in the form of little bubbles and white flocculi, which by washing and igniting become perfectly pure and snow-white silica. Pulverized silica, when mixed with an alkaline carbonate and fused, dispels the weaker carbonic acid, and itself combines with the alkali, thus exhibiting its properties as an acid. But these are too feeble to act upon test paper. An excess of silica in the alkaline mixture determines the production of glass, which is insoluble in water or common acids; but if no more silica be added to the melted mass after this ceases to effervesce on its introduction, the product after being cooled may be dissolved in water. When silica is separated from its alkaline combination by hydrochloric acid, it appears before evaporation as a jelly, which is a hydrate of silica, soluble in a large excess of water; but once deprived of water by heat, it can no more be dissolved. Silica of this character is met with in several mineral compounds. It constitutes the opal, in which the proportion of water varies from 3 to 10 per cent., and also great deposits of a white silicious earth made up of infusorial remains. The zeolites are hydrated silicious compounds, which when finely pulverized and treated with hydrochloric acid swell up into the transparent jelly.—Silica is an important element in the composition of the grasses, and forms in chief part the hard external coat of the reeds. It combines with bases and forms silicates, among which are found a large proportion of the minerals. Their variety is multiplied by the number of bases, as lime, alumina, magnesia, protoxide of iron, and several of the other metals, and by the diversity in the relative proportions of the different silicates, the substitution of one base for another. They comprise the hydrous and anhydrous silicates, the former including, besides those already named, the talcs, serpentines, and chlorites, and the latter the augites, garnets, micas, and feldspars. They are for the most part fusible, and those melt easily which consist largely of fusible oxides. They are decomposed by vegetable acids, and gradually even by the carbonic acid gas of the atmosphere; but at high temperatures in a furnace the silica, not being volatile, takes the place of most other acids, expelling even sulphuric acid from its combinations.—Diatomaceous or infusorial silica, of which large deposits have been found in Nevada, New Jersey, and Virginia, is now employed in the arts for a great variety of purposes, among which are: as a polish for metals under the name of tripoli or electric silicon; as a non-conductor in refrigerators and fire-proof safes; as an absorbent of nitro-glycerine in the manufacture of dynamite; in the manufacture of glass, enamel, pottery, and soluble glass. Chloride of silicon, $SiCl_4$, is a transparent, colorless liquid, with a pungent, acid, irritating odor. It is very volatile and fumes strongly in the air, and is prepared by the action of chlorine on a heated mixture of silica and charcoal. Fluoride of silicon, $SiF_4$, is a colorless gas of a peculiar, pungent acid odor, which is evolved when equal parts of finely powdered fluor spar and silicious sand or powdered glass are mixed, in a capacious flask or retort, with 12 times their weight of oil of vitriol. The gas was converted into a liquid by Faraday. When a stream of gaseous fluoride of silicon is transmitted through water, it is partially decomposed and partially dissolved. Two atoms of water react on three of fluoride, and produce silico-fluoric or hydrofluosilicic acid, which is dissolved, while one third of its silicon is deposited as silica. Efforts have been made in metallurgical operations to economize the fluoride of silicon and hydrofluosilicic acid hitherto wasted, and to employ the latter in the beet-sugar refinery and for chemical uses.

**SILISTRIA** (Turk. *Dristra*), a fortified town of European Turkey, in Bulgaria, on the right bank of the Danube, 57 m. N. N. E. of Shumla and 230 m. N. N. W. of Constantinople; pop. with the garrison about 20,000. The river is here more than 1,200 ft. wide, and studded with numerous islands between the town and the Wallachian shore. There are several mosques, a large Greek church and convent, capacious

barracks, public baths, and a custom house with magazines for storing grain and flour. It has no important manufactures, and the chief trade is in wood and cattle. It is a very ancient place, and near the city are remains of fortifications erected during the Byzantine empire. In 971 the emperor John Zimisces here routed the Russians under Sviatoslav. It was besieged by the Russians in 1773, and again in 1779, when they suffered a severe loss. It capitulated to them in 1810. In 1828 they besieged it for several months, and were obliged to retire; but in 1829 it was reduced by them, and held for some years as a pledge for the payment of an indemnity by the Porte, but was eventually returned. In 1849–'53 the fortifications were greatly strengthened by the addition of 12 detached forts, of which that on the hill commanding the town is one of the best military works of the time. In May, 1854, it was invested by Gortchakoff, and afterward by Paskevitch; but after bombarding it for 39 days the Russians retreated with a loss of about 12,000 men and most of their armament. During the siege the town was laid in ruins by the Russian batteries and mines.

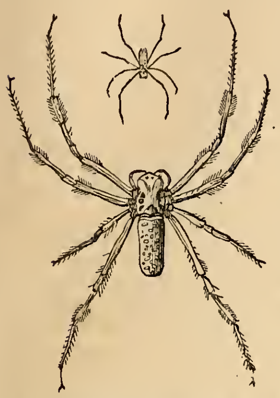
**SILK**, a fibre obtained chiefly from the cocoons of the caterpillar of the mulberry tree moth (*bombyx mori*). The fibre produced by other species of the genus *bombyx* and by other genera of the same family is inferior to that of *B. mori*. For an account of these silk-producing insects, see SILKWORM. The spider's thread resembles silk in character, but the rearing of spiders is so difficult, and the produce of each individual so small, that all attempts to convert the fibre into textile fabrics have been abandoned. The byssus of the *pinna nobilis*, a shell fish inhabiting the Mediterranean, consists of long, silken filaments, which have sometimes been woven into fabrics, but rather for curiosity than for use. The manufacture of silk doubtless originated in China. It is asserted by Chinese historians that the wife of the emperor Hwang-ti (about 2600 B. C.) was the first who unwound the silkworm's cocoon. As early as the time of Aristotle silken fabrics were woven in the island of Cos, but the fibre there employed appears to have been imported from the country of the Seres (Chinese). Later the product of the Coan looms was famous throughout the Roman empire as *Coa vestis*, a transparent gauze. The silkworm was unknown to Europe prior to the reign of Justinian (A. D. 527–565), when some "grains" or eggs of the insect were brought to Constantinople by two Persian monks, the introduction of the white mulberry following soon after. The silk manufacture made rapid progress, its chief centres being Thebes, Corinth, and Argos. In 1147 many inhabitants of Grecian cities who were skilled in this art were taken prisoners by Roger, king of Sicily, and carried to Palermo. The silk industry soon spread into Italy, and Venice, Milan, Florence, and Lucca were distinguished for the excellence of their fabrics. The Moors at an early period introduced the manufacture into Spain, and a flourishing silk trade was already established at Granada when that city was captured by Ferdinand the Catholic. Louis XI. of France in 1480, and Francis I. while the French occupied Milan in 1521, introduced workmen from there for the purpose of establishing the production of silk in France; but the attempts were not successful till 1564, when a gardener at Nîmes had cultivated the white mulberry trees and prepared suitable food for the worms. The silk manufacture had a rapid development in the south of France, and England began to import thence costly fabrics, such as she had previously imported from Italy and China. The manufacture of silk goods made great progress in England during the reign of James I., and it is said that in 1666 the trade had become so important as to give employment to 40,000 persons. In 1685 a large body of silk weavers, driven from France by the revocation of the edict of Nantes, took refuge in England and settled in Spitalfields, London, where they established several new branches of the art. In 1783 the value of the silk products was rated at £3,350,000. James I. early sought to establish silkworm culture in the American colonies. He himself forwarded eggs to Virginia, and high rewards were offered with the hope of placing the culture upon a permanent footing. But it was all in vain; tobacco superseded silk. In Louisiana the cultivation of silk was introduced in 1718 by the "Company of the West." Government grants were made to the settlers in Georgia, to encourage the cultivation of the mulberry tree. Artisans were sent to that colony in 1732 from different parts of Europe to direct the management of the worms and winding of the silk, and trees, seed, and silkworm eggs were abundantly furnished. In 1734 the first export of raw silk, amounting to 8 lbs., was made to England. More was sent the next year, and being manufactured into organzine by Sir Thomas Lombe, it was much admired. At the German settlement of Ebenezer, on the Savannah river, the production in 1749 had amounted to over 1,000 lbs. of cocoons, and the silk was so well reeled that it commanded in London the highest prices. In 1751 the trustees of the Ebenezer settlement erected in Savannah a public filature or silk house, to instruct in the management of private filatures. At the end of 1754 the exports of raw silk for the four preceding years amounted in value to $8,880, and for the next 18 years the annual exports averaged 546 lbs. The cocoons delivered at the filature in 1757 were 1,050 lbs.; in 1760, 15,000 lbs.; and in the next eight years they amounted altogether to nearly 100,000 lbs. But when parliament in 1766 reduced the price of cocoons from 3*s.* (one half of which had been in the way of bounty) to 1*s.* 6*d.*, the production rapidly declined from 20,000 lbs. of cocoons in 1766 to

290 lbs. in 1770. The business was entirely broken up by the revolutionary war. In South Carolina silk growing was practised before the revolution by the Swiss settlers at Perrysburg, and also by the French, who wrought it up with wool into fabrics. In 1765, 630 lbs. of cocoons were raised upon a plantation in St. Thomas parish; but though some progress continued to be made in the business, it was at last brought to an end by the same causes that broke it up in Georgia. In Connecticut the culture of silk was also undertaken at an early period, and was encouraged by the home government as in the other colonies. Dr. Aspinwall succeeded in establishing the business in Mansfield, Conn., where it is still carried on, and before the revolutionary war it was already in a very promising condition. In 1789 about 200 lbs. of raw silk, worth $5 a pound, were made at Mansfield; it was mostly manufactured into stockings, handkerchiefs, ribbons, buttons, and sewing silk worth $1 an ounce. In 1790 about 50 families in New Haven were engaged in the business, and in Norfolk about 30 families raised and spun 1,200 "run of silk." In 1839 the product of Mansfield and its vicinity is reported to have been about five tons of raw silk. In Massachusetts attention was also directed to the silk culture in the latter part of the last century. The town of Ipswich was noted in the manufacture of silk and thread lace. A filature was opened in 1770 at Philadelphia, and 1771 from June to the middle of August it received 2,300 lbs. of cocoons. In some of the interior towns of Pennsylvania, as Washington in the S. W. part, silk is still produced to a moderate extent, and not only converted into sewing silk, but also woven. In Ohio, the E. parts of Kentucky and Tennessee, and N. Georgia, the production has proved well adapted to the soil and climate, and many have anticipated for it a great success in this portion of the country. There seem in fact to be no natural obstacles to the prosecution of the business over all the middle and southern portion of the United States. Several species of mulberry, quite as well adapted for feeding the worms in the early stages of their growth as the white mulberry, grow wild from Pennsylvania southward, and are easily cultivated in other districts. The foreign species of the tree have also been introduced, and are now almost as well known as the native sorts. The total product of silk raised in the United States in 1840 was reported at 61,552 lbs., worth about $250,000. In 1844, according to the report of the commissioners of the census, it was 396,790 lbs., worth $1,400,000; but in 1850 it was only 14,763 lbs. The United States census of 1870 gives no statistics of native silk culture; neither is there any mention of American silk in the "Report of the Silk Association of America" for 1875. The growth and manufacture of silk have been successfully attempted in California. Just before the breaking out of the Franco-German war, French coöperation had been secured for the establishment of a silk colony in San Bernardino co.; but the project failed, owing to the disastrous termination of that conflict. There was in San José in 1875 one cocoonery with about 1,000,000 silkworms, and a silk manufacturing company has been organized in San Francisco. In the same year Sonoma co. had an association for the promotion of silkworm culture.—SILK MANUFACTURE. The cocoons consist of the sheath of loose filaments attached to the twigs that support the whole, and beneath this the external coat of soft flossy silk, within which is the compact oval ball, or cocoon proper. The thread, as laid by the worm in successive coats in his constantly diminishing tenement, is not wound regularly around the inside of the hollow ball, but is passed back and forth in one place after another in such manner that many yards may be wound off without turning over the ball. It is produced through two orifices in the nose of the worm, and the two fibres on issuing forth are secured together by the glutinous matter which accompanies them and forms nearly one quarter of their weight. The average size of each one of the primary fibres is about $\frac{1}{2000}$ of an inch. Raw silk consists of any number of the double filaments slightly twisted and agglutinated together to form one thread, called single. This is commonly of a golden yellow color, of specific gravity 1·3, and is the strongest of all fibres used for weaving, threads made of it being three times stronger than those of the same size made of flax, and twice as strong as those of hemp. Some of the best cocoons are kept for breeding; the remainder are classified, each sort being worked by itself. Before the chrysalis matures and the moth can begin to eat his way out, the cocoons are exposed to a moderate degree of heat, either in an oven, or in a steam bath, or in water heated to about 200° F. The floss covering being opened at one end, the cocoon is slipped out, and is then ready to be unwound. The cocoons are placed about five together in each one of four compartments in a sort of trough or basin holding hot water, which is kept at the necessary temperature by a steam pipe. The gummy matters are softened by the water, and the fibre is thus released. The ends are caught up by a little sort of broom with which the cocoons are stirred, and those from each compartment being brought together are passed through an eyelet, which strips off a portion of the gum, and still more is rubbed off by causing the threads formed by each bundle of fibres to cross and rub against each other, as they are conducted diagonally through a succession of eyelets toward the reel, just previous to reaching which all are united in one thread. The reel is set at some distance from the trough, to allow the gum to harden, and prevent the threads from sticking together; and it has a slight lateral motion, so that the threads are laid in spirals, and do not come in

contact while fresh from the bath. When a thread breaks, or a cocoon gives out, a fresh cocoon is substituted; and as the inner fibres are always much finer than the outer, new cocoons are added before the first lot have been unwound. These finer filaments, as also the immediate envelope of the chrysalis, constitute with the floss silk what is known as waste. The raw silk taken off from the reels is in China made up into bundles, called books, for exportation, and elsewhere the hanks are simply twisted so as to hold snugly together. They are then ready for the factory of the silk throwsters, where are conducted the operations connected with the throwing, a term variously used to express the putting a twist into fibres. For bandanna handkerchiefs the only preparation of the silk is winding the hanks and cleaning; bleaching is added for silk intended for gauze and similar fabrics. Winding, cleaning, and throwing prepare it, under the name of thrown singles, for ribbons and common silks. If simply doubled before throwing, it is known as tram, and is used for the woof or shoot of gros de Naples, velvets, and flowered silks. The twisting of each strand before doubling, as well as afterward, converts it into organzine, a streng thread suitable for warp. The winding is done from light six-sided reels called swifts, upon which the hanks, first washed in soap and water, are extended, and rows of which are set upon long shafts in an iron frame and connected each with its own bobbin, upon the top of the frame. The revolution of the latter carries around the reel beneath, and the movement is properly checked and regulated by appliances to the reel. The next process is that of cleaning the threads, which is effected upon the cleaning, drawing, or picking machine. The full bobbins are set horizontally upon plain spindles, from which each thread is conducted over an iron or glass guide rod, thence through an adjustable opening between two upright iron blades of an instrument called the cleaner, and then to the empty bobbins, which by their revolution wind it off from the full ones. Knots and other irregularities are stopped by the cleaner, and if not brushed off they stop the movement of the bobbin until they are removed by hand. The spinning or rather twisting process is conducted by means of machines similar to those used for the same purpose in cotton spinning. Doubling is the process of bringing two or more of the twisted threads into one and winding this. The bobbins of doubled thread are next twisted at the spinning frames, which completes the preparation of silk thread whether for sewing or weaving purposes. The American machines for doubling and twisting are much superior to those used in England, but for winding the same are employed in both countries. The thread is colored by dyeing after the gum has been removed from it by boiling for three or four hours in soap and water. It loses about one quarter its weight by this operation, but recovers nearly half the loss in the dye stuff it absorbs.—Waste silk is prepared for spinning by first hackling in the same manner as flax is hackled, and with the same sort of hand instrument. This is followed by machine hackling upon the filling engine, which more effectually combs out the filaments and removes the impurities. The sliver of parallel fibres is then chopped into lengths of about 1¼ in., which after scutching, as in the treatment of cotton, are converted into a sort of fine down. This is put into bags and boiled, first with soap and water for an hour and a half, and afterward with pure water. It is then powerfully squeezed under a Bramah press, dried by artificial heat, and again scutched. The succeeding operations of carding, drawing, and roving by the fly frames, and spinning by the spinning mill and throstle frames, are similar to those practised in the manufacture of cotton yarns. The product is adapted for the manufacture of shawls, bandanna handkerchiefs, and similar fabrics.—In the year ending Dec. 31, 1874, there were in the United States 180 silk manufactories, employing 14,479 operatives of both sexes, distributed as follows: New Jersey 42, with 5,414 operatives; New York 70, with 3,378; Connecticut 21, with 2,651; Pennsylvania 23, with 1,541; Massachusetts 11, with 1,249; California 3, with 100; Ohio 3, with 40; Illinois 2, with 35; New Hampshire, Maryland, Vermont, Missouri, and Kansas, each 1. The total capital invested was $14,708,184; total value of production, $20,082,482. Of this sum, thrown and spun silks amounted to $3,863,325; sewing silks and machine twist, $5,766,684; broad goods and ribbons, $6,154,-313; laces, braids, and trimmings, $4,298,196. The importations of silk into the United States for the year ending June 30, 1875, were as follows: raw silk, 1,101,681 lbs., costing at the foreign port of shipment, $4,504,306; sewing silk, $30,389; silk, satins, crapes, pongees, plushes, ribbons, &c., $19,226,672; gloves and hosiery, $71,053; mixed goods, $3,482,369; total, $27,314,787. There were imported besides 398,012 lbs. of cocoons. The silk crop of Europe in the year 1874–'5 was 9,000,000 lbs., of which Italy supplied 6,300,000, France 1,600,000, and Spain about 310,000. The import from Asia amounted to 11,500,000 lbs.

**SILK SPIDER** (*nephila plumipes*, Koch), a geometric spider of the family *epeiridæ*, first brought to notice by Dr. B. G. Wilder in 1865; he discovered it on the sea islands off the coast of South Carolina. The female is 1·1 in. long, with a longitudinal spread of legs 2¾ in., and a lateral extent of 3¾ in.; the cephalo-thorax is black above, mostly covered with silvery hairs; abdomen olive brown, with yellow and white spots and stripes; eye spots black and eight in number; it received its specific name from the closely set stiff brushes of hairs on the legs. They are found in forests, building strong viscid webs, 3 to 4 ft. in diameter, and usually over 10 ft. from the ground. The web

is made of a dry, inelastic, silvery gray silk, and of a very elastic, viscid yellow silk; the former is the supporting radiating framework, and the latter forms the concentric entangling circles. It sucks out the gum of its old web for making a new one; this is a circle minus its upper sextant, consisting of a continuous spiral viscid line laid upon the numerous radii. The spider remains quiet in its web, head downward, and is very active upon it when a fly is entangled; it is slow on the ground, and likes the full glare of the sun. The web is never vertical, but inclined at an angle of 70°; when it is touched, it shakes its web violently. Like most if not all geometric spiders, though well provided with eyes, it can distinguish only light; if the insect caught happens to be on a radius beyond her reach, she cannot see it, and returns to the centre to shake the web and ascertain what radius holds the weight; two spiders will often approach each other till their legs interlock before they are aware of their proximity. Hearing and touch are acute. The males are only a quarter of an inch long, with the legs spreading laterally and longitudinally about three fourths of an inch; the body and legs are dark brown; they make no webs, unless when very young, and seem to hang on to that of some female, or to some part of her body. Prof. Wilder had an idea that the silk of this spider might be useful in the arts, and devised several ingenious ways to procure it. He found that from one pair of spinners came white and from another yellow silk, which he was enabled to wind separately by a simple machine to the extent of nearly two miles, at 170 revolutions a minute, in less than five hours of winding time; he could not reel more than 300 yards at one time; the diameter varied from $\frac{1}{6000}$ to $\frac{1}{1000}$ of an inch, and its strength was very great. For details see the "Popular Science Monthly" for April, 1875.



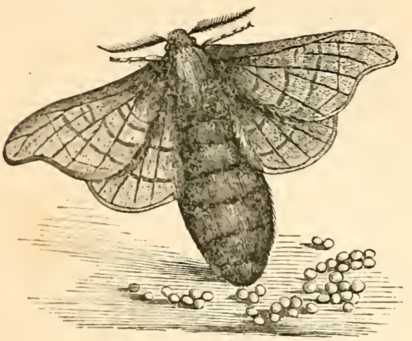
Silk Spider, Male and Female, one half the natural size.

**SILKWORM,** the larva of a lepidopterous insect of the moth division, family *bombycidæ*, and genus *bombyx* (Schrank). Of all the silk-producing larvæ, that of the common silkworm (*B. mori*, Schr.) is the most important, as from it is obtained all the European and most of the Chinese silk. The moth is about an inch long and 2 in. in alar extent, of a whitish or pale yellowish color, with two or three obscure streaks and a lunate spot on the upper wings; the trunk is very short; the superior wings decumbent, and the inferior extending almost horizontally beyond them; the antennæ of the males are pectinated; the males fly swiftly in the evening and sometimes by day, but the females are inactive; the latter live but a few hours after the eggs are deposited on the mulberry trees. The eggs are about the size of mustard seeds, and the young emerge in a few days if the weather or air of the breeding room is warm and dry; when first hatched they are one or two lines long, of a dark color, and very soon begin to eat voraciously, with short intervals of abstinence during the moultings, until full grown, when they are about 3 in. long, light green with darker marks, with blackish head, and fleshy protuberance on the last joint but one; there are 12 segments to the body, 9 stigmata or breathing holes on each side, and 16 legs, of which the anterior 6 are hooked, and the others, including the 2 on the last segment, end in disks;

Larva, Pupa, Cocoon, and Moth of Bombyx mori.

Silkworm Moth, Male.

the mouth has a vertical opening, with strong and serrated jaws; the stomach is very large, as would be expected in such a voracious larva. It lives exposed in the wild state, but none of the Chinese or European worms are allowed to incur the risks of life in the open air. According to the experiment of Count Dandolo, 100 newly hatched silkworms weigh 1 grain, after the first moult 15, after the second 94, after the third 400, after the fourth 4,628, and at full size 9,500 grains; each consumes an ounce of mulberry leaves during these stages, about 60,000 times its primitive weight, and its length increases from 1 to 40 lines during the same period; by calculation the product of an ounce of eggs eats upward of 1,200 lbs. of leaves, and should furnish 120 lbs. of cocoons. Like most other caterpillars, it changes its skin four times, at intervals depending on the temperature and on the quantity and quality of the food; if kept at 80° to 100° F. it moults in half the time required at ordinary temperatures. As usually treated, the first moult takes place on the 4th



Silkworm Moth, Female.

or 5th day after hatching, the second begins on the 8th, the third takes up the 13th and 14th, and the last happens on the 22d or 23d day; after this the fifth age lasts 10 days, making about 32 days for the whole process to maturity. The appetite increases with the size till after the fourth moult; during the last 10 days the silk gum is elaborated, the appetite diminishes, and the larva begins to spin its cocoon. The spinning apparatus is near the mouth and connected with the silk bags, which are long, slender, and convoluted, containing a liquid gum; they are closed below, and end above in slender tubes, one on each side, which unite to form the single spinning tube; the gum from which the silk is produced on contact with the air is elaborated by the long glandular organs; every thread of silk is made up of two strands. It is customary to supply to the worms a piece of rolled paper or some hollow substance into which they can retire, or a convenient twig, for the formation of the cocoons. They first make an outer covering of floss silk to keep off the rain; within this they spin fine silk, bending the head and body up and down and crossing to every side, entirely surrounding the body as a protection against wind and cold; and within this is a more delicate silk, glued firmly together for the inner chamber, resisting both cold air and water. After building the cocoon the larva is transformed into a chrysalis, and comes forth a moth, easily bursting through the case, the silk, and the floss. The cocoon resembles a pigeon's egg, and is from 1 to 1½ in. long, and bright yellow; the moth emerges from it in from 15 to 56 days, according to temperature, the former being the time in the southern United States; 18 to 20 days is the time in Connecticut, three weeks in France, and five to six weeks in England; the cocoon is made in from a few hours to three days, and is more pointed at one end than the other; the silk is not interwoven nor the glue applied at the pointed end, toward which the head is always placed. The chrysalis has no spines nor serrations on the edge of the abdominal rings, has a leathery skin, and the stomach filled with a yellowish nutritive fluid; the organs of the moth are gradually developed, and in two or three weeks the skin of the chrysalis gives way, the moth escapes into the cocoon chamber, and readily sets itself free, leaving within the remains of its former covering. In the wild state the cocoon is made about the middle of June. The silk from the cocoons containing males is finer and more tenacious than that from the female cocoons. It is fortunate that the threads do not adhere as they do in the cocoons of many other larvæ, else the operation of unwinding would be very difficult if not impracticable; even in the *B. mori* the silk is sometimes coarse and adherent, when the quality of the food has not been good. Like other caterpillars, the silkworm sometimes makes mistakes, and two or three are occasionally shut up in a single cocoon, in which they undergo metamorphosis perfectly well. The usual way of throwing the cocoons into boiling water kills the chrysalis; but merely steaming them over boiling water softens the glue sufficiently to allow the unwinding of the silk, and permits the moth to come forth alive from the interior layer and deposit the eggs or prepare for a new brood.—The whole secret in raising the silkworm consists in securing for it warmth, dryness, plenty of proper food, and pure air. The mulberry tree, the leaves of which constitute the food of the silkworm, requires for its perfect growth long continued dry and warm weather, and suffers in the rainy seasons of England and France; it is said to have no insect feeding upon it but the *bombyx;* it exhausts the earth where it is planted, as far as any other vegetation is concerned; one tree of the *M. multicaulis*, it is computed, will feed as many silkworms as would produce annually 7 lbs. of silk. Silkworms are very tender and liable to perish from slight changes of temperature and dampness, from foul air, and im-

proper or insufficient food; the periods of the moultings are times of sickness and danger; great destruction is caused by a disease called muscardine, which is a minute fungus (*botrytis Bassiana*) occupying the interior of the body and bursting through the skin. The disease called the "reds," manifested by red stains and blotches on the skin, is ascertained to be due to some acid, resulting from disordered digestion; the larvæ seem cramped and stupefied, the rings dry up, and they look like mummies.—The larvæ of several large moths of the genus *saturnia* (Schr.) form cocoons from which silk is obtained; among these are the arrindi silkworm, *S.* [*Samia*] *Cynthia* (Schr.), of India, and the *S. mylitta* (Schr.), whose moths have an alar expanse of about 8 in., and appear to be the wild silkworms of the East. The *S. mylitta* abounds in Bengal, and yields much coarse and dark-colored silk, highly prized by the Hindoos; it cannot be domesticated; the natives catch the caterpillars, put them on the asseem trees, and guard them from birds by day and bats by night; the natural food is the *rhamnus jujuba.* The *S. Cynthia* is domesticated in the interior of Bengal, on leaves of the castor oil plant (*ricinus communis* or *palma Christi*) and of the *ailantus glandulosa;* the cocoons are generally about 2 in. long and 3 in. in circumference, whitish or yellowish, of soft and delicate texture. There are eight or ten species of American silkworms; the *callosamia Promethea* and *C. angulifera* feed on the lilac and wild cherry; others are *platysamia Euryale*, *P. Columbia*, *P. Cecropia*, and *tropæa luna;* but practically the larva of *telea Polyphemus* is the only important one. This feeds on the leaves of the oak, maple, elm, willow, and several other trees. For descriptions and figures of this species, in all its stages, and the method of rearing the larvæ, see "American Naturalist," vol. i., 1867.

**SILLIMAN. I. Benjamin**, an American physicist, born in North Stratford (now Trumbull), Conn., Aug. 8, 1779, died in New Haven, Nov. 24, 1864. He graduated at Yale college in 1796, was appointed tutor in 1799, and was admitted to the bar in 1802. He accepted the new chair of chemistry at Yale college in 1802, and passed a part of the next two years in Philadelphia, as a student with Dr. Woodhouse. In the winter of 1805 he gave his first full course of lectures, and shortly after sailed for Europe. He visited the mining districts of England, attended lectures in London and Edinburgh, and resumed the duties of his professorship after an absence of 14 months. He published in 1810 "Journal of Travels in England, Holland, and Scotland in 1805–'6" (2 vols. 8vo; enlarged ed., 3 vols. 12mo, 1820). Not long after his return he made a geological survey of a part of Connecticut. In December, 1807, a meteorite of great size and splendor passed over New England, and threw off large fragments with loud explosions in the town of Western, Conn. Profs. Silliman and Kingsley visited the town and procured some fragments; and Silliman made a chemical analysis and published the earliest and best authenticated account of the fall of a meteorite in America. He afterward assisted Dr. Robert Hare in his experiments with the oxyhydrogen blowpipe, to which he gave the name now commonly used of "compound blowpipe." In 1813 he published in the "Memoirs of the Connecticut Academy of Arts and Sciences" an account of his experiments with this instrument, by which he had greatly extended the list of bodies known to be fusible. In 1812 he secured to Yale college the then unrivalled mineralogical and geological collection made by Col. George Gibbs in Europe. In 1822, while engaged in a series of observations on the action of a powerful voltaic deflagrator on the model of Dr. Hare, he first established the fact of the transfer of particles of carbon from the positive to the negative electrode of the voltaic apparatus, with the corresponding growth of the negative electrode, and the retransfer when the charcoal points are shifted. In 1818 he founded the "American Journal of Science and Arts," better known both in Europe and America as "Silliman's Journal," of which for 20 years he was sole, and for eight years more senior editor. He was one of the earliest American lecturers on scientific subjects to miscellaneous audiences, and delivered courses in the principal cities. He published an account of a journey between Hartford and Quebec (1820), an edition of Bakewell's "Geology" (1829), and a text book on "Chemistry" (2 vols., 1830). In 1851 he again visited Europe, and published "A Visit to Europe in 1851" (2 vols. 12mo, New York, 1853). In 1853 he resigned his professorship, and was made professor emeritus; but at the request of his colleagues he continued to lecture on geology till June, 1855. His life has been written by Prof. George P. Fisher (2 vols., New York, 1866). **II. Benjamin**, jr., an American physicist, son of the preceding, born in New Haven, Conn., Dec. 4, 1816. He graduated at Yale college in 1837, became an instructor there in chemistry, mineralogy, and geology, and in 1846 was appointed professor of chemistry applied to the arts in the scientific school of the college, now the Sheffield scientific school. He became associate editor of the "American Journal of Science" in 1838, and since 1854 has been associated with Prof. J. D. Dana as editor and proprietor. From 1849 to 1854 he was professor of medical chemistry and toxicology in the university of Louisville, Ky.; and in 1854 he succeeded his father as professor of general and applied chemistry in Yale college, which post he still holds (1876). In connection with C. R. Goodrich he prepared the "Illustrated Record" and the "Progress of Science and Art" published in connection with the international exhibition of 1853 in New York. He was for several years secretary of the American association for the advancement of science, and had charge of the

publication of its "Proceedings." He is also a popular lecturer. Besides numerous papers in the "American Journal of Science," he has published "First Principles of Chemistry," a popular text book (Philadelphia, 1846; revised ed., 1856), and "Principles of Physics" (Philadelphia, 1858; revised ed., 1868).

**SILLOWAY, Thomas William**, an American architect, born in Newburyport, Mass., Aug. 7, 1828. He began to practise his profession in Boston in 1851, and in the 20 years following more than 200 church edifices were built or remodelled under his superintendence. He designed the new capitol, Montpelier, Vt. (1859), Buchtel college, Akron, O. (1872), &c. While pursuing his profession as an architect, he acted as a Universalist preacher from 1852, and was ordained a clergyman in 1862. He has published "Theognis, a Lamp in the Cavern of Evil" (Boston, 1856); "Text Book of Modern Carpentry" (1858); "Warming and Ventilation" (1860); "Atkinson Memorial," a series of 18 discourses (1861); "The Conference Melodist" (1863); "The Cantica Sacra," a book of church service (1865); and "Service of the Church of the Redeemer" at Brighton (1867). With George M. Harding he edited an improved edition of Shaw's "Civil Architecture" (1852).

**SILPHIUM** (Gr. σίλφιον, the ancient name of some resin-bearing plant), a genus of coarse, robust, perennial plants of the composite family, which have a copious resinous juice and large heads of flowers, resembling those of the sunflower, but quite different in structure. In *silphium* the numerous ray flowers are pistillate and fertile; those of the disk, though they are apparently perfect, are sterile; the broad flat akenes are winged and without pappus. The genus comprises about 20 species, all North American; some are very abundant on the western prairies, while others are peculiarly southern. The best known species is *S. laciniatum*, called rosin weed; it has a large thick root, from which arise numerous radical, long-petioled leaves, from 12 to 30 in. long; they are very thick, and rough with bristly hairs; their general outline is ovate, but they are deeply pinnately cut and parted, and the divisions themselves often cut-lobed; the stem, usually 3 to 6 ft. high, sometimes reaches 11 ft., and bears near its base numerous leaves similar to those from the root, and fewer leaves above. The flower heads, borne in a kind of raceme at the upper part of the stem, are 3 to 5 in. across, and, as in all the other species, yellow. The resinous juice of this and others exudes either spontaneously or from the puncturing of insects, appearing in small translucent tears upon the stem and foliage. This resin and the plant itself have been regarded as useful remedies in asthma and similar diseases of horses. A tincture of the root and leaves is sometimes used as a domestic tonic and diaphoretic. The erect leaves of this plant, when growing in the open prairie, commonly stand with their edges pointing north and south; hence it has been called compass plant, pilot weed, and polar plant. This species occurs from the prairies of Michigan southward and westward. A closely related species, found from Ohio west and south, called prairie burdock or prairie dock, is *S. terebinthinaceum*, having also large and coarse leaves, which are not cut, but only serrate on the margins, and rough and scurfy especially on the under surface; the tall stems are smooth, and the heads of flowers are smaller than in the preceding. This species produces resin abundantly, the leaves being often sprinkled with it. One of the most striking species is *S. perfoliatum*, called the cup plant; its square stem bears opposite leaves, a foot or more long; these are united by their bases around the stem, and form a concave disk, which after a rain contains a considerable quantity of water. This has a similar geographical range to the preceding, but having long been cultivated in gardens on account of its curious leaves, it has been introduced much further east.

Rosin Weed (Silphium laciniatum).

**SILURIAN**, the name of one of the geologic ages, the age of mollusks and other invertebrates. The name is derived from that of the ancient Silures, who inhabited that portion of England and Wales where these rocks abound. The formation lies upon the Cambrian of Sedgwick, according to some classifications, and immediately below the Devonian. Murchison includes in it the upper Cambrian of Sedgwick. The subdivisions of the Silurian age differ in Europe and America, and also in different parts of the same continent. In North America the transition of the rocks and life from the lower to the upper Silurian is abrupt. In Great Britain the transition in life is gradual, although the rocks are unconformable in stratification. In Bohemia there is no break in the rocks, but there is marked change in the life. Dana has adopted the subdivision into periods and epochs derived from the succession of rocks in the state of New York, where the strata are well displayed, and have been carefully studied. In this arrangement the lower Silurian, beginning from below, includes the primordial or Cambrian, the Canadian, and the Trenton periods; the upper Silurian embraces, in the same ascending order, the Niagara, Salina, lower Helderberg, and Oriskany periods. The Oriskany formation was until recently placed as the lowest period of the Devonian age; but from

the relations of its fossils it has been transferred to the Silurian. The Cambrian period has two epochs, the Acadian and the Potsdam. The Canadian period has the calciferous, the Quebec, and the Chazy epochs. The Trenton period embraces the Trenton, Utica, and Cincinnati epochs; the Niagara period, the Medina, Clinton, and Niagara epochs; while the Salina, lower Helderberg, and Oriskany periods have each one epoch, correspondingly named. The lower Silurian animal fossils are sponges, radiates, mollusks, and articulates; among the last are numerous trilobites, a species of which found near Braintree, Mass., in the Acadian formation, was 20 in. long. The calciferous and Quebec epochs of the Canadian period are remarkably rich in fossils and economic products, the latter including copper and silver ores. In Newfoundland the Quebec formation reaches a thickness of 6,600 ft., the upper half being sandstone and shales and the lower half mostly limestones. The Trenton period, abounding in fossils and economic products, among which is petroleum, has its formation along the Appalachians and over a large part of the Mississippi basin, including the galena limestone of Wisconsin and other states. Trenton limestone has been found in the arctic regions, upon King William's island, North Somerset, and Boothia. The Niagara formation in North America covers a large part of the interior of the continent, and the arctic and other parts of British America, and also contains petroleum. At Niagara falls 85 ft. of limestone rest on 80 ft. of shale, and near the falls the shale is covered with 165 ft. of limestone. The Salina period includes the rocks which yield the salt brines of central New York. Through the Mississippi basin the Salina formation is for the most part absent. This formation contains numerous beds of gypsum, which are not stratified like the other rocks, and have been formed by the action of sulphuric acid upon limestone, the sulphuric acid being derived from sulphur springs. The Oriskany period contains no land plants in New York, but at Gaspé, province of Quebec, a small species of *lycopodium* or ground pine has been found. The most common animal fossils are bivalve mollusks. In Maryland there are five species of crinoids, but in New York they are rare. The rocks of both the lower and upper Silurian are widely distributed over the globe, although the lower are the most extensive. The upper Silurian in Europe, besides invertebrate fossils, contains the vestiges of the earliest fishes, some of which are of the shark tribe; so that although the Devonian is the age of fishes, they really originated in the Silurian. It was formerly thought that the Silurian formation contained the earliest vestiges of organic life, but organic remains have recently been found in older formations. (See GEOLOGY, vol. vii., p. 694, and PALÆONTOLOGY, vol. xii., pp. 811, 813, 816.)

**SILVER,** one of the precious metals, distinguished by its whiteness, its brilliant lustre when polished, its malleability, and its indifference to atmospheric oxygen. It is one of the most widely distributed of metals. Since it occurs frequently in a native state (though never chemically pure, being invariably alloyed with gold or copper, and sometimes antimony, arsenic, bismuth, quicksilver, or iron), and is easily fusible, it naturally became known to mankind in the earliest ages. The alchemists called it *Luna* or *Diana*. The Greek name ἄργυρος is from ἀργός, white, and is the source of the Latin *argentum*. Silver is one of the first metals named in the Old Testament, being included among the enumerated riches of Abraham. At that period, as in later times, it was used as a medium of exchange and as a material in the arts. In Solomon's reign it is said to have been so abundant as to be nothing accounted of, and the king had made it to be as stones in Jerusalem. Among other ancient nations it was also abundant. Polybius says the tiles upon the roof of the temple at Ecbatana were of solid silver, and the beams and pillars of the temple were covered with plates of silver and gold. These metals were obtained from Nubia, Ethiopia, Attica, Epirus, and the distant countries of eastern Asia. The rich Spanish silver mines were developed at an early day, and furnished the main supply of the metal for Phœnicia, Carthage, and Rome. Pliny speaks of a mine opened by Hannibal, which supplied him with 300 lbs. of silver daily, and was worked by adits reaching a mile and a half into the mountain. This was at Guadalcanal, at the foot of the Sierra Morena, in the modern province of Seville.—Pure silver, in its massive state, is the whitest of metals. It takes by burnishing a brilliant lustre, though inferior to that of its white alloys with copper. When granulated by falling molten into water, it acquires a rough but exceedingly beautiful surface. Reduced from the chloride in the humid way, it appears as a gray, spongy powder. It crystallizes in cubes and octahedrons when allowed to cool from the molten condition or precipitated from solution—for instance, by copper or zinc. Sometimes it is precipitated black by the galvanic current or by zinc. In hardness and strength it is superior to gold and inferior to copper; a slight alloy of copper hardens and strengthens it. In malleability and ductility it is inferior to gold only. (See METAL.) Leaves less than $\frac{1}{100,000}$ of an inch thick can be obtained by beating, and wires may be drawn out of extreme tenuity. Its chemical symbol is Ag, its equivalent 108. According to G. Rose, the specific gravity of cast silver is 10·505, of pressed or hammered silver 10·566. Other authorities give for the former 10·474, and for the latter 10·510. Lengsdorf found the specific gravity of silver wire which had been repeatedly drawn to be 10·47 before heating and 10·43 afterward. The specific heat of silver is given by Regnault as 0·057. Its heat-conducting power is greater than that of any other metal, as is also its power of reflecting

light and heat when highly polished; but its radiating capacity in the same condition is very small. By virtue of these properties vessels of silver are best adapted to retain the heat of liquids. It melts at a full red heat, about 1000° C. (1832° F.). It shrinks in cooling, and hence fills but imperfectly the moulds in which it is cast. At a very high temperature it is volatile. Melting silver mechanically absorbs 20 volumes of oxygen, which in solidifying it expels, sometimes with sufficient force to throw off particles of metal. Alloyed with 1 or 2 per cent. of copper or with gold, it apparently loses this property. Silver is oxidized neither by exposure at ordinary temperature to dry or moist air, nor by heating in air; but it burns to an oxide when melted upon charcoal in the oxyhydrogen flame, or when exposed to a galvanic current of great intensity, or to ozone. Chlorine, bromine, and iodine act upon it at ordinary temperatures. It has strong affinity for sulphur (with which it can be easily fused to a sulphide), and is hence readily tarnished by sulphuretted hydrogen, which is present in small quantities in the ordinary air of cities. To protect silver vessels not in use, they may be wrapped in paper saturated with wax, which keeps out the impure air, or in paper painted with white lead, which decomposes sulphuretted hydrogen. Articles of food, with the exception of eggs and salt, scarcely affect silver, and it is therefore a favorite material for table ware. The discoloration from eggs is due to sulphur; that from salt, to chlorine, which forms argentic chloride. This may be removed by rubbing with a linen rag moistened with aqua ammoniæ. The caustic alkalies in solution or fusion do not attack silver as they do platinum, and it is consequently employed for the evaporation of such solutions, and for crucibles in which minerals are fused with potassium or sodium hydrate. Silver foil is sometimes used in blowpipe analyses, for detecting sulphur and the sulphides of the metals. Melted with carbonaceous matter, silver forms a carburet, white like the metal. This is also formed when compounds of silver oxide are decomposed by organic acids.—Silver may be easily alloyed by melting with most metals. The alloys with base metals are in general not useful enough to counterbalance the cost of the silver. The alloy with copper, which in subordinate quantity enhances the valuable qualities of the silver, is an exception. The alloys with lead and zinc, serving an important purpose in metallurgy, will be mentioned further on. An alloy of 100 parts of aluminum with 5 of silver gives a handsome white malleable compound, susceptible of high polish. A small quantity of iron, chromium, cobalt, or nickel imparts great hardness to silver. Steel may be made to retain about $\frac{1}{500}$ of its weight of silver, which is said to improve its quality; the alloy is called silver-steel. Combined with mercury, silver forms a most brilliant amalgam for mirrors. An alloy of 20 to 30 parts of silver with 30 of nickel and 50 of copper is said to be equal in all respects to the ordinary standard silver, which is 9 parts of silver with 1 of copper. Small coins have been made in Switzerland of an alloy of silver and copper with 10 per cent. nickel. Two parts zinc and one part silver give a ductile, white, fine-grained alloy. Three parts of silver to one of tin give a hard, and one part of silver to two of tin a soft alloy. Bismuth, antimony, and arsenic yield brittle alloys. The alloys of silver and copper are the most important of all, being used both in coinage and in the arts. The copper alloy is harder than pure silver, takes a finer polish, and wears better; and the white color of silver may be retained if the contents of copper do not exceed a certain proportion, while even those alloys containing a larger proportion of copper may be so treated by "pickling" in acid as to deprive them of copper on the surface, and thus restore their silver-white color. The standard silver for coinage, on the continent of Europe and in the United States, is a compound of 9 parts of silver to 1 of copper; in England, of 37 silver to 3 copper. For plate the legal fineness varies in different countries, or is, as in the United States, left to the choice of the manufacturer. In North Germany the usual fineness is inferior to that of coin.—Silver does not dissolve in any hydrated acids by taking the place of the hydrogen; on the contrary, hydrogen displaces it from the solutions of its salts and precipitates it in metallic form. Concentrated sulphuric acid oxidizes silver at boiling heat, forming argentic sulphate and sulphurous acid. Nitric acid, even when diluted with an equal bulk of water, acts rapidly upon silver, and at high temperature with great violence, argentic nitrate and nitric oxide being formed. A solution of chromic acid changes silver to a red argentic chromate. Muriatic acid, even at a high temperature, has little effect upon silver. Argentic oxide combines at high temperatures with silicic acid; hence, silver heated or melted with glass or other silicious compounds becomes oxidized and colors the mass yellow. All of the more easily oxidizable metals and many compounds susceptible of higher oxidation (so-called deoxidizing substances), as well as many organic substances, precipitate silver from solution. Silver forms three oxides: a suboxide, $Ag_4O$; argentic oxide, $Ag_2O$; and a peroxide (probably $Ag_2O_2$), which does not combine with acids. The second of these is of special interest as the basis of the salts of the metal. It is separated from the nitrate, or any soluble silver salt, by adding an alkaline solution, as a brown hydrated oxide, which parts with its water at 60° C. (140° F.), and with its oxygen at a red heat. Its solution in ammonia deposits on exposure to the air a black micaceous powder supposed to be a compound of silver oxide and ammonia ($Ag_2O, H_3N$), or amidide of silver ($AgH_2N$),

or nitride of silver ($Ag_3N$). It is terribly explosive, and is hence called fulminating silver (Berthollet's). This most dangerous compound may also be unintentionally produced by precipitating an ammoniacal solution of argentic nitrate by the addition of caustic potash. The chlorate of this oxide is likewise very explosive, as is also the fulminate proper (Brugnatelli's). (See EXPLOSIVES.) The sulphate is formed by treatment of the metal at a high temperature with concentrated sulphuric acid. Upon this reaction is based one method of separating silver and gold. (See GOLD.) The nitrate ($AgNO_3$) is the most important salt of silver. (See NITRATES, vol. xii., p. 463.) It is employed in the preparation of other compounds of silver, the most important of which is the chloride, produced by adding to the nitrate solution chlorine or a soluble chloride, such as common salt. It is a dense white flocculent precipitate, which under exposure to light turns first violet, then black, probably by partial reduction to subchloride. Chlorine restores the white color. The chloride is slightly soluble in boiling concentrated muriatic acid, more readily in strong solutions of chlorides, ammonia, alkaline cyanides, and hyposulphites; insoluble in water and dilute acids; scarcely affected by any oxygen acid, even concentrated sulphuric; reduced to metal by zinc, iron, copper, or any metal more oxidizable than silver, heated hydrogen, organic compounds containing hydrogen, alkalies and alkaline earths, and by heating upon charcoal before the blowpipe. The insolubility of the chloride in oxygen acids permits the precipitation of silver from solutions of almost all its salts by the addition of hydrochloric acid or of other chlorides, thus giving a convenient means of determining its presence or separating it from other metals. On the other hand, the solubility of the chloride in brine or sodium hyposulphite constitutes an important means of silver extraction by the humid method of metallurgy described below. This salt occurs in nature as an ore. It is used in photography, and its ammoniacal solution is employed to color mother-of-pearl. The bromide ($AgBr$) and the iodide ($AgI$) also occur in nature, the latter rarely. Their chemical relations are similar to those of the chloride, but the bromide is but slightly dissolved in dilute aqua ammoniæ, and the iodide scarcely at all. They likewise have the property of darkening by exposure to light. (See PHOTOGRAPHY.)—*The Metallurgy of Silver.* Silver is obtained partly from true silver ores, partly from other ores containing silver as an accidental or variable constituent. To the former class belongs the native metal, which is usually more or less alloyed with gold, and sometimes with other metals, as above remarked. The occurrence of gold and silver in variable natural alloy is so general that they may almost be said to constitute but one mineral species, ranging from silver with a slight trace of gold to gold with a slight trace of silver. Native silver is found in masses and in arborescent and filiform shapes in veins of quartz, calcite, &c., or as segregations accompanying other silver ores. The masses are sometimes crystalline, showing cubical and octahedral forms. Very pure silver occurs with the native copper at Lake Superior. The most famous masses of native silver, several of which exceeded 500 lbs., have been found at the mines of Kongsberg in Norway, of Freiberg, Schneeberg, and Johann-Georgenstadt in Saxony, and in the Bohemian, Hungarian, Peruvian, and Mexican mines. In the silver mines of Nevada, Idaho, and Utah it is not uncommon, though it has not been found in large masses. Silver amalgam occurs in small quantities in some European mines, and contains 26 to 35 per cent. of silver, the remainder being mercury. The variety known as arguerite, from Coquimbo in Chili, is an important ore in that region, and contains 43 to 63 per cent. of silver. The antimoniuret and the telluret of silver are comparatively rare. The most important silver ores are the chloride, the sulphide, and the combinations of sulphide of silver with other sulphides. The chloride of silver, or horn silver ($AgCl$), is a common ore in Chili, Peru, Mexico, and the western regions of the United States, particularly in certain districts of Nevada, and in the Owyhee district of Idaho. It has been met with in small quantities in many of the European mines. When pure, its composition is silver 75·2, chlorine 24·8. It has a waxy appearance, resinous lustre, and pearl-gray, greenish, whitish, or bluish color, turning brown in the air; hardness 1 to 1·5; sp. gr. 5·3 to 5·5. It occurs chiefly near the outcrops of argentiferous deposits as a product of the decomposition of other ores. In Chili and Peru, for instance, it is found in cubical crystals in the ferruginous gossan known as *pecos* and *colorados.* The bromide and iodide, which also occur in nature, closely resemble it, but are far more rare. The sulphide of silver ($Ag_2S$, silver glance, vitreous silver, or argentite), containing 87·1 silver and 12·9 sulphur, is, next to the native metal, the richest ore. It has a blackish lead-gray color, metallic lustre, and shining streak; H. 2 to 2·5; sp. gr. 7·196 to 7·365; is easily cut with a knife, and readily melts on charcoal before the blowpipe. It forms a considerable portion of the ores of the silver mines of Saxony, Bohemia, Hungary, Mexico, Peru, and the United States. It is commonly associated with other argentiferous minerals, and sometimes is finely disseminated through the gangue or the accompanying ores. The double sulphides of silver and antimony constitute a very valuable class of ores, of which the chief are: stephanite ($Ag_5SbS_4$), with 68·5 per cent. of silver and sometimes small quantities of iron, copper, and arsenic, having metallic lustre, iron-gray color, black powder, H. 2 to 2·5, sp. gr. 6 to 6·27, occurring in Saxony, Bohemia, Hungary, Mexico, and

Nevada, particularly in the Comstock lode; miargyrite ($AgSbS_2$), with 36·9 silver, steel-gray to iron-black, metallic lustre, dark cherry-red powder, H. 3, sp. gr. 5·2, occurring in Saxony, Spain, and Mexico; pyrargyrite ($Ag_3SbS_3$), dark ruby silver or antimonial silver blende, with 59 silver, sometimes a little arsenic, black or by transmitted light deep red, H. 2 to 2·5, sp. gr. 5·759, occurring in Saxony, Baden, Cornwall, Norway, Mexico, South America, and Nevada; and polybasite ($Ag_9SbS_6$), with from 64 to more than 72 silver, the antimony being partly and sometimes wholly replaced by arsenic, and the silver partly by copper or to less extent iron and zinc, color iron-black, streak black, H. 2·5, sp. gr. 6·2, occurring in the Hartz, Saxony, Hungary, Mexico, and Nevada. Proustite, or light ruby silver ($Ag_3AsS_3$), similar to pyrargyrite, except that the color is lighter and the antimony is replaced with arsenic, occurs in the same localities, but more rarely; it contains 65·4 silver. Copper silver glance or stromeyerite ($CuAgS$), with 53 silver and 31 copper, iron-black, black shining powder, H. 2·75, sp. gr. 6·2, occurs in Silesia, Chili, and elsewhere. The foregoing are the principal true silver ores. The chief argentiferous ores of other metals are those of lead, copper, and zinc. Iron pyrites and arsenical pyrites, as well as bismuth, cobalt, and nickel ores, may be argentiferous, but it is usually by reason of finely disseminated silver ores throughout their mass. Galena is always more or less argentiferous. In the United States, the galena of the Appalachian range and of the Mississippi valley is usually poor in silver, while that of the Rocky mountains and the interior basin to the Sierra Nevada is highly argentiferous. Oxidized ores are usually poor in silver, but the carbonate, &c., occurring in the limestone of New Mexico, Utah, and the Eureka district, Nevada, are exceptions, being smelted in large quantities for lead and silver. The peculiar ore known as stetefeldtite, which occurs abundantly in Nevada, is an oxidized but massive mineral containing antimony and other base metals, and often very rich in silver. The variable mineral or class of minerals known as tetrahedrite (*Fahlerz*, argentiferous gray copper, freibergite, tennantite, hermesite) seems to be a combination of metallic sulphides with sulphides of antimony and arsenic, or a sulphide of antimony and copper, in which the antimony may be partly replaced by arsenic, and the copper by iron, zinc, silver, and even, as in freibergite, lead, or, as in hermesite, quicksilver. The percentage of silver varies from a mere trace to 32 per cent. Pure zinc blende is usually poor in silver, but is frequently found in intimate association with true silver ores or native silver, and particularly with argentiferous galena; and in some notable instances the blende is richer than the galena. —The mechanical concentration of silver ores by water is attended with heavy loss, by reason of their usual association with base ores of nearly the same specific gravity, and their property of cleaving when crushed into fine scales and splinters or dust, which are usually carried away by the current. The yield of silver ores is generally rated in this country in ounces troy to the ton of 2,000 lbs. avoirdupois, or 29,167 oz. troy. About 1 per cent. of silver would be equivalent to 292 oz. to a ton. A yield of a little less than 3 oz. is represented by the decimal ·0001 or ·01 per cent. This small proportion will not pay for the mining and reduction of the ores; but where lead is produced containing ·01 per cent. of silver, the latter can still be extracted and saved by refining processes. (See LEAD.) The pig lead (variously called work lead, crude bullion, and base bullion), mainly produced from argentiferous galena, carries from 20 to 200 oz. of silver to the ton.—The methods of producing silver from ores and furnace products may be divided into three classes: smelting, amalgamation, and humid extraction. The smelting processes are mostly based upon the capacity of metallic lead, as well as its oxide and sulphate, to separate silver under fusion from its combinations, the liberated silver alloying itself with an excess of lead and accumulating in the metallic bath in the hearth of the furnace. The following chemical equations indicate the typical reactions of the lead smelting processes: $Ag_2S + Pb + xPb = Ag_2,xPb + PbS$; $Ag_2S + PbO = AgPb + SO_2$; $Ag_2S + PbSO_4 = Ag_2Pb + 2SO_2$. (See METALLURGY.) From the argentiferous lead thus produced the silver is obtained directly by an oxidizing fusion (cupellation), transforming the lead into litharge and leaving metallic silver upon the cupel; or the argentiferous lead is first submitted to treatment in a battery of melting kettles, in which at a low temperature a portion of the liquid mass crystallizes, while another portion, rich in silver, remains liquid; and the crystals being ladled from each kettle to the next, and there submitted to remelting and recrystallization, while the liquid is passed down the series in an opposite direction, the contents of silver are at last chiefly concentrated into a small quantity of so-called rich lead, which is then cupelled (the Pattinson process); or the silver is extracted from the molten lead by means of the superior affinity between silver and zinc, metallic zinc being added to the bath and the zinc-silver alloy rising to the surface and being skimmed off and submitted to further treatment by means of smelting, liquation, or distillation (the Parkes process, with the modifications of Cordurié, Flach, and others). In smelting argentiferous copper ores, the silver is often concentrated in a copper matte or black copper, which may then be smelted with lead, or treated in the humid way. The liquation of argentiferous copper consists in alloying it with a certain quantity of lead, and afterward heating the alloy above the melting point of lead, but below that of copper. The lead "sweats" out, carrying the silver with it, and leaving

behind the spongy copper. This process has almost everywhere given way to humid methods. (See COPPER, LEAD, and METALLURGY.)—The method of amalgamation, invented in Mexico in 1557 by Bartolomé de Medina, led to the enormous production of silver there and in South America during the next 200 years, and has remained substantially in extensive use ever since. The Mexican, known as the *patio* process, is suited to ores which contain native silver or silver chloride (bromide, iodide) and sulphide, and are measurably free from other sulphides and from arsenides and antimoniurets. The ore is first crushed and then ground fine in arrastras. If gold is present, 50 or 60 per cent. of it may be saved by introducing silver or copper amalgam into the arrastra. Ores containing pyrites, antimony, or arsenic are incompletely roasted, to break up the combination of silver with these elements. The presence of silver sulphide does not necessitate roasting as a preliminary for patio amalgamation. The fine paste from the arrastra is spread on the patio floor (of stone, calked boards, or asphaltum) in round heaps (*tortas*) about 0·3 metre high and 10 to 16 metres in diameter, containing each from 5,000 to 100,000 kilos; average, about 60 tons. The paste having stiffened by the evaporation of its water, from $2\frac{1}{2}$ to 10 per cent. of impure salt is added, according to the contents of silver in the ore. This is intermixed with shovels and subsequently by the treading of mules or men, and occasionally by means of kneading machines, with travelling wheels, set up in the torta. After one or two days the *magistral* is added; this is copper vitriol and salt, or rich oxidized copper ores mixed with pyrites which has been roasted with salt, or simply copper pyrites which has been so roasted. The quantity of magistral required varies according to the season, the temperature, and the quantity of the ore; it usually ranges from $\frac{1}{2}$ to 1 per cent. Its function is to cause certain reactions with the salt and the sulphide of silver and promote the formation of amalgam. Too much of it causes too high a temperature in the mass, particularly in winter; hence cold weather and poor ores require the smallest amount. After another treading, quicksilver is sprinkled over the torta by squeezing through a leather or canvas bag. The quantity used is six to seven times the weight of silver in the ore, sometimes much more. It is rarely added all at once; the usual practice is to give fresh quicksilver every alternate day, treading the mass for six to eight hours on each intervening day. The termination of amalgamation is observed by panning samples (see GOLD) from the torta, and examining the amount and condition of the quicksilver and amalgam. The period required for the whole operation down to this point varies from 5 to 30 days; average, about 19 days. Various theories have been proposed concerning the chemical reactions of the patio. Too low a temperature stops the reactions, and may be remedied by more frequent treading or by additional magistral. The amalgam is collected in settlers, which are circular vats of wood or masonry, about 9 ft. in diameter and 8 ft. in depth, in which the mass, thinned with water, is stirred and allowed to deposit its heavy amalgam, while the lighter portion is drawn off. The amalgam, being concentrated still further, is at last collected in a leather or canvas bag, where it is freed by squeezing from free mercury, which passes through, carrying a little silver with it, while the mass remains in a coherent, plastic condition. The former is used again on the patio; the latter is moulded into 30 lb. blocks, piled on an iron plate, covered with a large iron bell, and heated by means of a charcoal fire around the bell. The mercury is vaporized, and (the joint at the edge of the bell being carefully luted) passes down through a pipe in the iron plate into a cistern of water. The bell furnace is less economical of fuel and mercury than muffle or retort furnaces; it loses 0·8 per cent. of mercury. The silver, found in solid masses when the bell is raised, is cast into ingots of 80 or 90 lbs. By the patio process the usual product of silver is 50 to 66 per cent. of that contained in the ore; the most docile ores, under favorable circumstances, have yielded 90 per cent. The loss of quicksilver is given by Kerl as 3 to 5 per cent. of the quantity used; earlier accounts make it considerably greater. This loss is due to the formation in the torta of soluble mercury dichloride (calomel), which is afterward washed away.—The *cazo* process, used in Mexico and Chili, is a hot amalgamation in kettles. The ore (in Mexico chloride, in Chili sulphide) is placed, in the form of a watery pulp, in a vat with copper bottom and wooden or stone sides. Here it is heated and stirred with salt and quicksilver, copper vitriol being added in the treatment of sulphides. The process is rapid and effects a tolerably complete extraction of silver, but involves great loss of quicksilver (2 to 2·5 times the weight of silver) when applied to sulphide ore. Silver ores free from sulphides of other metals are amalgamated at Guanajuato, Mexico, in arrastras, by simple grinding and mixing with quicksilver and water.—Pan amalgamation, called the Washoe process, consists in rubbing together in pans (usually of cast iron) the watery mixture of crushed ore (pulp) with quicksilver, with or without the addition of other chemicals. The simplest form of it may be thus described: The ore suitable for this process (usually containing silver sulphide or chloride and native silver, with little antimony, arsenic, base sulphides, in a gangue of quartz) is first crushed in a stamp mill, similar in most respects to that employed for gold-bearing quartz. (See GOLD.) The screens which regulate the size of the crushed particles are of wire cloth with 40 to 60 meshes to the inch, or of Russia sheet iron, perforated with holes $\frac{1}{40}$ to $\frac{1}{24}$ in. in diameter. The pulp reduced to this fineness

is ground and amalgamated in pans, of which there are numerous forms. The charge for a pan is 800 to 1,500 lbs.; the very large pans, treating tailings which have been already ground fine, can take 3,000 to 4,500 lbs. To maintain a proper temperature, steam is introduced into the pulp or into a steam chamber under the bottom, and a wooden cover is usually kept on the pan. The pulp is generally ground for one or two hours; then the quicksilver is sprinkled in (usually 60 to 70 lbs. to a charge of 1,200 or 1,500 lbs.), and, the mullers being raised to avoid too much grinding, which would "flour" the mercury, stirring is continued for two or three hours longer, after which the pulp is diluted and drawn off into a settler. The modification of the Washoe process invented by Mr. Henry Janin, consisting in the use of large quantities of copper vitriol (blue stone) and salt, has proved very successful in the reduction of refractory ores not otherwise amalgamable. The quicksilver, charged with amalgam, is washed, skimmed, and strained through a canvas bag, which retains the amalgam. This is then distilled in cast-iron retorts, the mercury being collected under water, while the "retort bullion" remains behind. About one sixth of the charge retorted, or 200 lbs. of bullion from 1,200 lbs. of amalgam, is usually obtained from the retort, to be broken up, melted, and cast into ingots; it loses 2 to 3 per cent. in melting. The ingots are assayed, and their fineness in thousandths of gold and silver is stamped upon them. The coin value of the Comstock bullion is $1 75 to $2, one third of which is due to the gold it contains. The pulp escaping from the apparatus in which the amalgam is collected is called "tailings." The tailings are often concentrated upon blankets or otherwise, or are simply allowed to settle in reservoirs, for reworking. The "slimes" or "slums" comprise that part of the ore which is crushed under the stamps to an impalpably fine condition, and escapes in the battery water without ever getting into the pans. Since many silver ores yield much fine powder in crushing, the slimes are often far richer than the tailings, the value of the latter being largely in the particles of quicksilver and amalgam which they contain. The chemistry of the Washoe process is summed up by Mr. Arnold Hague as follows: that the ore submitted to it consists chiefly of native gold, native silver, and argentiferous sulphurets, associated with varying proportions of blende and galena; that the action of sodium chloride and copper sulphate in the pan produces copper chloride, while the presence of metallic iron causes the formation of copper dichloride; that both the chlorides of copper assist in the reduction of the ore by chloridizing the sulphurets of silver and decomposing the sulphurets of lead and zinc; that sulphate of copper enhances the amalgamating energy of mercury, by causing the formation of a small quantity of copper amalgam, and also tends to expel the lead; but that the quantities of chemical agents usually added in the Washoe process are too small to be effective, and that the principal agents in the reduction are in general mercury and the iron of the pan, aided by heat and friction. The essential condition in the amalgamation is the keeping of the mercury bright and pure, that it may come into direct contact with the iron and sulphide of silver. The consumption of mercury in the Washoe process may be considered chiefly a mechanical loss, and only to a limited extent a chemical one. The pan amalgamation of slimes and refractory ores, with the addition of large proportions of copper sulphate and salt, involves a greater loss of mercury.—Refractory ores, not suitable for "raw" amalgamation by the Washoe or the patio process, are treated in many localities by the Freiberg process, consisting in the chlorination of the ore by roasting with salt, and its subsequent amalgamation. At Freiberg in Saxony, where this method originated, it has been abandoned, the ores formerly amalgamated being now treated by smelting. But in districts where fuel is scarce and labor dear, and lead ores for smelting are not at hand (which is the case in many parts of Nevada, for instance), the Freiberg system is still successfully employed, though greatly modified as to apparatus. The ore is crushed in stamp mills, without water, and the fine powder is further dried, usually by spreading on the top of the arch or the dust chambers of the roasting furnace. Either in the battery, during crushing, or on the drying or the charging floor, 6 to 7 per cent. (for rich ores, up to 20 per cent.) of salt is mixed with the ore. The mixture is then roasted, to chloridize the silver; this was done abroad in reverberatory furnaces, which have been used in Colorado and Nevada also, but are now generally replaced in the west by Stetefeldt's showering furnace or Brückner's cylinder. From the roasting furnace the ore is conveyed to the pans, where it undergoes an amalgamation similar to that of the simple Washoe process, except that less grinding is necessary. The Freiberg amalgamation was performed in revolving wooden barrels, which are still employed at some places in the United States. Each apparatus has its partisans. A peculiar method of amalgamation pursued in Chili avoids the chloridizing roasting, substituting a humid chlorination by means of copper dichloride (Kröncke's process). It is highly praised, but not yet widely employed. The use for this purpose of copper chloride, which is of earlier origin, involves a loss of quicksilver as calomel.—The processes of humid extraction of silver are of two classes. Either the silver is converted into a soluble compound and separated by leaching and precipitation, or the baser metallic constituents of the ore are rendered soluble and removed by leaching, leaving an auriferous and argentiferous residuum for further treatment. The methods of the first class convert the silver

into chloride or sulphate, the former by a chloridizing, the latter by an oxidizing roasting. The chloridizing roasting is essentially that of the Freiberg amalgamation process, and is effected by mixing salt with the charge. The silver chloride is extracted from the mass by lixiviation with hot brine (old Augustin process), cold brine (Hungarian improvement), sodium hyposulphite (Patera process), or calcium hyposulphite (Kiss process in Hungary and Russia, Hofmann in Mexico). The latter extracts also gold chloride if it is present, which brine will not do, unless it has been, as Patera recommends, impregnated with free chlorine gas. Experiments conducted at Wyandotte, Mich., by Messrs. Courtis and Hahn, indicate the availability of other chlorides than common salt (particularly calcium chloride, or a solution obtained by treating common limestone with muriatic acid) as a solvent for the silver chloride. The novel and important results of these investigations are given in the "Transactions of the American Institute of Mining Engineers." From its hyposulphite or chloride solution the silver is precipitated with metallic copper, as cement silver, which is washed, pressed, melted, and cast into bars. Ziervogel's method of extracting silver by roasting the sulphuretted ore to produce silver sulphate, leaching this with hot acidulated water, and precipitating with copper, is the simplest and cheapest of all; but it requires very skilful and delicate roasting, and ores comparatively free from lead, antimony, arsenic, and zinc. The three latter tend to cause volatilization of silver; the sulphide of antimony and lead cause a sintering of the roasting charge; copper dioxide, or too high a temperature in the furnace, leads to the formation of metallic silver, instead of the desired sulphate. Hence the application of this process is limited. Its best field is the treatment of the copper mattes of Mansfeld, containing 70 to 72 per cent. of copper, and 0·33 per cent. of silver. The so-called acid extraction is principally used upon cupriferous furnace products, which contain too much lead, antimony, arsenic, &c., to permit treatment by the Augustin or the Ziervogel method. In this process, the base metals are dissolved out by treatment with sulphuric or muriatic acid, and the residuum, containing gold and silver, is further reduced by smelting, or in rare instances by humid methods. For full discussions of all the foregoing processes, see Percy's "Metallurgy," and Bruno Kerl's *Metallhüttenkunde.* The details of American practice, and critical comparisons of different American and foreign methods, are given in the reports of R. W. Raymond, United States commissioner of mining statistics, and in the "Transactions of the American Institute of Mining Engineers."—The principal uses of silver have been mentioned already in this article; see also COINS, GALVANISM (section on electrotyping), MINT, and PLATED WARE. The real value of silver as compared to gold has varied in different ages from one eighth to less than one sixteenth; but the mint rates have often been arbitrarily established by government for the profit of the treasury, in spite of the market price of the metals. At present it is lower than at any previous period. The average ratio of value of silver to gold in the London market for the year ending Dec. 31, 1874, was 1 to 16·27. The following table shows the estimated product of silver at various periods in the present century:

The following estimate of the world's product of silver in 1873 is based upon returns for Germany, Austria, France, Great Britain, Spain, and the United States, and for other countries upon the most recent available accounts: Great Britain and colonies, $1,000,000; Sweden and Norway, $250,000; Russia, $500,000; Austro-Hungarian monarchy, $1,600,000; German empire, $3,000,000; France, $2,000,000; Spain, $2,000,000; Italy (Sardinia), $500,000; Mexico, $20,000,000; Central and South America, $8,000,000; Canada, $900,000; United States, $36,500,000; total, $76,250,000. According to Humboldt and Danson, the value of silver produced in Mexico and Peru from 1492 to 1803 was $4,152,650,000. The production in Europe during the same period was about $200,000,000. For the period from 1804 to 1848 Danson gives $1,244,380,794 as the production of Mexico and South America, that of Europe and Asiatic Russia for the same period having been about $325,000,000. For the period from 1848 to 1868, Prof. W. P. Blake, in his "Report on the Production of the Precious Metals," gives the following estimate of the silver product: United States, $73,000,000; Mexico, $380,000,000; South America, $200,000,000; Australia, $20,000; Europe and Asiatic Russia, $160,380,000; total, $813,400,000. From 1868 to 1875 the product of silver may be approximately estimated at $163,000,000 for the United States, $140,000,000 for Mexico, $56,000,000 for South America, and $63,000,000 for the rest of the world. (None of these estimates include the produce of Japan, China, and central Asia, of which nothing is known.) We have then, as the grand total of the silver product from the discovery of America to the present time, $7,150,000,000.—*Mines.* The silver produced in Great Britain is extracted from an argentiferous lead, to the amount of 550,000 to 700,000 oz. annually (in 1872, 628,000 oz.). The celebrated Kongsberg mines in Norway, discovered in 1623, have been worked almost continually since. The ore occurs in parallel belts of rock, intercalated in gneiss and crystalline schists, and impregnated with sulphides of iron, copper, zinc, and sometimes lead, cobalt, and silver. Fissure veins traverse these belts occasionally, and are argentiferous at the intersection only. Beautiful specimens of native silver occur. The total product of the Kongsberg mines from 1624 to 1864 was 1,817,510 lbs. troy of silver, of which 1,332,485 lbs. was produced before 1805 and 463,498 lbs. after 1815, the intervening period being one of discouragement. The yield for the 30 years preceding 1865 averaged $350,000 annually. The silver mines of Sweden are at present insignificant, and the total product in 1871 was officially reported at but 975 kilos. The silver mines of the Austro-Hungarian monarchy are principally comprised in Hungary, Transylvania, and Bohemia. The Schemnitz district in Hungary (the seat of a celebrated school of mines, founded in 1760 by Maria Theresa) is traversed by a group of veins in porphyry, associated with syenite, &c. The ores comprise numerous argentiferous minerals, of which silver glance and galena are the chief. The Schemnitz mines were first opened more than 800 years ago, and have been worked to a depth of more than 1,200 ft. Near Schemnitz are the mining districts of Kremnitz and Neusohl. The Joachimsthal mines in Bohemia are very ancient, very deep (nearly or quite 2,000 ft.), and have been very productive, but now yield an insignificant amount of silver. This district belongs to the Erzgebirge, a chain of mountains composed of crystalline rocks, on the border of Saxony, in which kingdom it includes the four mining districts of Altenberg (tin), Freiberg, Marienberg, and Schwarzenberg. The official statistics of Saxony show that the total product of silver in these districts in 1872 was 48,753 lbs., and in 1873 43,354 lbs. The Freiberg district is by far the most important, containing nearly 100 mines, many of which are more than 1,400 ft. deep, producing almost the whole of the above amounts. Previous to the 10th century it was a wilderness. The lead ores were discovered in the tracks made by wagon wheels, and in 1169 the veins were opened. They are very numerous, but comparatively small. In 1873 only 24 mines were producing silver ore, and of these only 6 paid dividends. The Himmelfahrt, which is now the leading mine, in 1873 yielded 11,912 metric tons of silver, copper, and lead ores, valued at about $430,000. In 1874 it produced about 7,100 tons of dressed ores, sold to the furnaces for about $328,000. The total yield of this mine to the end of 1874 had been 527,103 kilos of silver (worth about $23,000,000), besides lead, copper, zinc, sulphur, arsenic, and nickel. The chief other productive mines near Freiberg, with the value of their total product (including lead, &c.), as paid by the smelting works, for 1873, are as follows: Himmelsfürst, $202,500; Vereinigt Feld, $114,750; Churprinz, $74,000; Alte Hoffnung, $61,000; Gesegnete Bergmannshoffnung, $60,750; Alte Hoffnung Gottes, $52,750; Junge hohe Birke, $45,450; and Beschert Glück, $34,600. The principal silver mines of Prussia are in the Hartz, formerly belonging to Hanover. The product of Prussian smelting works in 1872 was 162,553 lbs. of silver, worth about $3,600,000; in 1873, 231,920 lbs., worth about $5,000,000. The total product of silver from the smelting works of all Germany was as follows in the years named:

| YEARS. | Centner. | Value in round numbers. |
|---|---|---|
| 1850 | 101,448 | $2,234,000 |
| 1860 | 124,103 | 2,764,000 |
| 1870 | 185,847 | 4,162,000 |

A considerable portion of this increase is due to the importation of rich silver ores from

North and South America for metallurgical treatment, and another portion to the improved processes of extraction. The product from German ores is probably not more than $3,000,000. France is not a silver-ore producing country; but the separation of silver from argentiferous lead ores is carried on to a considerable extent. In 1865 it produced 31,997 kilos of silver, worth $1,414,000; in 1869 (the year before the war), 46,299 kilos, worth $2,020,000. No Spanish silver mines were specially important after the middle ages down to 1825, except those of Guadalcanal and Cazalla, N. E. of Seville, which were profitably worked by the government in the 16th century, producing altogether 400,223 marks of silver; afterward they passed into private hands, and in the beginning of the 17th century are said to have produced 170 marks daily. They were finally abandoned, and allowed to fill with water. In 1825 mining was revived in Spain; in 1839 the famous silver mines of the Sierra Almagrera (N. and S. veins in slate, carrying argentiferous galena, with some silver chloride), in the province of Almeria, were discovered, and in 1843 those of Hiendelaencina (narrow E. and W. veins of silver sulphide and chloride, without lead), in the province of Guadalajara. The Herminia mine, in the Sierra Almagrera, in 1874 produced 18,940 quintals of ore, containing 342,325 lbs. of lead and 41,670 Spanish oz. (3,205 lbs. troy) of silver. The product of the mine in the early part of 1875 was at the rate of about 10,000 lbs. troy per annum. The average value of the work lead is about 20 oz. troy per ton avoirdupois. The product of the mines of Hiendelaencina from January, 1847, to July, 1866, was 7,578,536 oz. troy. They have declined in yield since 1858. By the application of the Pattinson process to the argentiferous galenas of the numerous lead mines of Spain, the production of silver has been increased. The export of lead in 1874 was 86,802,271 kilos, valued at 47,034,022 pesetas. This indicates a value of about $1,700,000 for the silver in the lead. The product of Russia in 1871, from 21 mines of argentiferous galena, was 1,740 tons of lead and 29,000 lbs. of silver. —The conquest of Mexico by Cortes in 1519–'21 was soon followed by the development of the wonderfully rich silver mines of that country. The metal was known to the ancient Aztecs, and was worked by them into numerous ornamental and useful articles; but among the treasures of Montezuma the quantity of silver was small compared with that of gold, and gave little promise of the unbounded resources of the argentiferous mines of his territories. During the 16th century these were opened and extensively worked by the Spaniards in Guanajuato, Zacatecas, and other neighboring districts; and in the 17th and 18th centuries their production was greatly increased by reason of the greater abundance of quicksilver and its more general employment in separating the metal from its ores. At the time of the visit of Humboldt operations were carried on in from 4,000 to 5,000 localities, which might all be included in about 3,000 distinct mines. These were scattered along the range of the Cordilleras in eight groups, the principal of which, known as the central group, contained the famous mining districts of Guanajuato, Catorce, Zacatecas, and Sombrerete, and furnished more than half of all the silver produced in Mexico. The mines of Guanajuato, opened in 1558, are all upon the great vein, known as the *veta madre*, in the range of porphyritic hills the summits of which are from 9,000 to 9,500 ft. above the sea, but only about 3,000 ft. above the high plateau of central Mexico upon which they stand. The great vein is contained chiefly in clay slate, and crosses the southern slope of the hills in a N. W. and S. E. direction, dipping with the slates (the range of which it follows) from 45° to 48° toward the S. W. It is of extraordinary thickness, often more than 150 ft. across, and is said to have been traced for about 12 m.; but the productive portions are chiefly upon a length of about 1¼ m. The vein is made up of quartz, carbonate of lime, fragments of clay slate, together with large quantities of iron pyrites, and sulphurets of lead and zinc with some native silver, sulphuret of silver, and red silver. Near the surface they are partially decomposed and colored red, whence they are termed *colorados*. In their unchanged condition below they are designated *negros* or black ores. These are the main dependence of the mines. The vein has been penetrated to the depth of about 2,000 ft., but not much below the level of the plateau. For the two years ending in July, 1873, 115 mines in this district produced 202,125 kilos of silver ($8,045,425), 36 *haciendas* and *zangerros* being employed in reduction. In 1873 the number of miners and laborers was 8,979, and the amount of ore raised was 1,815 tons weekly; average contents of silver, about 34 oz. troy to the ton avoirdupois. The mine of Valenciana, opened in 1760, upon a rich portion of the vein, averaged for many years a product of $1,600,000, or about $\frac{1}{15}$ of the total product of the 3,000 mines of Mexico, and a quarter of that of the whole of the *veta madre*. It declined in productiveness at the beginning of this century, was suspended in 1810 on account of the war of independence, reopened in 1822 by the Anglo-Mexican company, and abandoned after much expenditure to the Mexican owners. It is the deepest mine in the country, and the lower workings are now flooded. In 1873 it employed 1,950 laborers, and yielded about 195 tons of ore weekly. The mines of Zacatecas, opened in 1548, are also upon a single vein called the *veta grande*, averaging in thickness about 30 ft. The formation is of greenstone and clay slate, the former the most productive. The veins of Catorce are in limestone supposed to be of carboniferous age. The

greatest proportion of silver in every mining district of Mexico is obtained from the sulphuret of silver, an ore of gray color disseminated through the quartz matrix in minute particles, and more or less combined with other metals. The other varieties of argentiferous ores are numerous, but comparatively small in quantity; they are the chloride of silver, ruby silver, native silver, argentiferous pyrites, and argentiferous galena. The comparative quantities of these at the different mines are very variable. Until the present century the ores were extracted altogether by the rude methods of the native Indians. They brought them upon their backs up the long flights of thousands of roughly formed steps, in loads of 240 to 380 lbs. each, while exposed all the time to the great heat of the mine. In 1821 the Mexican government offered facilities for foreigners to become interested with the natives in the mines. English mining companies were formed, and operations were undertaken with powerful machinery; but the adventures were almost universally unsuccessful, the nature of the country being extremely unfavorable for the introduction of heavy machines, as well as for keeping them in operation and repair. From the opening of the Mexican mines in the 16th century their production of silver has exceeded that of all other countries. A great stimulus was given to it by the amalgamating process devised by Medina at that early period in Mexico, and it soon attained an annual rate of from $2,000,000 to $3,000,000. This continued to increase till in the 18th century it rose to $23,000,000, which was about the production for the first ten years of the present century. After 1850 it increased, till for some years it exceeded the yield of all past periods. The total product, from the first working of the mines by the Spaniards to their expulsion by the Mexicans in 1821, was $2,368,952,000. A very promising field for silver mining is found in the state of Sinaloa and along the western slope of the Sierra Madre of Durango and Chihuahua. The port of Mazatlan is the base of supplies. Sinaloa is well wooded and watered; the ores are largely true silver ores, which can be treated by the Freiberg or the modified Washoe process. Some of the mines in the interior are exporting rich silver ores to Europe; others are reported to be earning good profits with stamp mills. Central America has no silver mines that are worked to much extent; but rich ores are known to exist in Honduras, Nicaragua, and Costa Rica.—The famous mines of Potosí in Peru (now in Bolivia) were discovered in 1545 by an Indian hunter, Diego Hualca, who, according to Acosta, accidentally exposed native lumps of the precious metal in the roots of a bush which he pulled from the ground. For 20 years succeeding 1557 the annual production of the mines of this region was about $2,200,000, and the total product up to the present time is rated at over $1,300,000,000. The mines, like so many others in Mexico and South America, are now reported to be flooded in their depths. In the Cerro de Fernando at Hualgayoc, near Micuipamba, rich ores were discovered in 1771, and now, it is said, about 1,400 pits are opened in the hill. Other mining districts in Peru are Gualanca in the province of Huamalies, Pasco, Lucanas, and Huantajaya. Cerro de Pasco has been especially famous for its large production. A town is built upon the site of the mines, and the openings to many of them are through the houses of the miners. The production of Peru until within a few years was very small, probably not more than $2,500,000 annually, and it is a very difficult field for mining. Roads, mules, labor, and fuel are all wanting. The ores (except the *pacos* or ferruginous earths of Cerro de Pasco), being complex sulphurets, are exceedingly refractory. In the absence of better fuel, llama dung is employed for roasting at several establishments. But the country is full of undeveloped veins, and coal has been discovered in abundance, while railroads are rapidly extending into the interior. In Bolivia, besides the mines of Potosí, are those of Portugalete in the province of Chichas, celebrated for the richness of their ores, which produce six to eight times as much silver to the ton as those of Potosí. Other mines are worked in the same district. The mines of Lipes have been very productive, and those also of La Plata, Porco, Carangas, and Oruro. The earlier silver mines worked in Chili were in the province of Santiago and in the mineral district of Arqueros, about 17 leagues from Coquimbo. The production was not large, and almost ceased upon the opening of the rich mines near Copiapó in the province of Atacama. Within a circuit of 25 leagues from this city there are 19 silver-mining districts, of which those of Chañarcillo and Tres Puntas are the most important. The metal is found in a variety of combinations, as a sulphuret, chloride, chlorobromide, and iodide; it is also associated with arsenic, antimony, and mercury, and is sometimes abundant in a native state. The mines are in a country difficult of access, quite unproductive even in the timber and fuel required for mining, almost entirely destitute of water, and cold and dreary. A new and rich district has been developed at Caracoles, where the ores, like most of those of Copiapó, are chlorides, and easy to reduce.—Silver mining in the western United States, apart from the early operations of the Spaniards in New Mexico and perhaps Arizona, dates from the discovery in 1859, on the E. flank of the Sierra Nevada, in the present state of Nevada, of the now famous Comstock lode. (See Nevada.) No equally important argentiferous deposit has since been discovered; and, in view of the most recent exposures of vast bodies of ore at great depth on the Comstock, it may be doubted whether its

equal was ever known before. There is no other authentic record of the extraction in a single year of more than $23,000,000 in gold and silver from one vein, which was the product of the Comstock in 1874. And the total estimated product of this lode from 1861 to 1874 inclusive was more than $169,000,000, or about the same as the yield of the score of veins at Potosí for the first 15 years after their discovery in 1545. The bullion from the Comstock lode has averaged about one third gold in value, or say 0·02 in weight. As a consequence of the excitement (almost equal to that attending the discovery of gold in California) which followed the success of the Comstock mines, the districts of Nevada, Idaho, Montana, Arizona, and finally Utah and Colorado, were overrun with prospectors. The mining districts of Owyhee in Idaho, and Unionville, Reese River, Belmont, Pioche, White Pine, and Eureka in Nevada, have been the scenes of successive excitements, and are still productive. In Eureka district, as in the principal districts of Utah, and some of those in Montana, Colorado, New Mexico, and California, argentiferous cerussite and galena are smelted, to produce work lead containing silver. This industry has suddenly grown to large dimensions in the west, as may be seen from the following table of the product of work lead:

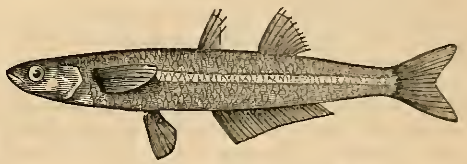
| WHERE PRODUCED. | 1873. Tons. | Gold, silver, and lead, value. | 1874. Tons. | Gold, silver, and lead, value. |
|---|---|---|---|---|
| Nevada........... | 12,812 | $5,043,235 | 11,516 | $3,865,419 |
| Utah............... | 9,566 | 2,901,191 | 15,474 | 4,332,720 |
| California......... | 4,000 | 920,000 | 5,095 | 1,680,000 |
| Montana, Colorado, &c. (estimated).. | 300 | 144,000 | 375 | 180,000 |
| Total........... | 26,678 | $9,008,426 | 32,460 | $10,058,139 |

The Washoe (Comstock) ores and those of Pioche and Owyhee, as well as of many minor districts, are treated by the Washoe process; those of Reese river, Belmont, and Unionville, in Nevada, and of Georgetown, Colorado, receive a preliminary chlorinating roasting. From Colorado and Utah considerable quantities of rich ore are shipped to American and foreign smelting works. Silver mining in Arizona, near the Gila vein, has been rendered unprofitable hitherto by Indian warfare, now apparently ended. The total product of the United States since 1848 is estimated by R. W. Raymond, commissioner of mining statistics, as follows:

| | | | |
|---|---|---|---|
| 1848–1858, inclusive, $50,000 per ann., | $550,000 | 1867............. | $13,500,000 |
| 1859............... | 100,000 | 1868............. | 12,000,000 |
| 1860............... | 150,000 | 1869............. | 13,000,000 |
| 1861............... | 2,000,000 | 1870............. | 16,000,000 |
| 1862............... | 4,500,000 | 1871............. | 22,000,000 |
| 1863............... | 8,500,000 | 1872............. | 25,750,000 |
| 1864............... | 11,000,000 | 1873............. | 36,500,000 |
| 1865............... | 11,250,000 | 1874............. | 38,200,000 |
| 1866............... | 10,000,000 | Total.... ...... | $225,000,000 |

The Atlantic and Mississippi states produce little silver. The amount found with the native copper of Lake Superior is not considerable; but over $2,000,000 has been obtained at the smelting works in Wyandotte, Mich., from the ores of the Silver Islet mine, on the island of that name, on the N. side of Lake Superior. The galena of the Mississippi valley is usually poor in silver, and that of the Atlantic slope is but moderately argentiferous, with an occasional exception, as in the recently discovered deposits near Newburyport, Mass.

**SILVERSIDE, or Silver Fish,** the common name of the small marine spiny-rayed fishes of the family *atherinidæ*, characterized by a protractile mouth, without notch in upper jaw or tubercle in lower, small crowded teeth on the pharyngeals, the first branchial arch with long pectinations, two dorsals most commonly distant, and ventrals behind pectorals; the eyes are very large. In the genus *atherina* (Linn.) the body is elongated, and a broad silvery band runs along each side. The dotted silverside (*A. notata*, Mitch.) is from 3 to 5 in. long, greenish brown with black points on the edges of the scales, and the fins translucent; the dorsals are contiguous, the second reaching as far back as the anal; it is found from New England to South Carolina. It accompanies the smelt in spring and autumn into our riv-



Dotted Silverside (Atherina notata).

ers, and is popularly called capelin. Several other species, about 4 in. long, are found in the southern states and West Indies. More than 20 are described by Cuvier and Valenciennes in vol. x. of the *Histoire naturelle des poissons* (1835); they are much valued as food; they swim in shoals, and are easily taken in nets; the flesh resembles that of the smelt, whence the *A. presbyter* (Cuv.) is often called sand smelt; many species, salted, are sold as sardines, and some are called anchovy.

**SIMART, Pierre Charles.** See p. 879.

**SIMBIRSK. I.** An E. government of European Russia, bordering on Kazan, Samara, Saratov, Penza, and Nizhegorod; area, 19,108 sq. m.; pop. in 1870, 1,205,881. The surface consists generally of a plain, with hills toward the east. The government is drained in the east by the Volga, and in the west by its tributary the Sura. Gypsum, alabaster, limestone, sulphur, and naphtha are found. The soil is fertile, producing grain, hemp, flax, hay, and tobacco. Leather, woollen and linen cloth, tallow, potash, and glass are manufactured. The inhabitants belong chiefly to the Greek church, but there are a few other Christians, and a large number of Mohammedans. **II.** A city, the capital of the government, on the

right bank of the Volga, 105 m. S. S. W. of Kazan, and 435 m. E. S. E. of Moscow; pop. in 1867, 24,607. It stands in the midst of a wide and fertile plain, and contains 16 churches, two convents, and a monument to the historian Karamsin. It has manufactories of soap and candles, and an important trade in grain and fish.

**SIMCOE, Lake.** See ONTARIO, vol. xii., p. 635.

**SIMCOE**, a W. county of Ontario, Canada, bounded N. E. by the Severn river, N. W. by Georgian bay, and S. E. by Lake Simcoe; area, 1,846 sq. m.; pop. in 1871, 64,247, of whom 31,642 were of Irish, 15,020 of English, 11,585 of Scotch, 3,031 of French, and 1,754 of German origin or descent. It is traversed by the Northern railway. Capital, Barrie.

**SIMEON**, the second son of Jacob and Leah. He and his brother Levi were guilty of gross deception and ferocity in their murder of the Shechemites, for which they received their father's curse. Simeon's inheritance as a tribe was not a compact territory, but a small district within the limits of that of Judah, and some tracts in Mount Seir and the district of Gedor. The descendants of Simeon amounted at the exodus to 59,300; but only 22,200 entered the promised land.

**SIMEON, Charles**, an English clergyman, born in Reading, Sept. 24, 1759, died Nov. 13, 1836. He was educated at King's college, Cambridge, and was presented in 1783 to the living of Trinity church, Cambridge, which he held till his death, and was eminently distinguished for devotion to pastoral duty. He published several series of skeleton sermons, forming a commentary upon the whole Bible. They were edited, with his other works, by the Rev. T. H. Horne (21 vols., 1832–'3, and many later editions), and his life has been written by the Rev. William Carus (1847).

**SIMEON STYLITES.** See STYLITES.

**SIMFEROPOL**, or SIMPHEROPOL (Turk. *Akmetchet*), a town of European Russia, capital of the government of Taurida, in the Crimea, on the Salghir, 192 m. S. E. of Odessa, and 37 m. N. E. of Sebastopol; pop. in 1867, 17,797. It stands on a plateau at the foot of lofty hills. The old part of the town, built by the Tartars, is very irregularly laid out, and has a miserable appearance; the new, built by the Russians, has wide straight streets and a spacious square.

**SIMLA**, a town and the summer capital of British India, in a Himalayan district of the same name belonging to the Ambala division of the Punjaub, 170 m. N. of Delhi; lat. 31° 7′ N., lon. 77° 8′ E.; pop. in the height of the season, about 15,000 natives and 1,500 Europeans. It stands on a long and lofty ridge 7,000 ft. above the sea, amid grand forest and mountain scenery, a few miles S. of the Sutlej. The British government purchased the station from the native state of Koonthal about 1822, and founded Simla as a sanitarium. The climate is for the most part cool, exhilarating, and healthful, though there is a heavy rainfall at the time of the S. W. monsoon, and the difficulties of drainage are considerable. Since 1866 the supreme government of India has been administered during the summer months from Simla, whither the viceroy and all the chief officials retire from Calcutta early in the hot season. It is about 60 m. N. E. of the Punjaub and Delhi railway. The town is an organized municipality.

**SIMMONS, Franklin.** See p. 879.

**SIMMS, William Gilmore**, an American author, born in Charleston, S. C., April 17, 1806, died there, June 11, 1870. For some years he was a clerk in a drug store, but at 18 he began the study of law, and in 1827 was admitted to the bar. From 1828 to 1832 he was editor and part proprietor of the "Charleston City Gazette," in which he opposed nullification, thereby reducing himself to poverty. He then devoted himself entirely to literature, living for a time at Hingham, Mass., and afterward principally on a plantation at Midway, S. C., and occasionally holding public offices. His poetical works are: a "Monody on the Death of Charles Cotesworth Pinckney" (1825); "Lyrical and other Poems" and "Early Lays" (1827); "The Vision of Cortes, Cain, and other Poems" (1829); "The Tricolor, or Three Days of Blood in Paris" (1830); "Atalantis, a Story of the Sea" (1833); "Southern Passages and Pictures" (1839); "Donna Anna" (1843); "Grouped Thoughts and Scattered Fancies" (1845); "Lays of the Palmetto" (1848); "Poems, Descriptive, Dramatic, Legendary, and Contemplative" (2 vols., 1854); and "Areytos, or Songs and Ballads of the South" (1860). A collective edition appeared in 1864. He also edited a volume of "War Poetry of the South" (1867). He produced two dramas, "Norman Maurice, or the Man of the People," and "Michael Bonham, or the Fall of Alamo," and adapted Shakespeare's "Timon of Athens" for the stage, with numerous additions of his own. His works of imaginative fiction comprise "The Book of my Lady" (1833); "Carl Werner" (1838); "Confession, or the Blind Heart" (1842); "Castle Dismal" (1845); "The Wigwam and the Cabin" (1845–'6); "Marie de Bernier" (1853); and "Ghost of my Husband" (18mo, 1867). His historical romances are: "The Yemassee" (1835); "Pelayo" (1838); "Count Julian" (1845); "The Damsel of Darien" (1845); "The Lily and the Totem, or the Huguenots in Florida;" "The Maroon and other Tales" (1855); "Vasconcelos" (1857); "The Cazique of Kiawah" (1860); and "Swamp Robbers" (1870). The following are founded on revolutionary events: "The Partisan" (1835); "Mellichampe" (1836); "The Scout," originally published as "The Kinsmen, or the Black Riders of the Congaree" (1841); "Katharine Walton" (1851); "Woodcraft," originally entitled "The Sword and the Distaff;" "The Forayers, a Raid of the Dog Days" (1855), and its sequel "Eutaw" (1856).

Romances of backwoods life: "Guy Rivers" (1834); "Richard Hurdis" (1838); "Border Beagles" (1840); "Beauchampe, or the Kentucky Tragedy" (1842); "Helen Halsey" (1845); "The Golden Christmas, a Chronicle of St. John's, Berkeley" (1852); and "Charlemont, or the Pride of the Village" (1856). A selected edition of his novels appeared in 1865 (17 vols., New York). To history and biography he contributed a "History of South Carolina," "South Carolina in the Revolution" (1854), and lives of Gen. Marion, Capt. John Smith, the chevalier Bayard, and Gen. Greene. Under this head may also be included a "Geography of South Carolina." His remaining works include "Views and Reviews in American Literature;" "Egeria, or Voices of Thought and Counsel for the Woods and Wayside," a collection of aphorisms in prose and verse; "Father Abbot, or the Home Tourist, a Medley;" "Southward Ho!" (1854); "The Morals of Slavery," &c. He also edited with notes the seven dramas ascribed to Shakespeare, but not published among his works, under the title of "A Supplement to Shakespeare's Plays."

**SIMON, Jules** (JULES FRANÇOIS SUISSE-SIMON), a French statesman, born in Lorient, Dec. 31, 1814. After teaching in various places, he lectured in 1838 at the normal school in Paris. In 1839 he succeeded Victor Cousin as professor of philosophy at the Sorbonne, from which post he was removed in 1851 on account of his opposition to the *coup d'état.* In 1848 he entered the constituent assembly, which early in 1849 elected him to the council of state; but not being confirmed by the legislative assembly, he retired in 1850. In 1855 and subsequently he lectured in Belgium on philosophy. He was elected to the legislative body in 1863, and reëlected in 1869 in two departments. He advocated popular education, free trade, the abolition of capital punishment, and the interests of the working classes; and in 1870 he opposed the plebiscitum in favor of Louis Napoleon and the declaration of war against Prussia. After the establishment of the republic (Sept. 4), he became a member of the government for the national defence, as minister of education, religion, and fine arts, and instituted many reforms, the most prominent of which was the obligatory school law. After the capitulation of Paris he went to Bordeaux to put an end to Gambetta's arbitrary proceedings. On Feb. 19, 1871, he became minister of education aud religion under Thiers, with whom he retired, May 24, 1873. He retained his seat in the national assembly, and in 1875 received from the government a pension of 6,000 francs. His works include *Histoire de l'école d'Alexandrie* (2 vols., 1844–'5); *Le devoir* (1854; 6th ed., 1859); *La religion naturelle* (1856; 5th ed., 1859; English translation by I. W. Cole, London, 1857); *La liberté de conscience* (3d ed., 1859); *La liberté* (2 vols., 1859); *L'École* (1864); *Le travail* (1866); *La politique radicale* (1868); *Le libre-échange* (1870); and *Souvenirs du 4 Septembre* (1874; new ed., 1875).

**SIMON, Richard,** a French Biblical critic, born in Dieppe, May 13, 1638, died there, April 11, 1712. He entered the congregation of the Oratory in 1662, was professor of philosophy successively in the college of Juilly and in that of the Oratory in Paris, and in 1671 became involved in a controversy with the Port Royalists by a publication entitled *Fides Ecclesiæ Orientalis.* In 1678 appeared his *Histoire critique du Vieux Testament,* in which he attributes the authorship of the Pentateuch to scribes of the time of Ezra. It was violently assailed by Bossuet and suppressed, and the author excluded from the Oratory. The opinions of Simon have since been adopted by many rationalistic theologians. Among his other works are: *Histoire critique de la créance et des coutumes des nations du Levant* (Amsterdam, 1684); *Histoire critique du texte du Nouveau Testament* (Rotterdam, 1689); *Histoires critiques des principaux commentateurs du Nouveau Testament* (Rotterdam, 1692); and *Nouvelles observations sur le texte et les versions du Nouveau Testament* (Paris, 1695).

**SIMONE DI MARTINO.** See MEMMI.

**SIMONIDES,** a Greek lyric poet, born at Iulis, in the island of Ceos, about 556 B. C., died in Syracuse about 467. His family is said to have held some hereditary office in connection with the worship of Bacchus. After reaching manhood he was invited by Hipparchus to Athens, where, with an interval of a few years, he lived until his 80th year, when he was crowned for his victory in the dithyrambic chorus. His elegies on those who fell at Marathon and Platæa, his epigram on the tombs of the Spartans slain at Thermopylæ, and his odes on the sea fights at Artemisium and Salamis, were celebrated. His latter years were passed in Sicily, at the court of Hiero of Syracuse. He is reproached by Pindar with avarice, having been the first poet on record who wrote for money. He was the most prolific and probably the most popular lyric poet that Greece ever produced. A few fragments are all that remain of his writings, the "Lament of Danaë" being the most celebrated. The best edition is that of Schneidewin, *Simonidis Cei Carminum Reliquiæ* (8vo, Brunswick, 1835).—A writer considered by some his grandson, and known as SIMONIDES THE YOUNGER, was the author of a genealogical work in three books, and of a treatise "On Inventions."—A few fragments remain, including a satire on women, of SIMONIDES THE ELDER, of Amorgos, who flourished about 650 B. C.

**SIMONIN, Louis Laurent,** a French author, born in Marseilles in 1830. He completed his studies at the mining school of St. Étienne, and was employed by the government in mineralogical explorations in the island of Réunion and in Madagascar. He has several times visited the United States, sketches of which he has writ-

ten for the *Revue des Deux Mondes*, and has been since 1865 professor of geology at the central school of architecture. Among his works are: *La richesse minérale de la France* (1865); *L'Étrurie et les Étrusques* (1866); *La vie souterraine* (1867); and *L'Histoire de la terre* (1867).

**SIMON MAGUS**, a magician of the time of the apostles, who by his skill had attained such influence as to be called "the great power of God." While Philip the Evangelist preached in Samaria, in A. D. 36, Simon's followers were converted, and he himself believed and was baptized. Soon after, when Peter and John came to Samaria, to impart to the new converts by means of prayer and the imposition of hands the gifts of the Spirit, Simon, seeing that through the laying on of hands the Holy Ghost was given, offered money to the apostles to impart to him this power. He was sternly rebuked by Peter, and appears no longer in connection with the rising Christian church. The statements of the ecclesiastical writers respecting his further life are contradictory; but it seems certain that he travelled through many countries to give exhibitions of his magic power, and that finally he settled at Rome, where, according to the testimony of Eusebius (with which a statement of Suetonius agrees), he met his death in an aëronautic attempt. About the middle of the 2d century his followers were still very numerous, and Eusebius in the 4th century represents the Simonians as a powerful sect. They early split into several parties, of which the Menandrians and the Dositheans were the most important. (See DOSITHEANS.) Simon wrote several works, the remaining fragments of which are contained in Grabe's *Spicilegium*, vol. i.

**SIMONOSEKI.** See SHIMONOSEKI.

**SIMOOM** (Arabic, from *samma*, to poison), or **Samiel** (Turkish, *sam*, poison, and *yel*, wind), a hot, dry wind common in Syria, Arabia, and India. It comes from the deserts, and is characterized by its excessive heat and suffocating effects, which are sometimes fatal to animal life. It never lasts over an hour, though it sometimes returns for several successive days. During its prevalence the inhabitants of towns and villages shut themselves up in their houses, and those in the deserts in their tents or in pits. The parching heat is derived from the sands, which are whirled up from the earth by the advancing wind, and the whole air is filled with an extremely subtle and penetrating dust. When the wind blows in squalls, death is often very suddenly produced by actual suffocation, and is followed by hæmorrhage at the nose and mouth. Persons exposed to it protect themselves by stopping the mouth and nose with handkerchiefs, and the camels instinctively bury their noses in the sand. The *khamsin* of Egypt and the *harmattan* of Guinea and Senegambia are winds similar to the simoom in their effects, but are of longer duration and more regular in the periods of their prevalence. In India the simoom of the deserts of Cutchee and Upper Sinde is sudden and mysterious in its appearance, invisible and singularly fatal. It usually occurs in June and July, by night as well as by day, sometimes preceded by a cold current of air. Its course is straight and well defined on a narrow path. It is not accompanied by dust, thunder, or lightning, but has a decided sulphurous odor.

**SIMPLON.** See ALPS, vol. i., p. 354.

**SIMPSON.** I. A S. county of Mississippi, bounded W. by Pearl river, and intersected by Strong river; area, about 625 sq. m.; pop. in 1870, 5,718, of whom 1,711 were colored. The soil is sandy, and there are extensive pine woods. The chief productions in 1870 were 72,832 bushels of Indian corn, 15,420 of oats, 29,520 of sweet potatoes, 2,134 bales of cotton, 8,240 lbs. of rice, 5,797 of wool, and 28,860 of butter. There were 871 horses, 1,631 milch cows, 1,237 working oxen, 2,713 other cattle, 4,211 sheep, and 7,793 swine. Capital, Westville. II. A S. county of Kentucky, bordering on Tennessee and drained by tributaries of Big Barren river and by Red river; area, 375 sq. m.; pop. in 1870, 9,573, of whom 2,167 were colored. The surface is level and the soil very fertile. The chief productions in 1870 were 107,242 bushels of wheat, 402,379 of Indian corn, 73,682 of oats, 1,072,401 lbs. of tobacco, 14,572 of wool, 72,004 of butter, and 8,806 gallons of sorghum molasses. There were 2,091 horses, 1,311 milch cows, 1,928 other cattle, 7,410 sheep, and 13,951 swine. The Louisville, Nashville, and Great Southern railroad passes through the capital, Franklin.

**SIMPSON, Sir James Young**, a Scottish physician, born at Bathgate, Linlithgowshire, June 7, 1811, died in Edinburgh, May 6, 1870. He was educated at the university of Edinburgh, where in 1832 he received his degree of M. D. In 1836, as assistant to Prof. Thomson, he delivered a course of pathological lectures; and in 1840 he was elected professor of midwifery in the university of Edinburgh. He was the first to apply the new discovery of anæsthesia to midwifery practice, which he did Jan. 19, 1847. He subsequently discovered the anæsthetical properties of chloroform, which in midwifery practice he regarded as more manageable and powerful, more agreeable to inhale, and less exciting than ether, and as giving greater control over the superinduction of the anæsthetic state. (See ANÆSTHETICS, and CHLOROFORM.) In 1849 he was elected president of the Edinburgh royal college of physicians, in 1852 president of the medico-chirurgical society, and in 1853 foreign associate of the French academy of medicine; and in 1856 he received from the French academy of sciences the Montyon prize of 2,000 francs "in consideration of his services to humanity by the introduction of anæsthesia into the practice of midwifery, and the discovery of the anæsthetic properties of chloroform." He

was very celebrated as a practitioner. Among his works are: "Homœopathy" (3d ed., Edinburgh, 1853; Philadelphia, 1854); "Obstetric Memoirs and Contributions," including his writings on anæsthesia (2 vols., Edinburgh and Philadelphia, 1855–'6); "Acupressure" (1864); and essays on ancient rock sculpturings in Great Britain and other archæological subjects. In 1871 appeared new editions and collections of his writings under the titles "Selected Obstetrical Works," "Anæsthesia and Hospitalism," and "Clinical Lectures on the Diseases of Women;" and in 1872, "Archæological Essays." He was created a baronet in 1866.—See "Memoir," by J. Duns, D. D. (Edinburgh, 1873).

**SIMPSON, Mathew,** an American clergyman, born in Ohio, June 10, 1810. He graduated at Alleghany college, Meadville, Pa., in 1832, and received the degree of M. D. in 1833, but in the same year entered the ministry of the Methodist Episcopal church. In 1837 he was elected professor of natural sciences in Alleghany college, and two years later president of Indiana Asbury university, at Greencastle, Ind. In 1848 he was appointed editor of the "Western Christian Advocate," Cincinnati, and in 1852 was elected bishop. He has been especially active in the promotion of educational and missionary enterprises. During the civil war he was employed on important commissions, and delivered many addresses in support of the Union. In 1863–'4 he made an extended tour, studying the missionary status and wants of his church in Syria, European Turkey, Switzerland, Germany, and Scandinavia. He has been three times a member of general conference, and a fraternal delegate to the British Wesleyan conference and to various ecclesiastical bodies. In 1875 he was appointed to visit again the mission conferences in Europe. His present residence (1876) is Philadelphia.

**SIMPSON, Thomas,** an English mathematician, born in Market-Bosworth, Leicestershire, Aug. 20, 1710, died there, May 14, 1761. He was a weaver, and while young married a widow 50 years of age, having two children, both older than himself; but the family lived in harmony, and Simpson employed his evenings in study, especially of mathematics, and in keeping a school. In 1733 he went to Derby, and in 1735 or 1736 to London, where he soon established himself as a teacher of mathematics, while employing his leisure hours in researches into the higher branches of science. In 1743 he was appointed professor of mathematics in the royal military academy at Woolwich, a post which he filled until the beginning of 1761, when with impaired mental faculties and disordered health he retired to his native town. In 1746 he was elected a fellow of the royal society. He published works on fluxions, the laws of chance, annuities and reversions, algebra, geometry, trigonometry, logarithms, &c.; but his most valuable publication was a volume of "Miscellaneous Tracts" (1754), consisting of four papers on pure mathematics and four on physical astronomy.

**SIMROCK, Karl,** a German author, born in Bonn, Aug. 28, 1802, died July 18, 1876. He studied law at Bonn and Berlin, and was employed in the judicial service from 1823 to 1830, when he was removed on account of his poem on the July revolution in France. In 1850 he was appointed professor of ancient German literature at Bonn. He became famous by his translations of the *Nibelungenlied* (1827; 32d ed., 1876) and many other early German and Scandinavian poems, including the Edda (1851; 4th ed., 1871), and a modernized German version of Hartmann von der Aue's *Der arme Heinrich* (2d enlarged ed., 1875). One of his most celebrated original poems is *Wieland der Schmied* (1835; 3d ed., 1851). In 1867 appeared his translation of Shakespeare's poems, and among his other works are: *Die Quellen des Shakespeare in Novellen, Märchen und Sagen* (1831; new ed., 1872); *Das malerische und romantische Rheinland* (4th ed., 1865); *Handbuch der deutschen Mythologie* (new ed., 1869); and *Faust* (new ed., 1873).

**SIMS, James Marion,** an American surgeon, born in Lancaster district, S. C., Jan. 25, 1813. He graduated at the South Carolina college in 1832, and studied medicine in Charleston and at the Jefferson medical college, Philadelphia. In 1836 he settled at Montgomery, Ala., and soon became widely known as a skilful operator in general surgery. About 1845 his attention was directed to the treatment of vesico-vaginal fistula, hitherto deemed incurable, and he established for the diseases peculiar to women a private hospital, which he supported for four years at his own expense. A protracted series of experiments were crowned with success by the substitution of sutures of silver wire for silken and other sutures, and he afterward extended the use of metallic sutures into every department of general surgery. In 1853 he removed to New York, where through his efforts a temporary and afterward a permanent woman's hospital was established under his charge. In 1861 and 1864 Dr. Sims visited Europe, and in 1870 he organized in Paris the Anglo-American ambulance corps. He has published "Silver Sutures in Surgery" (8vo, New York, 1858) and "Clinical Notes on Uterine Surgery" (London and New York, 1866; translated into French and German).

**SINAI,** a group of mountains in Arabia Petræa, in the southern portion of the peninsula of the same name, which projects between the two forks of the Red sea, the gulf of Suez separating it from Egypt on the west, and the gulf of Akabah from Arabia on the east. The peninsula of Sinai is triangular, about 140 m. in length from N. to S., and nearly the same in breadth at its widest portion. The northern portion is an arid and desert plain, with sand hills and mountains of small elevation; S. of

lat. 29° 20′ N. it rises into several ranges of mountains. There are numerous peaks, varying from 1,000 to over 9,000 ft. above the sea, divided by deep wadys or narrow sand valleys, except in the case of the Wady er-Rahah and the Wady esh-Sheikh, two wide valleys, the former separating the Jebel Ghubsheh from the Jebel el-Fureiah, the latter the Jebel ed-Deir from the same mountain summit, and the two uniting in a wide plain in front of the Ras Sufsafeh, the abrupt northern termination of the Jebel Musa or Mount of Moses, the traditional Sinai. The summits of most historic and Biblical interest, beginning at the S. point of the peninsula, are the Jebel et-Turfa, a long low mountain sloping on either side to the sea and terminating in the low promontory of Ras Mohammed; the Jebel et-Tur, a series of summits of somewhat greater height surrounding the Jebel Musa, and separated from it by narrow steep wadys; the Jebel Katherin or Catarina, S. S. W. of the Jebel Musa, and forming the termination of the range known as the Jebel Humr; and the Jebel Musa, an isolated summit, with a plateau about 3½ m. long and nearly 1 m. in width, gradually descending toward the north. The S. point, from which until recently it was supposed that Israel received the law, is 9,274 ft. high, but is still overlooked by the higher peaks of Jebel Katherin and the Tinieh ridges, and the wadys in front of it are so narrow that the immense congregation could not have seen the summit of the mountain. To avoid this difficulty, Burckhardt, and after him Lepsius and some others, have attempted to demonstrate that the Jebel Serbal, which was sometimes called "the mount of God," lying some distance W. of the Jebel Musa, and having a valley of considerable extent, the Wady Feiran, at its N. face, is the true Sinai, with which Horeb, the Scriptural "mount of God," is so closely connected as to appear identical. But it seems that tradition rather points to that mountain as the site of Rephidim. The N. extremity of the Jebel Musa, called by the monks Horeb, and at its highest point Ras Sufsafeh, or "the mountain of the Willow," is supposed by Robinson and others to be the Sinai from which the law was dispensed. It is divided from the Jebel ed-Deir on the east by a narrow valley, on one of the slopes of which the convent of St. Catharine is situated; but from the termination of the Ras Sufsafeh there open out the two wide valleys already mentioned, the Wady er-Rahah and the Wady esh-Sheikh, the only ones in the Sinaitic peninsula capable of containing the vast host of Israel. Opposite, in a succession of terraces, rises the Jebel Sona, the termination of the Fureiah ridge. The Ras Sufsafeh is 6,541 ft. high, and about 800 ft. lower than Jebel Musa, but it is the commanding point of the amphitheatre upon which it opens. There are three churches and three chapels on this mountain, all small and in a ruinous condition; and on the W. side, 2,000 ft below the summit, is the monastery, celebrated alike for its antiquity, its manuscript treasures, and the hospitality of its monks. The Arabs point out in the Wady er-Rahah the "hill of Aaron," the "pit of Korah," and the place where the molten calf was made. Carl Ritter suggested that Serbal was known before the giving of the law as "the mount of God," and that Pharaoh probably understood it as the mount to which they were going to sacrifice. Its distance and location well agree with this theory, for which early traditions give much ground. Dr. Beke supposed the ancient Mt. Sinai to be a mountain E. of the meridian of the gulf of Akabah and valley of the Jordan. He was sent in 1874 on an expedition to establish his hypothesis. Advancing N. from the town of Akabah, by the route E. of the Jebel esh-Sherah, through the Wady el-Ithm, he found what answered his expectations in Mt. Baghir, also called Jebel en-Nur, or "mountain of Light." He bases his identification on an argument that, according to Scripture, the land of Midian, to which Moses fled, formed part of the east country, *i. e.*, E. of the Jordan, and that he conducted the children of Israel there; and hence it follows that he crossed with them the gulf of Akabah, and not the present gulf of Suez. Dr. Brugsch also has recently advanced a theory which takes the Scriptural Mt. Sinai out of the so-called Sinaitic peninsula. He is of opinion that the Israelites marched along the Mediterranean coast, and that the disaster of the Egyptians occurred on the narrow strip of land which separates the sea from the Serbonian lake. There are many difficulties in the way of harmonizing these views with the details of the Biblical narrative. As to Horeb in Scriptures, it seems probable that the whole desert of Sinai was so called (Heb. *'hareb*, parched), and that the name was also specially applied to Sinai itself. From a period certainly not later than the first half of the 3d century, the caves of Jebel Musa, the traditional Mt. Sinai, were a refuge of persecuted Christians; in the 4th century they were the resort of anchorites and ascetics, and these were repeatedly attacked and murdered by the Arabs. In the 5th and 6th centuries the monks of Mt. Sinai were represented in the great councils of the eastern church. During the period in which the Mohammedan power was at its height, the monks lived in fear and disquiet, often threatened and occasionally attacked. From the crusades onward they have held more peaceful possession, but with greatly diminished numbers and influence.—See Robinson, "Biblical Researches" (3 vols., Boston, 1856); Stanley, "Sinai and Palestine" (London, 1858); Wilson and Palmer, "Ordnance Survey of the Peninsula of Sinai" (London, 1872); Palmer, "The Desert of the Exodus" (London and New York, 1872); Ebers, *Durch Gosen zum Sinai* (Leipsic, 1872); and Maughan, "The Alps of Arabia" (London, 1874).

**SINALOA.** **I.** A N. W. state of Mexico, bounded N. by Sonora, E. by Chihuahua and Durango, S. by Jalisco, and W. by the Pacific and the gulf of California; area, 25,927 sq. m.; pop. in 1869, 163,095. The entire eastern portion is mountainous, being traversed by a branch of the Sierra Madre; while the western comprises extensive plains gradually declining toward the coast, which is generally low. The coast is indented by bays, the largest of which is that of Navachiste, and presents several harbors, such as Mazatlan, Angeles, Altata, Tamazulla, Popolobampo, and Navachiste, none of which are very commodious. The chief rivers are the Fuerte and Cañas, forming respectively the northern and southern boundaries, Sinaloa, and Culiacan; some of these, with their affluents, periodically overflow their banks, fertilizing the surrounding country. The mineral productions include gold, silver, platinum, copper, iron, lead, and sulphur; but mines of the first two only are worked, the average annual yield being $500,000, of which seven eighths is silver. The climate is excessively hot, and in many parts unhealthful, particularly in the south and in the coast region. The soil is for the most part fertile; the principal agricultural products are coffee, rice, and sugar cane. Many of the tropical fruits, particularly guavas and bananas, are very abundant, though the last are so extensively consumed as to be imported in immense quantities. The chief occupations are agriculture and mining, the manufacture of castor oil and the liquor called *mezcal*, and pearl and tortoise fisheries along the coasts. Brazil wood, pearls, gold, and silver are exported in large quantities. Sinaloa is divided into the districts of Rosario, Concordia, Mazatlan, San Ignacio, Cosalá, Culiacan, Mocorito, Sinaloa and Fuerte. The capital is Culiacan, and the chief port Mazatlan. **II.** An inland town of the preceding state, on the right bank of a river of the same name, in the midst of a gold-mining district, 220 m. N. N. W. of Mazatlan; pop. about 9,000. It has good houses, a church, and a school; and the inhabitants are chiefly engaged in mining. It was the capital of the old province of Sinaloa.

**SINCLAIR.** **I.** Sir **John,** a Scottish agriculturist, born at Thurso castle, Caithness, May 10, 1754, died Dec. 21, 1835. From 1780 to 1810 he was a member of parliament. He had an estate of 100,000 acres in Caithness, and devoted himself to the development of agriculture, the improvement of wool, and the revival of coast fisheries; and he built up the village of Thurso into a flourishing port. In 1786 he was created a baronet. The board of agriculture was established by act of parliament in 1793 mainly through his efforts, and he was its first president. He was the author of numerous volumes and pamphlets on agriculture, finances, and other subjects, and also published "Observations on the Scottish Dialect" (1782); "History of the Public Revenue of the British Empire" (3 vols., 1785-'9); "Statistical Account of Scotland" (21 vols., 1791-'9); and "Code of Health and Longevity" (4 vols., 1807). **II.** Sir **George,** a Scottish author, son of the preceding, born in Edinburgh, Oct. 23, 1790, died Oct. 9, 1868. For several years he represented Caithness in parliament. He published "Selections from the Correspondence on the Scottish Church Question" (1842); "Letters to the Protestants of Scotland" (1852); "Miscellaneous Thoughts on Popery, Prelacy, and Presbyterianism" (1853); "Two Hundred Years of Popery in France, 1515-1715" (1853); and "Popery in the First Century" (1855). His life has been written by James Grant (London, 1869). **III. John,** a Scottish clergyman, brother of the preceding, born Aug. 20, 1797, died in London, May 22, 1875. After graduating at Pembroke college, Oxford, he took orders, and in 1843 was made archdeacon of Middlesex. In 1853 he visited the United States in behalf of the society for the propagation of the gospel. He published a life of his father (2 vols., Edinburgh, 1837), and "Sketches of Old Times and Distant Places" (London, 1875). **IV. Catharine,** a Scottish authoress, sister of the preceding, born in Edinburgh, April 17, 1800, died in London, Aug. 6, 1864. She was her father's secretary in the latter part of his life. Besides numerous books for children and miscellaneous works, she published several novels, including "Modern Accomplishments" (1835); "Holiday House" (1839); "Modern Flirtations" (1841); "Jane Bouverie" (1845); "Lord and Lady Harcourt" (1850); "Beatrice" (1852); and "Torchester Abbey, or Cross Purposes" (1855).

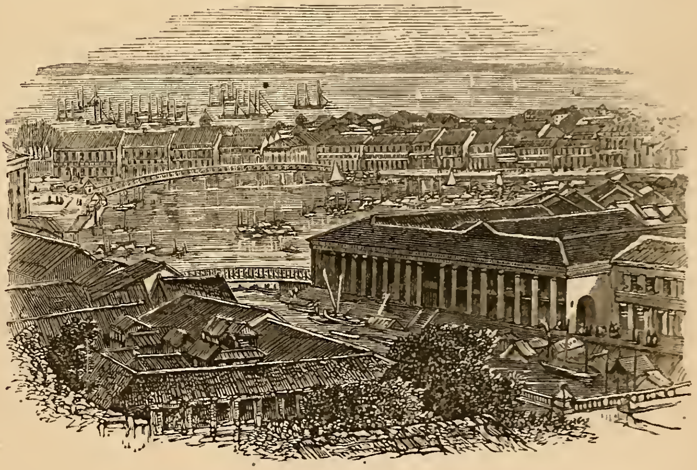
**SINDE, Scinde,** or **Sindh,** an administrative division or commissionership of the province of Bombay in British India, bounded N. by Beloochistan and the Punjaub, E. by Rajpootana, S. by the great western Runn of Cutch and the Indian ocean, and W. by the Indian ocean and Beloochistan; area, 54,403 sq. m.; pop. in 1872, 1,730,323. The sea coast, 150 m. in length, is low and swampy, except at its N. extremity, and at high water the shore is overflowed for a considerable distance inland. The interior is a vast and arid plain of sand and shingle, traversed throughout its entire length by the river Indus, with a belt of fertility on each side. Sinde and the Indus bear a striking resemblance to Egypt and the Nile. (See Indus.) The Hala hills extend along the W. frontier, but the most elevated points do not exceed 1,500 ft. above the sea. The E. part of Sinde is to a great extent desert, and covered with shifting sand hills, but affords some pasturage, more particularly for camels. In the north there are extensive tracts of jungle, now utilized as government fuel reserves. Upper Sinde and Lower Sinde are the respective designations of the northern and southern portions of the division, which comprises politically the collectorates of Kurrachee and Shikarpoor on

the W. side of the Indus, the collectorate of Hydrabad and the frontier district of Upper Sinde, bordering the river on the east, the native state of Khyerpoor between them, and the political superintendency of Thur and Parkur in the S. E. corner. The chief towns are Kurrachee, the seaport of the Indus, Hydrabad, the capital, Sukkur, Shikarpoor, and Larkhana, all organized municipalities except the first. The climate is hot, subject to sudden and great changes of temperature, and remarkably dry. Its aridity is due to the fact that the S. W. monsoon does not blow over Sinde, where the normal yearly rainfall is less than 15 inches, although the dews are exceedingly heavy. At Hydrabad the mean temperature of the six hottest months is 98°, but in winter frost is not unknown. In December, January, and February, a temperature of 32° F. at dawn is not unfrequently followed by a midday temperature of from 75° to 86° in the shade, at Kurrachee. Upper Sinde is tolerably healthful, and many of the natives attain a great age; but in the lower country, particularly toward the mouth of the Indus, there is much malaria and fever. Salt is the chief mineral product of the country, and alum, which is used to clarify the water of the Indus for drinking, occurs in considerable quantities. The soil of the delta of the Indus is a light clay mixed with sand, and the whole valley is fertilized by the annual inundation of the river; but away from the streams the surface is for the most part a sandy desert, or consists of vast tracts overspread with acacia-like trees, salvadora, and a leafless caper shrub. The forests of Sinde comprise the babul (*acacia Arabica*), the tamarisk, and the Euphrates poplar, and border the Indus at various points, having formerly been the favorite hunting grounds of the ameers; they cover an area of 350,000 acres. Irrigation is essential to cultivation, and the canals for that purpose are kept up at great expense, owing to the accumulation of silt. The only perennial canal in the division is above Sukkur, and is 24 m. long; all the others are inundation canals. Cotton is now grown experimentally, and sugar cane and tobacco succeed well, besides rice, wheat, barley, mustard, and the other common crops of such a climate; but the methods of agriculture are inferior and carelessly applied. The zemindary land revenue system prevails, under which the land is cultivated on shares. The fauna of Sinde is remarkable for number and variety. Tigers and leopards, hyænas and jackals, buffaloes, hog-deer, antelopes, and wild boars are prominent among the mammals. Among the very numerous species of birds are two eagles, bustards, falcons, partridges, quails, snipe, cormorants, herons, flamingoes, pelicans, and wild ducks of many sorts. The fresh waters yield the gavial, a so-called river porpoise which weighs upward of 200 lbs., and many varieties of fish; while pearl oysters are abundant along the coast. The common insects are locusts, ants, mosquitoes, and black flies.—The Sindians are tall, well made, and handsome, and the women are remarkably good-looking. They are made up of mixed races, principally Jats and Beloochees, the proportion of Mohammedans to other sects in the population being as four to one. The people are described as idle, exceedingly immoral, ignorant, and bigoted. Wool raising is an important industry. Some manufactures are carried on in the principal towns, and the people are very ingenious workmen. Coarse silk goods are made from materials imported from Persia and China, and a peculiarly soft and durable leather, several different kinds of cloth, earthenware, and cutlery are manufactured. The foreign trade in 1872–'3 was worth nearly £1,000,000, comprising exports valued at £657,994, and imports worth £324,250; and the coast trade was valued at £2,640,561. Some traffic is carried on with Cabool through the Bolan pass, but in Lower Sinde there are no regular highways, as the constantly shifting sand renders it difficult to maintain them. A railroad connects Kurrachee and Hydrabad, and the Indus valley line, which is to unite it with the railway system of India, is in process of construction. The government of Sinde is administered by a special commissioner.—Khyerpoor, the only native state in the division, extends 120 m. in length and 70 m. in width, between the Indus on the west and the Rajpoot state of Jessulmeer on the east, and is a great alluvial plain watered by six canals and having an area of 6,109 sq. m.—When Alexander the Great invaded India, Sinde was ruled by Hindoo princes, who had extended their conquests over all the countries lying between the Indus and the Ganges. Little is known of Sinde from that time till about A. D. 715, when it was conquered by a Mohammedan army sent from Bassorah; but these invaders did not long hold it. It was subsequently governed by a Rajpoot tribe for nearly three centuries, and was then conquered by Mahmoud of Ghuzni, whose successors held it until they were overthrown by the house of Ghore. About 1225 it fell under the dominion of the rulers of Delhi, who held it for upward of a century. They were succeeded by native princes, and about 1520 the country became subject to Shah Beg Argoon of Candahar. In 1592 it was incorporated with the Mogul empire under Akbar, in 1739 with the Persian under Nadir Shah, after whose death it reverted to the former, and in 1756 passed by dowry to the ruler of Cabool, remaining a nominal dependency of Afghanistan, though governed by native princes, till 1786, when a Belooche chief named Meer Futteh Ali obtained supremacy and divided the country into three independent states, each under several rulers known as ameers. Under these chiefs the government was a military despotism, and the relations between them and the English East India company were never very friendly.

About the beginning of the present century the company's agent was violently expelled, and a large amount of property in his custody confiscated. Subsequently several treaties were made; and in 1838, to facilitate the operations of its army in the contemplated Afghan war, the company extorted concessions from the ameers by which Sinde was made virtually one of its dependencies. The disasters of the British in Afghanistan having encouraged the ameers to commit hostile acts, a military force was sent thither under Sir Charles Napier, who, after concluding a treaty with the ameers of Lower Sinde, found himself compelled to take the field; the result was the brilliant victory of Meeanee (Feb. 17, 1843), the rapid conquest of the country, and the establishment of British authority. (See NAPIER, Sir CHARLES JAMES.) The rajah of Khyerpoor was allowed to retain his possessions, on account of his fidelity to the English. Sinde was constituted a commissionership in 1843.

**SINDIA, Family of.** See GWALIOR.

**SINGAPORE. I.** A province of the British colony of the Straits Settlements, consisting of the island of Singapore, and about 50 islets S. and E. of it in the strait of Singapore, lying between lat. 1° 8′ and 1° 32′ N., and lon. 103° 30′ and 104° 10′ E.; pop. in 1871, 97,111. The island of Singapore lies off the S. extremity of the Malay peninsula, from which it is separated by a strait about 40 m. long and ½ to 2 m. wide; it is about 25 m. long from E. to W., and 12 m. wide; area, 224 sq. m. On the coast are swampy tracts covered with mangrove trees, but inland are many small hills, from 100 to 500 ft. high. Iron ore abounds. Much of the soil is sterile, but in the lowlands it is richer. There are a few rivulets. Nutmegs, cloves, ginger, pepper, gambir, tapioca, and sugar cane are raised. The thermometer ranges from 71° to 89°, and the climate is healthful. Showers are frequent, and in 1871 the total rainfall was 120·4 inches. Tigers cross the strait to the island, and are said to carry off, on the average, a Chinaman every day. Of the inhabitants of Singapore in 1871, 74,351 were males and 22,763 females; 54,098 Chinese, 19,250 Malays, 9,297 Klings, 1,329 Europeans, 2,164 Eurasians, and the remainder natives of other parts of the East Indies. Malay is the prevailing language. **II.** A city, capital of the Straits Settlements, on the S. side of the island of Singapore, in lat. 1° 16′ 13″ N., lon. 103° 53′ 15″ E.; pop. about 90,000. It is on a low plain fronting the harbor, with hills in the rear, and is intersected by a salt-water creek called the Singapore river. On the W. side is the Chinese quarter, which contains also the great mercantile warehouses and counting houses. On the E. side are the official buildings, churches, hotels, and many of the European residences; and still further E. is the Malay quarter. Behind the Chinese quarter, on Pearl hill, is a fortress which commands it, and on another elevation, back of the European quarter, is the government house, a fine building of cut stone. Many neighboring hills are occupied by country houses. Near the shore are ample parade grounds and drives. The botanical garden has a splendid collection of tropical plants. Among the public buildings are the Singapore institution for the study of the languages of the East, which



Singapore.

contains a museum, library, and reading room; a prison, in which are generally confined about 2,000 criminals, mostly Hindoos, who are employed on government works; Protestant and Roman Catholic churches, a splendid Chinese temple, and a Mohammedan mosque. There are two mission schools, attended chiefly by Chinese, Malays, and Eurasians. The Chinese have also private schools. The port of Singapore, which is divided into two by a tongue of land, is capacious, and the water is deep enough for the largest vessels. The harbors are provided with every facility for an extensive commerce, and for fitting out and repairing ships. Singapore is a free port. Vessels pay three cents a ton light dues on entering and leaving. In consequence of its geographical position, it is the entrepot of the commerce of S. Asia and the Indian archipelago, and is resorted to by vessels of all nations. The entrances in 1872 were 1,665, tonnage 918,652; 729 were

steamers, tonnage 612,929. The total value of imports was $43,415,383; exports, $39,020,-121. During the year ending Sept. 30, 1874, 29 United States vessels entered; the total value of the exports to the United States for the same period was $3,750,831. The exports are tin, gambir, pepper, rattans and Malacca canes, coffee, nutmegs, tapioca, sago, caoutchouc, gutta percha, sapan wood, buffalo hides, and gums.—The city of Singapura ("lion's town"), capital of a Malayan kingdom, occupied the site of Singapore in the 12th century. In the 13th century it was captured by a king of Java, when the royal residence was removed to Malacca, and it gradually fell into decay; and in 1819, when the British built a factory on the site, the whole island had only 150 inhabitants. In 1824 the sultan of Johore, in consideration of $60,000 and a life annuity of $24,000, transferred the sovereignty and fee simple of the island, and all the seas and islands within 10 geographical miles, to the British. (See Straits Settlements.)

**SING SING,** a village in the township of Ossining, Westchester co., New York, beautifully situated on high ground on the E. bank of the Hudson river, at its widest part, called Tappan bay, 30 m. above New York; pop. in 1875, 6,500. There are several manufactories, the principal being two of files, one of lawn mowers, two of carriages, one of Brandreth pills, and one of porous plasters. The village contains a national bank, a savings bank, a public school, a Roman Catholic school, a female seminary, a school for preparing boys for West Point, three military schools, 12 private schools, two weekly newspapers, and six churches. It is the seat of one of the state prisons. The male division was erected by convicts, the first draft of whom, from Auburn state prison, began work in May, 1825. It contains 1,200 cells, is 484 ft. long by 44 ft. wide, and six stories high, with ranges of workshops running at right angles, 40 ft. wide and two and three stories high. The female division, with 120 cells, is on the E. side of the male division, and under separate management; it was begun in 1835. Both buildings are of white marble. (See New York, vol. xii., p. 367.)

**SINIGAGLIA** (anc. *Sena Gallica*), a town of central Italy, in the province and 18 m. N. W. of the city of Ancona, at the mouth of the Misa in the Adriatic; pop. in 1872, 22,197. It is the seat of a bishop, and has a beautiful cathedral. The ramparts are protected by a citadel. The port admits only small craft. The annual fair, July 20 to Aug. 8, at which large transactions are made in silk, is of great antiquity. The town was plundered by the troops of Pompey in 82 B. C. Under the exarchs of Ravenna it was for some time one of the cities of the Pentapolis, but afterward fell into decay. It is the birthplace of Pius IX.

**SINOPE** (Turk. *Sinub*), a fortified seaport town of Asia Minor, in the Turkish vilayet of Kastamuni, on the S. shore of the Black sea, 325 m. E. N. E. of Constantinople; pop. about 10,000. It stands on an isthmus which connects the mainland with a high rocky peninsula called Cape Sinope, forming on its S. E. side a roadstead, which is the best anchorage on that shore. The town has an arsenal and the only ship yard in Turkey except that at Constantinople, and many Turkish war vessels are built there. There is a massive castle erected in the time of the Greek emperors, and new fortifications are nearly completed (1876). It is a coal depot for steamers between Constantinople and Trebizond. Oak timber is largely exported.—Sinope became important after its second colonization from Miletus, about 630 B. C., and continued independent till 183, when it was captured by Pharnaces, king of Pontus, of which country it became the capital. It was much ornamented and improved by Mithridates the Great. Having been conquered by the Romans, it was made a colony by Cæsar. It was taken by the Turks in 1461. In the Crimean war the Turkish fleet, with the exception of one steamer which escaped, was destroyed here by the Russian fleet under Nakhimoff, with a loss of about 4,000 men, Nov. 30, 1853. The town was bombarded and suffered very severely.

**SINTO,** or **Shinto.** See Japan, vol. ix., pp. 537 and 562.

**SIOOT,** or **Osioot** (anc. *Lycopolis*), a city of Egypt, capital of a province of the same name, and residence of the governor of Upper Egypt, near the left bank of the Nile, about 250 m. above Cairo, under a hilly ridge of sand cliffs, which have been extensively excavated; pop. about 25,000. A magnificent embankment studded with trees leads to the town, which has several beautiful mosques and good bazaars; but the streets are narrow and unpaved, and most of the houses are mere hovels. There are successful schools under the care of American missionaries, and British and American consular agents. Sioot was formerly much frequented by caravans from the interior. The most important manufacture is that of pipe bowls. There are ruins here of a Roman amphitheatre, vast rock tombs of the 12th dynasty, and ancient alabaster quarries in the opposite range of hills. The city was once devoted to the worship of the wolf, or of the deity to which that animal was sacred, from which its ancient Greek name is derived.

**SIOUX,** or **Dakotas,** a tribe of American Indians, dwelling near the head waters of the Mississippi when first known by the whites. In 1640 the Algonquins informed the French of them as the Nadowessioux, whence they came to be called Sioux. In 1660, or soon after, the Chippewas and Hurons began a war with them, which continued into this century. In 1680 Duluth set up the French standard in their country at Izatys near the St. Peters. In the next year he rescued Hennepin from them. Nicolas Perrot, having entered their

domain in 1685, took formal possession for France in 1689, erecting a breastwork near Lake Pepin. In 1689–'99 Le Sueur visited the Dakotas, and describes them as divided into seven eastern and nine western tribes. They joined the Foxes against the French, and in war with the Chippewas many were forced down the Mississippi, and, driving other Indians from the buffalo plains, took possession of them. Several bands wandered into the plains of the Missouri. Some remained at or near the St. Peter's. The English agents secured the services of the Sioux in the war of 1812; but most of the bands soon made peace. The treaties then made were renewed in 1825 by the Tetons, Yanktons, and Yanktonais, Siounc, Ogallalas, and Oncpapas. The nation, estimated in 1822 at 5,000 on the St. Peter's and 7,750 on the Missouri, comprised the Aldewakantonwans, or Spirit Lake village; the Wahpetonwans, or village in the Leaves; the Sisitowans, or village of the Marsh, called also Isantis; the Yanktonwans, or End villages; and the Tetonwans, or Prairie village, which includes the Ogallala and Oncpapa bands. Their territory extended from the Mississippi to the Black hills, and from Devil's lake to the mouth of the Big Sioux. On Sept. 29, 1837, the Dakotas ceded to the United States, for $300,000 and some minor payments, all their lands east of the Mississippi. The American board began missions among the Wahpetonwans near Fort Snelling in 1835, and the Methodists in 1836. Schools were introduced, and elementary books printed in the language. In 1851 the nation ceded to the United States all their land east of a line from Otter Tail lake through Lake Traverse to the junction of the Big Sioux and the Missouri, retaining a reservation 20 by 140 m.; 35,000,000 acres were thus acquired for $3,000,000. The government's neglect to carry out the provisions of these treaties caused bitter feelings, and in 1854 Lieut. Grattan, in the attempt to arrest a Dakota, attacked a village and was cut off with his whole party. A series of hostilities by some of the Sioux ensued; but Gen. Harney defeated them on Little Blue Water, Sept. 3, 1855, and a general council at Fort Pierce consented to a treaty of peace. But in July, 1857, the band of Inkpadutas massacred 47 whites near Spirit lake, Iowa, and murders were committed elsewhere. Five whites were killed at Acton, Minnesota, Aug. 17, 1862. Enraged by the failure of annuities and the frauds practised on them, the Sioux then made a general uprising and killed nearly 1,000 settlers. New Ulm, a town of 1,500 people, was abandoned and almost destroyed.. Fort Ridgely was besieged, and was saved with difficulty. The Sioux of the Missouri and the plains also became hostile, and were reduced by Gen. Sibley of Minnesota and Gen. Sully of the United States army. After a severe struggle a number of captive white women and children were rescued, and many Indians captured and sent to Davenport. Of more than 1,000 Indians held captive, many were tried and condemned, but only 39, convicted of specific acts, were executed; the others were finally released. Many bands fled into Dakota territory, and the war, disease, and want largely reduced the nation. In 1863 the Minnesota Sioux were removed to Crow creek. About 1866 treaties were made with nine bands, promising them certain annuities, to be enlarged as they should give increased attention to agriculture. An act of Feb. 11, 1863, annulled all previous treaties with the Sioux; but to the innocent bands a part of the amount pledged was restored, the government reserving compensation for damages. The most guilty bands fled north, and are still in the British territory. A few bands continued longer in hostility, cutting off Lieut. Fetterman and his party in December, 1866, and besieging for a time Fort Phil Kearny. In 1874 the Dakotas comprised the Santee Sioux in the reservation at the mouth of the Niobrara, Nebraska, numbering 791, with five schools under the care of the Episcopalians and the American board; the Yankton Sioux on the Missouri, with the same missionaries; the Sissetons and the Wahpetons at Lake Traverse and Devil's lake; the Oncpapas, Blackfeet Sioux, Lower and Upper Yanktonais, Sans Arcs, Upper and Lower Brulés, Two-Kettle, Minneconjous, and Ogallalas in the Crow creek, Grand river, Whetstone, Cheyenne river, and Red Cloud agencies, 46,342 in all, in Dakota; Santee, Yanktonais, Oncpapa, and Cuthead Sioux at Milk river agency, Montana, 5,309. In 1873 the government liabilities to the Dakota tribes, including payments not yet due, were estimated at $10,387,800, with annual payments for their benefit of $27,400. A treaty hastily made by Gen. Sherman, April 29, 1868, was unsatisfactory on both sides; and as gold had been discovered in the Black hills, the United States wished to purchase the tract, and induce the Sioux to abandon their hunting grounds south of the Niobrara, or even to emigrate to the Indian territory. The Sioux showed great reluctance to treat. Sitting Bull, Red Cloud, and Spotted Tail, with other chiefs, visited Washington in May, 1875, but President Grant could not induce them to sign a treaty. Commissioners deputed by him met an immense gathering of the Sioux at the Red Cloud agency in September; but as the Sioux set an exorbitant price on their lands, the negotiation failed. Hostile feelings have been excited by alleged frauds at the Sioux agencies, which have been investigated, but as yet (1876) without result.—Much attention has been given to the Dakota language. A very good grammar and dictionary by Riggs have been issued by the Smithsonian institution. The missionaries have also supplied portions of Scripture, hymns, catechisms, and educational works in it, and newspapers issue lighter reading. It lacks the sounds *f*, *r*, *v*, but has peculiar sounds of its own.

**SIOUX**, a N. W. county of Iowa, bounded W. by the Big Sioux river and intersected by Rock river and affluents of Floyd's river; area, about 750 sq. m.: pop. in 1870, 576. The surface is nearly level and the soil productive. The Sioux City and St. Paul railroad passes through it. Capital, Calliope.

**SIOUX CITY**, a city and the county seat of Woodbury co., Iowa, on the Missouri river, between Perry and Floyd's creeks, at the intersection of the Sioux City and Pacific, Sioux City and St. Paul, Illinois Central, and Dakota Southern railroads, 156 m. N. W. of Des Moines; pop. in 1870, 3,401; in 1875, about 5,500. The business portion of the city is built upon a dry, well drained bench, which almost imperceptibly slopes N. from the river. N. and W. of the thickly settled part of the city rise low ranges of bluffs, upon whose sides are built some of the finest residences. The streets cross each other at right angles, and the principal ones are graded and furnished with sidewalks. The city is lighted with gas and has a fire department. It has an extensive trade with N. W. Iowa, N. E. Nebraska, and S. Dakota. There are four grain elevators, a pork-packing establishment, a national bank, a private bank, a savings institution, three saw mills, two flouring mills, a foundery and machine shop, three breweries, a gun factory, marble works, &c. The workshops of the Sioux City and St. Paul railroad employ about 75 men. The city has two fine graded school buildings and three or four ward school houses, attended by about 1,000 pupils; one daily and three weekly (one German) newspapers; a public hall, seating 1,000 persons; a library association; and six churches.—Sioux City was laid out in 1854 and incorporated in 1857.

**SIR DARYA.** See JAXARTES.

**SIREDON.** See AXOLOTL.

**SIREN**, a North American long-tailed batrachian, with stout eel-like body, naked skin, persistent branchiæ, and only the two anterior legs. The best known species, the *S. lacertina* (Linn.), or mud eel, has a small and short head, with elevated forehead and depressed and truncated snout, three branchial tufts, and three spiracles on each side; the mouth is small, with distinct lips, and arrow-shaped tongue free at the tip and sides; no teeth in the upper jaw, but a broad band of very minute ones along the outer border of the palate bones; nostrils and eyes small, the latter black; the tail laterally compressed, with a rayless fin above and below; limbs with four short and small fingers with horny tips. It attains a length of from 2 to 3 ft., and is dusky above with numerous whitish spots, and purplish below; it lives chiefly in the mud and muddy water of the Carolina rice fields, and occasionally comes on land. Its food consists of worms, insects, and the eggs of fish and frogs; it is found from lat. 35° N. to E. Florida. In this group there are about 90 vertebræ, connected by conical cavities filled with a gelatinous substance, as in fishes; eight pairs of short ribs, of which the first pair is attached to the second vertebra; no trace of pelvis; three cartilaginous branchial arches attached to an osseous tongue bone; the lungs two long sacs, accessory to the gills, but, as in the menobranchus, insufficient for respiration.

**SIREN**, in acoustics. See LIGHTHOUSE, vol. x., p. 458, and SOUND.

**SIRENIA**, an order of placental mammals containing the dugong and manatee, formerly called herbivorous cetaceans. They are whale-like in the swimming paddles of the anterior limbs, the absence of the posterior, and in the transverse tail fin; they differ from cetaceans in having the nostrils at the anterior part of the muzzle, molar teeth with flat crowns adapted for a vegetable diet, a head not disproportionately large, a tolerably distinct neck, more fleshy and bristly lips, and more hairy body.

**SIRENS** (Gr. σειρῆνες, from σειράειν, to draw, to entice), mythical female beings who enchanted the listeners to their song, and after getting them into their power destroyed them. In the legends of the Argonauts they are said to have endeavored to entice those wanderers, but Orpheus surpassed them in singing; thereupon they threw themselves into the sea, and were changed into rocks, as it had been fated that they were not to live after any one passed by them unaffected. In Homer the sirens are connected with the voyage of Ulysses, who, preparatory to sailing by the islands on which they were sitting, by the advice of Circe plugged the ears of his companions with wax and fastened himself to the mast of the vessel, until he was out of the sound of their voices. The island in Homer's account was between Ææa and the rock of Scylla, in the strait of Messina; but the Roman poets place them near the shore of Campania, in the island of Capreæ (Capri) or in the Sirenusian islands near Pæstum. They were called daughters of Phorcus, of Achelous and Sterope, of Terpsichore, of Melpomene, of Calliope, or of Gæa. While Homer mentions only two sirens, the later traditions assume that there were three, and sometimes four. In later times they were represented as birds with the face of a woman. —See Schrader, *Die Sirenen im Alterthum* (Berlin, 1868).

**SIRHIND. I.** A geographical designation applied to that part of India lying between the upper courses of the Sutlej and the Jumna, but not now coterminous with any political division, being for the most part a plain sloping from N. E. to S. W., and having an area of about 17,000 sq. m. In the extreme northeast a spur of the Himalaya, which divides the head waters of the Sutlej from those of the Jumna, projects into the territory, which is bounded N. and S. by certain outlying districts of the Punjaub, E. by the Northwest Provinces, and W. by Bhawalpoor. It comprises the Punjaub districts of Ambala, Loodiana, Ferozepoor, Sirsa, Hissar, and Kurnal,

as well as nine independent native Cis-Sutlej states in subsidiary alliance with the British government, as follows: Patiala, area 5,412 sq. m., pop. 1,650,000; Jhind, 863 sq. m., pop. 189,475; Nabha, 863 sq. m., pop. 227,-155; Kalsia, 155 sq. m., pop. 62,000; Maler-Kotla, 165 sq. m., pop. 46,200; Furidkot, 643 sq. m., pop. 68,000; Dyalgurh, Mumdot, and Raikot. Separate from the group, on the banks of the Beas, but usually classed with the Sikh states of Sirhind, is the state of Kapurthala, with an area of 598 sq. m.; pop. 253,-293. The Sikhs predominate, except in Maler-Kotla, which is Mohammedan, and Furidkot, where the ruler is a Jat. Sirhind is traversed by the Saraswati, Ghaggar, and other affluents of the Sutlej, but, although fertile, requires additional irrigation, which will be supplied by the canal system now in process of construction by the government, to have a total length of 554 m. The Feroze canal, in the S. part of Sirhind, was originally constructed from the Jumna to Hissar by Feroze Shah (1351–'87), in order to water his hunting grounds, and has been restored by the British. The railway from Delhi to Lahore crosses Sirhind. Those portions of the Punjaub directly subject to the government of India were mainly acquired during the Sikh wars. The sovereign states were guaranteed their independence, under British protection, by treaty with Runjeet Singh in 1809. **II.** A town in the Sirhind state of Patiala, lat. 30° 36′ N., lon. 76° 25′ E., founded by Feroze Shah in 1357, and once an important city, but subjected to repeated captures during the Sikh wars, and now largely in ruins. It is on the line of the Delhi railway.

**SIRIUS.** See Dog Star.

**SIRMOND, Jacques,** a French scholar, born in Riom in October, 1559, died in Paris, Oct. 7, 1651. He was a Jesuit, and in 1590 became secretary to the general of the order, Claudio Acquaviva. In 1608 he went to Paris to edit a collection of the histories of the French church councils. In 1637, to prevent his returning to Rome, he was chosen by Louis XIII. as his confessor. He was involved in controversies with Salmasius, Saint-Cyran, and others. His principal original works are: *Notæ Stigmaticæ* (4to, Frankfort, 1612), directed against Richer's work on the temporal and spiritual powers; *Concilia antiqua Galliæ* (3 vols. fol., Paris, 1629); and *Historia Pœnitentiæ Publicæ* (1651). A collected edition of his works appeared in 1696 (5 vols. fol.), with a life of the author by Labaune. He published many editions of ancient authors.

**SIROCCO,** or **Scirocco,** a S. E. wind of a suffocating and parching heat, which at certain intervals, especially in spring and autumn, blows with great violence in the islands of the Mediterranean and on the S. coasts of Italy, for 36 or 48 hours together, and sometimes even for a week or more, and which exerts a most pernicious influence on animal and vegetable life. It is regarded as similar in character to the simoom, though of longer duration, and tempered while passing over the Mediterranean. It is hottest in Malta and Sicily, but of short continuance. In the Ionian isles it blows for a longer period, but usually not so fiercely. The inhabitants of these isles speak of the black and the ordinary sirocco. It produces very little change either in the thermometer or the barometer, but causes a sensation of terrible heat and suffocation, great prostration, and copious perspiration.

**SISKIN.** See Aberdevine.

**SISKIWIT.** See Trout.

**SISKIYOU,** a N. county of California, bordering on Oregon; pop. in 1870, 6,848, of whom 1,440 were Chinese. It formerly had an area of 8,740 sq. m., extending from Nevada to W. of the Coast mountains; but in 1874 the E. portion was set off to form Modoc co. It is intersected by the Klamath river, and watered by several of its tributaries. The surface is elevated. Mt. Shasta in the S. part, in the transverse range joining the Sierra Nevada and Coast mountains, is an extinct volcano, 14,442 ft. high, and covered with perpetual snow. The principal agricultural district is Scott's valley, 40 m. long by 7 m. wide. The chief productions in 1870 were 116,107 bushels of wheat, 131,383 of oats, 55,138 of barley, 17,066 of potatoes, 43,858 lbs. of wool, 95,800 of butter, and 12,392 tons of hay. There were 4,654 horses, 24,254 cattle, 12.844 sheep, and 7,499 swine; 8 flour mills, and 8 saw mills. Capital, Yreka.

**SISMONDI, Jean Charles Léonard Simonde de,** a French historian, born in Geneva, May 9, 1773, died there, June 25, 1842. He was the son of a Protestant clergyman, and of remote Italian descent. After completing his classical studies, he was placed in a commercial house at Lyons. He subsequently resided with his family in England for some time, and having returned to Geneva about 1794, he and his father were driven into exile for assisting a political refugee. He returned to Geneva in 1800, became a secretary of the chamber of commerce, and published in 1803 *Traité de la richesse commerciale, ou principes d'économie politique* (2 vols. 8vo). In this work he supported the principles of Adam Smith, but his views afterward underwent a radical change. The influence of Mme. de Staël, whom he accompanied to Germany and Italy, and of her friends, turned his attention to historical labors, in which he revealed his ardent love of humanity. In 1819 he married Miss Allen, a sister of Sir James Mackintosh's second wife, and declined chairs at the Sorbonne and the collége de France, to spend the rest of his life at Geneva. His principal works are: *Histoire des républiques italiennes du moyen âge* (16 vols., Zürich, 1807–'18; new ed., 10 vols., Paris, 1840); *La littérature du midi de l'Europe* (4 vols., 1813; 4th ed., 1840; English translation by Thomas Roscoe, with notes, 4 vols., 1823); *Nouveaux principes d'économie politique* (2 vols., 1819); *His-*

*toire des Français* (31 vols., 1821–'44; vols. xxx. and xxxi. by Amédée Renée, the last forming a general index); *Julia Severa, ou l'an 492*, a picture of Gaul during the 5th. century (3 vols. 12mo, 1822); "History of the Italian Republics," an eloquent summary of his great work on the same subject, and "The Fall of the Roman Empire," both originally written in English for Lardner's "Cabinet Cyclopædia" (1832 and 1834), and translated by himself into French; *Études sur la constitution des peuples libres* (1836; enlarged ed., entitled *Études des sciences sociales*, 3 vols., 1836–'8); and *Précis de l'histoire des Français* (2 vols., 1839), a summary of his larger work, bringing it down to the death of Henry IV.—See "Political Economy and the Philosophy of Government," selected from his works, with a notice of his life and writings by Mignet (London, 1847); *Sismondi, fragments de son journal et de sa correspondance avec Mlle. de Sainte-Aulaire* (Paris, 1863); and his *Lettres inédites à Madame d'Albany* (1864).

**SISTERHOODS. I. Roman Catholic**, associations of women bound together by religious vows, and devoted to works of charity. In this article only those sisterhoods are mentioned which profess to embrace exclusively or in a very special manner hospital work, and the care of the aged or infirm poor, orphans, and penitent women. The history of religious orders of women whose principal object is the pursuit of ascetic perfection, forms a part of the history of the great contemplative orders on which they depend for their origin, name, and spiritual guidance. (See MONACHISM, RELIGIOUS ORDERS, and special articles on the several orders.) Female congregations whose sole purpose is the instruction of youth, or who embrace at the same time works of public charity, are treated under SCHOOL BROTHERS AND SCHOOL SISTERS.—In the 5th century mention is made by ecclesiastical writers of associations of women at Rome, Milan, and other chief cities of the Roman empire, who gave up their wealth and time to the relief of the suffering poor. Congregations of female hospitallers existed throughout western Europe, dependent on the communities of canons regular, professing like these the rule of St. Augustine, and subject to the same changes and reforms. The earliest known sisterhoods of extensive influence, devoted solely to hospitality or hospital work, are the sisters of St. John of Jerusalem and the sisters of St. Lazarus. The former had a utility coextensive with that of the knightly brotherhood of the same name; the latter especially professed to care for lepers, incurables, the plague-stricken, and persons afflicted with every form of loathsome disease. The order of St. Lazarus is contemporaneous with the hospitallers of St. John of Jerusalem. A guild of men and women were in charge of several leprosy hospitals in that city when it was conquered by the crusaders; they were organized soon afterward into a religious order under the rule of St. Augustine, and their establishments multiplied rapidly both in the East and the West. The first female leprosy hospital in France was founded at St. Denis, near Paris, in 1109, by Louis VI., who also opened several others in various parts of the kingdom, among them one at La Saussaie, near Villejuif, and another at Étampes, besides founding many in the East. The sisterhood was recruited from among the nobility; and Henry II. of England, in founding a hospital for female lepers at Rouvray, near Rouen, stipulated that none but noble ladies of the sisterhood of St. Lazarus should belong to the community in charge of the lepers. The sisterhood also found protectors in Richard I. of England, St. Elizabeth of Hungary, Louis VII., Louis VIII., and Louis IX. of France, all of whom encouraged the daughters of the nobility to enter it. The popes bestowed many privileges on the sisters, and they soon spread throughout England, Germany, Poland, Italy, and Spain. Among the most noted Augustinian sisterhoods in France is that of the hospitallers of the Hôtel-Dieu in Paris, which existed at least as a guild before Charlemagne, and was formally organized as a religious community under Louis le Débonnaire in 814. Their numbers had to be repeatedly recruited during the "black plague" in 1348. Similar sisterhoods, all governed by the rule of St. Augustine, had charge from the beginning of the other Parisian hospitals, and of those founded since that period in French cities and in all the French colonies. Other nurseries of hospitallers in the 13th century were the abbey of Longchamp near Paris, the community of "Quinze Vingts" founded by St. Louis, as well as the Maison Dieu, and the *hostelleries des postes* for strangers and travellers, all in Paris, besides similar foundations by the same king in other parts of France. From these Augustinian communities came the hospitallers of the Hôtel-Dieu (1639) and general hospital (1693) in Quebec, as well as those of the Hôtel-Dieu of Montreal, founded in 1659 by a colony of nuns from La Flèche. Four sisterhoods devoted to hospital work and the care of the poor under the title of the "Presentation" have existed: one founded in 1627 by Nicolas Sanguins, bishop of Senlis, approved by Urban VIII., but which only possessed a few establishments; a second in Paris, with the mitigated rule of St. Benedict; a third and more important order, founded by Cardinal Federigo Borromeo (died 1631) at Morbegno in the Valtellina, living under the Augustinian rule, and very popular in the north of Italy; and a fourth founded in Ireland and described in the article SCHOOL BROTHERS AND SCHOOL SISTERS. In England, the Gilbertine nuns, founded about 1170 by St. Gilbert of Sempringham, embraced hospital work with every other form of public charity. They numbered 1,200 in 1189.—In the year 1100 arose in France the order of Fontevrault, which united the care of leprosy hospitals with that of asylums for fallen

women. These were all placed under the protection of St. Mary Magdalen, and, spreading rapidly with the order itself, effected a great moral reform in France and elsewhere. The "Sisters of Penitence" originated at Marseilles in 1278, and were specially devoted to the same purpose. A host of similar sisterhoods arose afterward, among which were the "Sisters of Charity" established at Marseilles in 1290, who soon opened houses in the chief cities of southern France; the Jesuates of St. Jerome, founded in 1358 at Siena, approved by Pope Martin V., and suppressed by Clement IX.; the "Congregation of Our Lady of Charity" in Paris; and the numerous communities of noble ladies popularly known as Magdelonettes, but united under the patronage of St. Mary Magdalen, established at Metz in 1452, at Paris in 1492, at Naples in 1524, and at Rouen and Bordeaux in 1618. In the Magdelonette establishments, the women under care of the nuns were classed in three categories: the congregation of St. Martha, formed of persons supposed to be thoroughly reformed, and permitted to bind themselves by religious vows; the daughters of St. Martha, who, though penitent, are not permitted to make vows; and the daughters of St. Lazarus, who are either unwilling to reform or are placed in the establishment by the public magistrates. Similar sisterhoods were organized at Rome by Leo X., and confirmed and endowed by Clement VIII. The congregation of the "Sisters of Our Lady of Providence," founded in 1830 for the same purpose in the south of France by Mlle. Lamouroux, has several large establishments, one of which is at Laval.—Of the communities whose sole care is that of the aged and homeless poor, two deserve special mention. The "Little Sisters of the Poor" were founded in 1840 at St. Servan in Brittany, by Abbé Le Pailleur, with the aid of two poor girls. They give a home to the aged of both sexes, depending solely on the alms collected from door to door and on the labor of the sisterhood. They were much opposed at first, but were soon called to open houses in all the cities of France. They were approved by Pius IX., July 9, 1854, and recognized by the French government in 1856. A house was given to them in London in 1860, and their labors were warmly recommended by Charles Dickens and other public men, and from London they spread all over Great Britain and Ireland. In 1868 they came to Brooklyn, N. Y., Cincinnati, and New Orleans, in 1869 to Baltimore and St. Louis, and afterward to New York, Philadelphia, Louisville, and Boston. They also have establishments in Algeria, Asia Minor, and Constantinople. The other community is that of the "Sisters of the Poor of St. Francis," a congregation which originated at Aix-la-Chapelle in the present century, and came to the United States in 1857. Besides the care of the aged poor, they take charge of hospitals, into which they bind themselves to receive at all times and without distinction the sick and wounded of every creed and nationality. They have many establishments in most of the large cities of the United States.—Among the communities devoted to the care of the insane are the "Sisters of the Good Saviour" at Caen in Normandy. The community was founded in 1720 by two poor girls, who taught little outcast children, visited the poor, nursed the sick, and in 1730 opened asylums for homeless children, female penitents, and insane persons. They were suppressed in 1789, but continued to labor among the needy till May 22, 1805, when 15 sisters once more met in community under Abbé Jamet, their former chaplain. In 1817 and 1818 they were first charged by government with the care of insane women, and soon afterward with that of insane men. Besides, Abbé Jamet having invented a new method of instruction for deaf and dumb orphans, his school gradually became a normal school to which pupil teachers of the deaf and dumb resort from France, Belgium, and the British isles. In 1874 the mother house at Caen numbered 300 sisters and upward of 1,000 insane patients. There are three associated establishments of equal importance at Albi, Pont-l'Abbé, and Brucourt. In Canada, the care of the insane at Quebec devolved on the sisters of the general hospital till 1844; and the sisters of Providence founded at Montreal in 1828, and canonically approved in 1844, have charge of the insane asylum near that city. **II. Protestant.** In the church of England several communities of charitable women have been organized in the present century. A community of "Sisters of Mercy" was founded at Devonport about 1845 by Miss Lydia Sellon, who began with the establishment of industrial, infant, and ragged schools. Several ladies joined her in her work, and they took a house and formed a community under Miss Sellon, at first subject to the visitorial control of the bishop of Exeter. The society was composed of three orders, viz.: those living in community, working among the poor, and leading an active laborious life; those who were unable to undertake this work, but who wished to live a calm life, engaged in prayer, reading, and quiet occupations; and married and single women who lived in the world, but maintained a certain connection with the community, and assisted its work in various ways. The sisters were bound by no vows except a promise of obedience to their superior. They were free to abandon their vocation at will, but while connected with it adopted a peculiar garb, and shared their property in common. The sisters also undertook the entire charge and support of a large number of orphan children. At East Grinstead a sisterhood was founded in 1855 by the Rev. Dr. John Mason Neale, with the object of nursing the sick, poor and rich, in their own homes, and in hospitals or infirmaries, in town or country. In 1874 the society had branch houses in London, Aberdeen, Wigan,

and Frome-Selwood.—The parent house of the "Sisterhood of St. John the Baptist" was founded at Clewer in 1849. The sisters have there a house of mercy, St. John's orphanage, St. Andrew's convalescent hospital, St. Andrew's college for accommodating women recovering from illness or requiring change of air and nourishing food, and St. Stephen's mission, embracing an upper class boarding school, a middle class school for girls and boys, and an infant school. The sisterhood has established branches at London, Oxford, Torquay, Gloucester, and other places. This organization embraces: 1, choir and lay sisters living in community; 2, a second order formed in 1860 of ladies who enter on the sisters' life for periods of three years at a time, to be renewed continuously at their own desire and with the consent of the sisters; 3, associates, who live in their own houses and give such assistance to the work as their circumstances may permit. The "Sisterhood of St. Mary," Wangate, was established in 1850, and has branches at Bedminster, Plymouth, and other places. The "Sisterhood of St. Mary the Virgin" established its parent house at Wymering in 1859. The society consists of sisters of charity, who, being resident and under a religious rule, constitute the sisterhood, and ladies of charity or associates, who undertake to promote the interests of the society in their several spheres of private life. The sisterhood has established branches at Manchester and Aldershott. The "Sisterhood of St. Thomas the Martyr," which has its parent house at Oxford, has branches at Liverpool and Plymouth. The society of the "Sisters of the Poor," founded in 1851, has its parent house in London and branches at Edinburgh, Clifton, Eastbourne, and West Chester. —In the Protestant Episcopal church of the United States, an organization of women for voluntary service as nurses in hospitals, infirmaries, &c., called "Sisters of the Holy Communion," was founded in 1845 by the exertions of the Rev. W. A. Muhlenberg, D. D., in connection with the Protestant Episcopal church of the Holy Communion in New York. They are bound by no vows, and though it is desirable that they should remain in their work for life; they are free to leave whenever they are so minded. They are usually received between the ages of 25 and 40 years; if under 25, the written consent of parents or guardians must be obtained. Candidates for the sisterhood are required to spend one year of probation before entering upon their vocation. They have no marked uniform, though the dress is generally black, with a white muslin collar and head dress. The sisters managed for several years the infirmary of the Holy Communion, and since 1858 have had charge of St. Luke's hospital, New York, under Dr. Muhlenberg's superintendence. (See DEACONESS.)

**SISTOVA**, or **Shistov**, a fortified town of Bulgaria, on a height overlooking the right bank of the Danube, which is here navigable for vessels of 500 tons, 35 m. W. S. W. of Rustchuk and 23 m. E. by S. of Nicopoli; pop. about 15,000. It is defended by a citadel or castle, now much dilapidated. The houses are ill built, but the mosques are of considerable beauty. A treaty of peace between Turkey and Austria was concluded here Aug. 4, 1791.

**SISYPHUS**, in Greek mythology, son of Æolus and Enarete, and married to Merope, by whom he became the father of Glaucus and others. Some later accounts make him the son of Autolycus and the father of Ulysses. To him are attributed the foundation of Corinth (Ephyra) and the establishment of the Isthmian games. He and his family were considered the most deceitful of men, and he was punished in the lower world by being set to the task of rolling a huge marble block up hill, which as soon as it reached the top always rolled back again. The crimes which induced this penalty are, according to different legends, that he betrayed the plans of the gods, killed travellers, and revealed the abduction of Ægina by Jupiter.

**SITKA.** See ALASKA, vol. i., p. 239.

**SIVA.** See INDIA, RELIGIONS OF.

**SIVAS. I.** A vilayet of Turkey, in Asia Minor, bounded N. by Trebizond, E. by Trebizond, Erzerum, and Diarbekir, S. by Marash, Adana, and Konieh, and W. by Angora and Kastamuni; area, about 25,000 sq. m.; pop. estimated at about 600,000. The most important town, besides the capital, is Tokat, and its principal seaport is Samsun. It is traversed by several branches of the Anti-Taurus mountains. It is drained by the Kizil Irmak (anc. *Halys*), the Yeshil Irmak (*Iris*), and their affluents, and several smaller streams which flow into the Euphrates. Among the minerals are iron, copper, lead, alabaster, marble, slate, and especially salt. Most of the soil is exceedingly fertile, but not thoroughly cultivated. The pastures are extensive. In ancient times the province formed parts of Pontus and Cappadocia. **II.** A city (anc. *Sebastia*), capital of the province, in an extensive plain on the Kizil Irmak, 440 m. E. S. E. of Constantinople; pop. about 25,000. The town is defended by two old castles, and contains fine mosques and many ruins. Access from the Black sea is easy, and the trade is active in the large bazaars.

**SIVORI, Ernesto Camillo**, an Italian violinist, born in Genoa, June 6, 1817. At the age of four years he was able to perform whatever he heard his sisters play or sing. He received lessons successively from Restano, Dellepiane, Costa, and Paganini, but modelled his playing chiefly upon that of the last named. His first concerts were given at Paris and in England when he was but ten years old. He then studied counterpoint for eight years under Serra, and afterward gave concerts throughout Europe. In 1846 he visited the United States in company with the pianist Herz, and went also to Mexico and South America. Next engaging in a mercantile enterprise in Italy, he lost all his earnings and was obliged to resume

his artistic career. He has composed a number of concertos, fantasias, and other pieces.

**SIWAH** (anc. *Ammon* or *Ammonium*), an oasis in N. W. Egypt, near the boundary of the disputed territory between Egypt and Tripoli, about 330 m. W. S. W. of Cairo, and about 160 m. from the coast of the Mediterranean sea; pop. about 8,000. It consists of several detached tracts, the principal of which is about 8 m. long and 3 m. broad. Its surface is undulating, rising on the north into high limestone hills. There are numerous ponds and springs, salt and fresh. The soil of the E. part is exceedingly fertile, its chief product being dates. The climate is delightful. The inhabitants are Berbers and negroes, all Mohammedans, governed by sheikhs or elders, some of whom hold office for life, others for ten years. The people understand Arabic, but have a mixed idiom of their own. Their principal town, Siwah (according to Rohlfs, who last visited it in February, 1874, in lat. 29° 12′ N., lon. 25° 30′ E.), is defended by a citadel on a rock, and by strong walls. The streets are irregular, narrow, and dark. It is divided into an upper and a lower town. No stranger is admitted to the former, nor are native bachelors permitted to live there. About 3 m. S. E. of the town are the ruins of the ancient temple of Jupiter Ammon, now called Om Baydah, sculptures of Ammon, with the attributes of the ram-headed goat, being among the remains. Near the temple is what is supposed to be the fountain of the sun, a pool 80 ft. long and 55 ft. wide, formed by springs, whose water appears to be warmer by night than by day, and is heavier than that of the Nile. In the vicinity are other ruins and inscriptions of Greek, Roman, and Roman-Egyptian character. In the W. part of the oasis is a lake, called Birket Arashiah, containing an island from which strangers were till lately excluded.—In ancient times this oasis was celebrated as the seat of the oracle of Ammon. Besides the temple, with its images of Jupiter Ammon set in precious stones, it contained a royal castle surrounded by three walls, and a remarkable spring called the "fountain of the sun," the water of which was quite cold at noon and boiling hot at midnight. Cambyses made an unsuccessful attempt to take the temple. In 331 B. C. Alexander the Great marched through the desert to visit it, and the priest addressed him as the son of the god. The emperor Justinian built here a Christian church.—See *Reise zu dem Tempel des Jupiter Ammon und nach Oberägypten*, by Minutoli (Berlin, 1824); "Adventures in the Libyan Desert," by Bayle Saint John (London, 1849); and *Das Orakel und die Oase des Ammon*, by Parthey (Berlin, 1862).

**SIX NATIONS.** See Iroquois.

**SIX PRINCIPLE BAPTISTS,** a small religious sect which first appeared in this country as a separate organization in Rhode Island in 1639. Their church polity and views on baptism are the same as those of the Baptists. In doctrine they are Arminian. They oppose the payment of any regular salary to their preachers, and have never connected themselves with any missionary efforts, or benevolent or reformatory societies. They hold as their distinguishing doctrines the six principles laid down in Heb. vi. 1, 2, viz.: repentance from dead works; faith toward God; the doctrine of baptisms, of which they distinguish four kinds, viz.: John's baptism, the baptism of the Holy Ghost on the day of Pentecost, the baptism of Christ's sufferings, and apostolic or Christian baptism, which alone remains since the resurrection of Christ; laying on of hands, which they regard as equally necessary with baptism; the resurrection of the dead; and eternal judgment. In 1874 they had 20 churches, 12 ordained ministers, and 2,000 members, mainly in Rhode Island.

**SIXTUS,** the name of five popes, of whom the following are the most important. **I. Sixtus IV.** (Francesco d'Albescola della Rovere), born at Celle, near Savona, July 21, 1414, died in Rome, Aug. 13, 1484. He was a Franciscan monk and a protégé of Cardinal Bessarion, taught philosophy and theology in the principal schools of Italy, and was chosen general of his order in 1464. He was created cardinal Sept. 18, 1467, and was elected pope Aug. 9, 1471. The efforts which he immediately made to reform the religious orders and general church discipline were thwarted by his endeavor to unite all Christian princes in a crusade against the Turks, for which purpose he vainly tried to reconcile Louis XI. of France and Duke Charles the Bold of Burgundy. He levied tithes on all church property in Christendom to equip a fleet, which, with contingents from Venice and Naples, only succeeded in capturing Smyrna. Louis XI. promised assistance in return for an extension of the royal power over benefices and all church revenues, and the abolition of ecclesiastical courts and immunities; but on these points Sixtus refused to yield. He has been justly reproached, however, with a too great facility in granting favors, and an excessive nepotism. To secure the coöperation of the Spanish and Austrian princes against the Turks, he sanctioned the nomination to the see of Saragossa of a child six years old, an illegitimate son of the house of Aragon; and he raised successively to the cardinalate five of his own nephews. Two of these cardinals, Riario and San Giorgio, were implicated in the conspiracy of the Pazzi in 1478, which caused the pope to be solemnly arraigned by the Florentine clergy as privy to the intended murder of Lorenzo de' Medici and the death of his brother Giuliano. The Florentine magistrates having hanged Archbishop Salviati of Pisa, one of the conspirators, they were excommunicated, and the city was laid under interdict. The republic was sustained by France, Venice, and the duke of Milan; the other Italian sovereigns sided with the pope,

and the quarrel ended in 1480. About the same time Sixtus became involved in a war with Ercole d'Este, duke of Ferrara, whom he wished to dispossess in favor of one of his own nephews. He was backed by the Venetians; but the duke of Ferrara being supported by the king of Naples and the emperor, Sixtus was forced to yield in 1484. During these troubles the Turks besieged Rhodes and ravaged the southern coast of Italy, capturing the city of Otranto and massacring 12,000 of the inhabitants. The pope once more attempted in vain to organize a crusade, but succeeded in driving off the invaders. Among the other acts of his pontificate were the confirmation of the religious order of Minims, May 23, 1474; the bull sanctioning the Spanish inquisition, 1478; the canonization of St. Bonaventura, April 14, 1482; the construction, among many other splendid public works, of the Sistine chapel in the Vatican; large additions to the Vatican library; and the sending of the first missionaries to the Canary islands. The *Regulæ Cancellariæ Romanæ* are attributed to this pope. He also left several Latin treatises, among which are *De Sanguine Christi* (fol., Rome, 1473), *De Potentia Dei* (fol.), and several letters. **II. Sixtus V.** (Felice Perretti), born at Grotte-a-Mare, near Montalto, Dec. 15, 1521, died in Rome, Aug. 27, 1590. He was a Franciscan, and distinguished himself as a lecturer on ecclesiastical law at Rimini in 1544 and Siena in 1546, as a popular preacher, and as an author by works on mystical theology and on the philosophy of Aristotle. In 1557 he became inquisitor general at Venice, and in 1570 he was created cardinal, when he assumed the name Montalto. He was elected pope by an almost unanimous vote, April 24, 1585. Both as pope and as secular prince he was distinguished for prudence, severity, and energy. He destroyed the power of the banditti and restored order and safety throughout his territory, administered law with the utmost impartiality and with an appalling rigor, built a great aqueduct, enlarged the library of the Vatican, and in many other ways encouraged industry. He fixed the number of cardinals at 70, required the Catholic bishops of all countries to visit Rome at certain intervals, and reorganized the entire administration of ecclesiastical affairs by the appointment of 15 congregations of cardinals and other officers. He founded a new university at Fermo, and new colleges at Rome and Bologna. From the printing press of the Vatican he published the revised edition of the Vulgate, which had been ordered by the council of Trent. He avoided war with the Christian princes as much as possible, though he encouraged and supported Henry III. against the Huguenots, Philip II. against England, and Archduke Maximilian when he was a candidate for the crown of Poland. He hurled his anathemas against the young king of Navarre, and against Elizabeth of England for putting to death Mary Stuart; and he summoned Henry III. to Rome for ordering the assassination of the duke of Guise. He left a vast treasure in the castle of Sant' Angelo, to be used by his successors only in circumstances strictly defined. His biography by Leti (*Vita di Sisto V.*, Lausanne, 1669) is considered untrustworthy, and that by Tempesti (*Storia della vita e geste di Sisto V.*, Rome, 1754) too partisan.—See J. A. von Hübner, *Sixte Quint, sa vie et son siècle* (2 vols., Paris, 1871; English translation by Jerningham, London, 1872; German, 2 vols., Leipsic, 1874).

**SKAGER RACK** ("the crooked strait of Skagen"), an arm of the North sea or German ocean, lying between the Danish peninsula of Jutland and the coast of Norway, and connecting the Cattegat with the North sea. It extends from N. E. to S. W.; length about 160 m., breadth nearly 80 m. It is much deeper on the Norwegian than on the Danish coast, ranging on the former from 150 to 200 fathoms, and on the latter from 30 to 40. It is subject to severe storms. The harbors are all on the Norwegian coast.

**SKAMANIA**, a S. county of Washington territory, bordering on Oregon, bounded S. by Columbia river and drained by several streams; area, 1,800 sq. m.; pop. in 1870, 133. The surface is generally mountainous, with fertile valleys. The Cascade mountains traverse it from N. to S. Mt. St. Helens, in the N. W. part, is 9,750 ft. high. Capital, Cascades.

**SKATE** (Dutch, *schaats*), a shoe or sandal with a steel runner for travelling over ice. It probably originated in Scandinavia. The earliest skates were made of bone, fastened to the foot with cords. Such skates have been discovered in England, Holland, Sweden, and Iceland, and there are accounts of their use in London in the time of Henry II. The introduction of iron skates was doubtless due to the Dutch, who for an unknown period have used them for travel on their canals and rivers. The best facilities for skating are afforded by the countries of N. W. Europe, where the ice is little covered with snow; but as a pastime it has become widely popular, and is practised with great skill by both men and women. The form of the skate has been much improved. Until within a few years it was a block of wood with a runner or keel of iron or steel about an eighth of an inch thick, channelled at the bottom so that two sharp edges cut into the ice, ending in a sharp angle at the heel, and turning up at the toe. It was secured to the foot by a peg or screw entering the heel of the boot, and by straps passing through the block, crossing the front part of the foot, and connecting with a broad strap around the heel. In improved skates the runner is of steel, thicker, and flat instead of channelled at the bottom, the cutting edge forming a little less than a right angle. It is generally curved slightly from front to back, and rounded up at both heel and toe. There have been many changes in the form of the body of the skate and the fastenings, the straps sometimes giv-

ing place to what is almost a complete shoe, while one of the favorite skates is made wholly of iron or steel, without straps, and fastened to the boot by metal clamps. Motion on skates is very rapid. It is said that the Frieslanders will go for a long time at the rate of 15 m. an hour, and for short distances this rate has been greatly exceeded.—"Parlor" skates, having in place of runners rollers of wood, metal, papier maché, or India rubber, arranged in a line, or like the wheels of a carriage, are used on floors and pavements. With these skates experts can execute the ordinary curves, and even many intricate figures.

**SKATE,** a fish. See Ray.

**SKEAT, Walter William,** an English philologist, born in London, Nov. 21, 1835. He graduated at Christ's college, Cambridge, in 1858, became a fellow there in 1860, mathematical lecturer in 1864, and afterward English lecturer. In 1873 he helped to found the English dialect society, and he has edited most of its publications. Besides continuing for the Cambridge press the Anglo-Saxon Gospels begun by J. M. Kemble, and editing several publications for the Oxford press, the philological society, and the early English text society, he has published "The Songs and Ballads of Uhland," translated from the German (1864); "A Tale of Ludlow Castle" (1866); "A Mœso-Gothic Glossary" (1868); "Hand List of some Cognate Words in English, Latin, and Greek" (1871); "Questions for Examination in English Literature" (1873); "The Gospels of St. Mark and St. Luke, in Anglo-Saxon and Northumberland Versions synoptically arranged, with Collations exhibiting all the Readings of all the Manuscripts" (2 vols., 1875); and "Plutarch-Shakespeare," biographies (vol. i., 1875).

**SKELETON** (Gr., a dried body, from σκέλλειν, to desiccate), the bony and cartilaginous framework of animals, and the ligneous structure of the leaves of plants. In the higher animals the skeleton is internal (endo-skeleton); in many of the lower it is external (exo-skeleton). When the bones are joined by natural ligaments, they form a natural skeleton; when they are joined by wires and straps, the skeleton is said to be artificial. The study of the skeletons of different animals belongs to the subject of comparative anatomy; the human skeleton only will be described here. Bones may be classified as long, round, flat, and short. (See Bone.) The human skeleton consists of 208 bones, exclusive of the teeth, which are in reality parts of the digestive apparatus, and are developed from the mucous membrane. For convenience the skeleton may be divided into four regions: 1, the skull; 2, the trunk; 3, the upper extremities; 4, the lower extremities. The skull contains 30 bones, in three divisions, cranium, ears, and face. There are 8 cranial bones, viz.: 1 frontal, 2 parietal, 2 temporal, 1 occipital, 1 sphenoid, and 1 ethmoid. The frontal bone forms the forehead, upper part of the eye sockets, and front part of the floor of the cranial cavity. Just above the inner angles of the eyebrows are two marked prominences called the superciliary ridges, at which points the two tables of the bone separate considerably, enclosing cavities called the frontal sinuses which communicate with the nasal passages. The parietal bones, occupying the upper part and sides of the skull, are separated from each other by the sagittal suture, and from the frontal bone by the coronal suture. A curved ridge traverses both frontal and parietal bones at each side, which marks the origin of the fibres of the temporal muscle, lying in a depression behind and below the ridge, called the temporal fossæ. The temporal bones, situated at the sides and base of the skull, consist each of three portions: an upright or squamous portion, a posterior or mastoid portion, and an internal or petrous portion. The upright portion articulates with the parietal bone by the squamous suture. The mastoid portion has a projection, felt behind the ear, called the mastoid process, which has a cellular structure, communicating with the middle ear or tympanum; the cells are not developed till after puberty. The petrous (hard, stony) portion is in the form of a triangular pyramid, and lies upon one of its sides in the base of the skull, its apex pointing forward and inward. One of the openings into it, the internal auditory canal, transmits the auditory and facial nerves, and it also contains the tympanum. The temporal bones are pierced externally by the external auditory canal, which transmits the sonorous pulsations to the membrane of the tympanum. The under surface of the bone articulates with the lower jaw bone to form the joint. Just in front of this, and a little above, a process called the zygomatic springs forward to meet another of the same name from the cheek bone, forming a horizontal arch, the zygomatic, under which the tendon of the temporal muscle passes. The occipital bone consists of an upright and a basilar portion; the latter contains a large orifice, the foramen magnum, through which the brain connects with the spinal cord. On each side of the foramen magnum there is a condyle having an articular surface which rests upon a corresponding condyle of the atlas, the upper bone of the vertebral column. The basilar portion articulates in front with the body of the sphenoid bone, fig. 4, which in turn articulates with the ethmoid, fig. 5, the latter being situated at the root of the nose and held in position by the frontal and several bones of the face. There are 8 ear bones, 4 in each ear, situated in the tympanum; they are described in the article Ear. The 14 bones of the face are 2 nasal, 2 upper jaw or superior maxillary, 2 lachrymal, 2 cheek or malar bones, 2 palate bones, 2 inferior turbinated (in the nose), 1 vomer (septum of the nose), and 1 lower jaw, or inferior maxillary bone. (See illustrations.) Each upper jaw bone contains a large cavity called the maxillary antrum, which communi-

cates with the nasal passage. The lachrymal bones are small oval plates situated at the inner angles of the orbits of the eyes. The palate bones are situated at the posterior part of the nasal passages, and enter into the formation of the roof of the mouth or palate and the back part of the floor of the orbits of the eyes. The lower jaw bone consists of a horizontal semicircular portion, having an alveolar process into which the lower teeth are set, and of a perpendicular portion, the ramus, divided into two branches, one of which terminates in the condyle to form the joint, and the other is the coronoid process, into which are inserted the fibres of the temporal muscle and a portion of those of the masseter, the two principal muscles of the jaw. The floor of the skull is divided into anterior, middle, and posterior fossæ, the two first lodging the anterior and middle lobes of the cerebrum, and the posterior fossæ lodging the cerebellum. (See BRAIN.) The bones of the trunk are 54 in number, viz.: the 24 bones called vertebræ, constituting, with the sacrum upon which they rest, the spinal column, 24 ribs, 4 pelvic bones, 1 sternum or breast bone, and 1 tongue bone. The two hip bones are naturally classified with the lower extremities, but as they are joined to the sacrum by immovable sutures, and form with it an important piece of animal mechanism, the pelvis, they are here included in the bones of the trunk. (See PELVIS.) The spinal or vertebral column, or backbone, forms the axis of the trunk, supporting it and the skull. All of the vertebræ but one have their principal features in common; *i. e.*, they have a body, a spinous process, a spinal foramen for transmitting the spinal cord, and four articular processes, two superior and two inferior for articulating with each other. The spinous processes which project posteriorly together form the "spine," which marks the course of the spinal column. The uppermost vertebra, called the atlas, has no body, but its place is occupied by a tooth-like process of the bone next below, called the axis, around which the atlas turns. There are 7 cervical, 12 dorsal, and 5 lumbar vertebræ. The seventh cervical is peculiar from having a longer and more prominent spinous process than the others, which may be felt at the base of the neck. Between the bodies of the vertebræ are placed the elastic intervertebral cartilages, which permit flexion of the spinal column and prevent concussion of the spinal cord in walking and leaping. The ribs, 24 in number, are long flat bones of a semicircular form, and have an oblique position, their posterior extremities being higher than their anterior. The middle part of the curve is also depressed, so that the contraction of the respiratory muscles expands the cavity of the chest. There are 7 true and 5 false ribs on each side, the true ribs articulating with the sternum, while the false ribs lap on to each other, except the last two, which are free, and are called floating ribs. The sternum is a kind of breastplate, composed of three pieces, to which the collar bones and the ribs are attached. The tongue bone supports the root of the tongue and gives attachment to muscles for moving it. The upper extremities contain 64 bones, 32 on each side, in six divisions: 1, the shoulder; 2, the arm; 3, the forearm; 4, the wrist or carpus; 5, the palm or metacarpus; 6, the fingers or phalanges. The shoulder contains two bones, the scapula and clavicle. The scapula is a flat triangular bone situated at the upper and back part of the chest on each side. It is traversed on its posterior surface by a spine which terminates in the acromion process, the prominent point of the shoulder. Below the acromion process is the head of the scapula, containing a shallow cup called the glenoid cavity, which receives the head of the arm bone or humerus. The outer extremity of the collar bone or clavicle (Lat. *clavis*, a key) articulates with the acromion process, forming a kind of brace. The scapula is held to the trunk by powerful muscles, which allow of sufficient motion to give a variety of positions to the shoulder joint. The arm contains one bone, the humerus, the lower end of which by its expanded articular surface forms with the two bones of the forearm, the radius and ulna, the elbow joint. The wrist or carpus contains 8 bones (see fig. 6), the palm or metacarpus 5, and the fingers or phalanges 14, the first and second phalanx containing 5 each and the third 4. The apparatus of the forearm is a marvel of animal mechanism. The upper extremity of the ulna forms with the articular surface of the humerus a firm hinge joint, but the head of the radius forms with it a rotatory joint by which pronation and supination of the forearm and hand are effected with grace and facility. The lower extremities contain 60 bones, 30 in each limb, in six divisions: 1, the thigh bone or femur; 2, the knee pan or patella; 3, the two bones of the leg, the tibia and fibula; 4, the 7 bones of the ankle or tarsus; 5, the 5 bones of the metatarsus; and 6, the 14 bones of the toes or phalanges. The femur is the longest, largest, and strongest bone in the skeleton. Its upper extremity contains the head, which fits into the socket of the hip bone, and the neck, which joins the shaft of the bone at an angle of nearly 45°, the union being marked by two strong

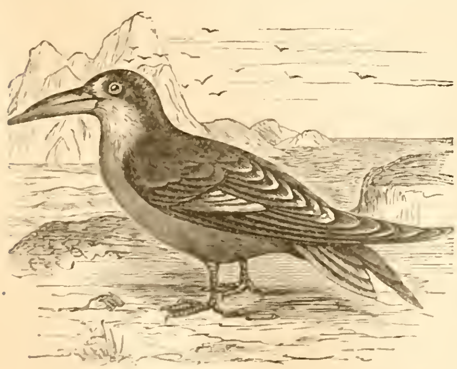
processes called the greater and lesser trochanters, to which are attached strong muscles, the chief office of which is to rotate the thigh, and also to move it outward and inward. Its lower extremity is expanded like that of the humerus, and articulates with the head of the tibia, the principal bone of the leg. The tibia articulates at its lower extremity with the astragalus, the bone occupying the summit of the arch of the foot, and the latter rests upon the calcis or heel bone, into which the tendo Achillis, the tendon of the strong extensor muscles of the calf, is inserted.

**SKELTON, John**, an English poet, born probably in Norfolk about 1460, died in Westminster, June 21, 1529. He graduated at Cambridge, entered holy orders, was tutor to the duke of York, afterward Henry VIII., became rector of Diss and curate of Trompington in 1504, and was appointed *orator regius* to Henry VIII. Anthony à Wood deemed him "fitter for the stage than for the pew or pulpit." He concealed the fact of his marriage, and was accused of keeping a concubine, and suspended by the bishop of Norwich. Among his writings are the drama "Magnyfycence," "The Bowge of Courte," "Collyn Clout," and a dirge on "Phyllyp Sparowe." The best edition of his works is by the Rev. Alexander Dyce, with an account of his life (2 vols., London, 1843).

**SKERRYVORE.** See Lighthouse, vol. x., p. 460.

**SKIDDAW**, a mountain near the centre of Cumberland, England, 3,022 ft. in height. It has the lake of Bassenthwaite Water on its west. Though there are some mountains in the same county of greater elevation, Skiddaw is the most imposing, as it stands so as to be seen at one view from the base to the summit.

**SKIMMER** (*rhynchops*, Linn.), a genus of web-footed birds of the gull family, and subfamily *rhynchopsinæ*. The bill is of singular shape, broad at the base, from which it is suddenly

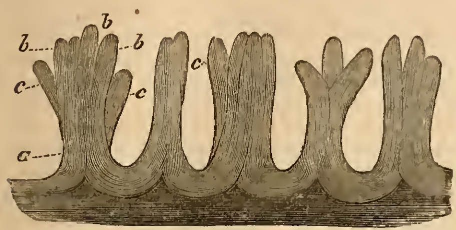


Black Skimmer (Rhynchops nigra).

compressed laterally to the end; the upper mandible is considerably the shorter, curving gradually to the tip, which is pointed and grooved underneath; the lower mandible is straight and truncated, more compressed, with a sharp cutting edge received into the groove of the upper; nostrils basal; wings very long and narrow, with the first quill the longest; tail moderate and forked; tarsi longer than middle toe; feet very small, toes short with indented web, hind toe elevated, and claws curved and sharp. Three or four species are described; they are most abundant in the tropics, where they frequent quiet bays and inlets; they feed chiefly at night on fish and crustaceans, which they catch as they skim along close to the water, dipping the under mandible beneath the surface and closing the upper suddenly upon it when prey is encountered; the flight is swift, graceful, and undulating, and the gait awkward; they rarely if ever swim or rest upon the water. The best known species is the black skimmer (*R. nigra*, Linn.), found on the Atlantic and gulf coasts of North America from New Jersey to Texas, on the E. coast of South America as far as the tropic of Capricorn, and, according to Lesson, on the W. coast. The length is about 19 in. and the alar extent 48 in.; the general color above is deep brownish black; the front to the eyes, throat, and under parts white; inner tips of four inner primaries white, and secondaries broadly tipped with the same; the central tail feathers dark brown, the others mostly white; the bill carmine for the basal half, thence black to the end, the upper mandible about $3\frac{1}{2}$ in. and the lower $4\frac{1}{2}$; tarsi and feet red, and iris hazel; the female is smaller. They are nocturnal, resting by day on the sand bars, in large flocks. The nest is a slight hollow in the sand, and the eggs are usually three, $1\frac{3}{4}$ by $1\frac{3}{8}$ in., white with large black or dark patches; the female sits only at night or in wet and cold weather; the young closely resemble in color the sand upon which the nest is made; they migrate to the south when the young are able to fly; their eggs are as good as those of the gulls. This species is sometimes called razor-billed shearwater, and scissors-bill. Other species are found on the W. coast of Africa.

**SKIN**, the external covering of the animal body, protecting the internal parts from external violence, and adapting itself by its elasticity to the various movements and changes of position; it also acts as the organ of touch, and as an excretory and absorbing surface. In the human skin, which may be taken as the type of that of the higher animals, the deepest portion is the *corium*, *dermis*, or *cutis vera*, as distinguished from the deciduous cuticle which overlies it, described under Epidermis. This true skin is dense and tough, somewhat elastic, composed of fibres interlaced in all directions, in whose interstices are masses of fat; the whole rests upon a layer of subcutaneous areolar tissue; within and below it are the sudoriparous or sweat glands (see Perspiration), the hair follicles (see Hair), and the sebaceous glands. From its upper surface rise the sensitive papillæ, which are minute conical elevations, most numerous on the palmar surface of

the hands and fingers, feet and toes, where they are arranged in double rows in parallel curved lines; the average length of the papillæ, including the height of the ridge upon which



Compound Papillæ of the Skin from the surface of the Hand, showing double, triple, and quadruple divisions.

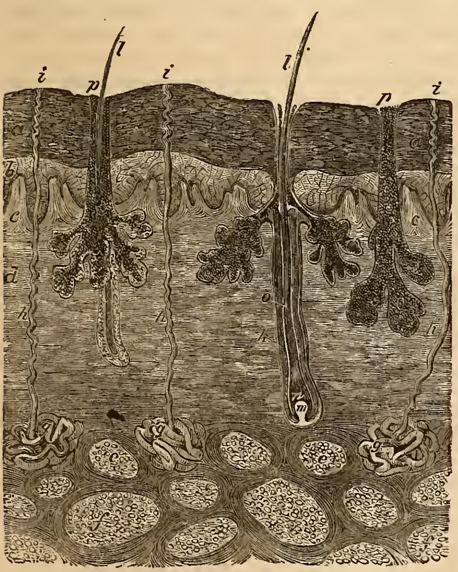
they are placed, is about $\frac{1}{100}$ of an inch, and the diameter at the base $\frac{1}{250}$; they are abundantly supplied with blood, which explains their erectile turgescence under stimuli; they adhere more or less firmly to the cuticle. The sebaceous or oil glands of the skin are formed on the same plan as the sudoriparous, and can



Vertical Section of the Skin, magnified.

*a.* Epidermis. *b.* Inferior layer of epidermis, or rete Malpighianum. *c.* Papillæ of the skin. *d.* Corium, or dermis. *e, f.* Lobules of adipose tissue. *g.* Perspiratory glands. *h.* Ducts of the perspiratory glands. *i.* Their external orifices. *k.* Hair follicle. *l.* Hairs projecting from the skin. *m.* Hair papilla. *n.* Hair bulb. *o.* Shaft of hair in the hair follicle. *p.* Openings of the sebaceous glands.

often be distinguished from them only by the nature of their oily secreted product; they are distributed over the whole surface of the body, being least abundant where the perspiratory glandulæ are most numerous, and *vice versa;* they are absent on the palms and soles, but abundant on the face and scalp; they vary considerably in size, but the tubes are generally wider and straighter than those of the sweat glands; the structure is sometimes complicated. In the parts of the skin covered with hair, there is usually a pair of sebaceous ducts opening into the follicle of each hair. The object of their secretion is doubtless to prevent drying and cracking of the hair by the sun and air; this secretion is most abundant in tropical nations, and in some dark races has a characteristic odor, as in the case of the negro; its protective action in the tropics is often assisted by vegetable oils applied externally. The Meibomian glands on the edges of the eyelids are a double row of sebaceous follicles set along a straight duct; they secrete an oily matter for the lubrication of these parts, which in diseased conditions frequently sticks them together. Another modification of sebaceous glands is to be found in the external ear passage, where is secreted the *cerumen* or waxy matter; they consist here of long, highly contorted tubes, well supplied with blood vessels. The color of the skin depends on pigment cells mixed with the inferior epidermic ones, in what is called the *rete mucosum*, or mucous layer, and considered by Flourens and other authors as a distinct membrane; all the hues of the races of man depend on the relative abundance of these cells and the tint of the contained pigment. The folds of the skin are for the most part produced by the contractions of the superficial muscles. The skin is pierced at the eyes, ears, nostrils, mouth, rectum, and genito-urinary opening; it is continuous internally with the mucous membrane, consisting of the same elements modified according to the variety of functions to be performed; it is very vascular, and freely supplied with nerves and lymphatics. The skin is the seat of the sense of touch in man, though in most animals hairs, scales, bony or horny plates and envelopes, and shells, render it nearly insensible to external influences, this sense in them being confined to particular portions or projecting organs; even in man the sensibility varies much in different parts, being most acute at the ends of the fingers and on the lips, and dullest on the back and limbs. Aëration of the blood takes place to a certain extent through the skin, and in some naked-skinned fishes and batrachians this is a very important part of the respiratory process. It has been shown by experiment that in a frog, after the removal of the lungs, one fourth of a cubic inch of carbonic acid is exhaled from the skin in eight hours; in man the amount of this gas given off by the skin varies from $\frac{1}{60}$ to $\frac{1}{30}$ of that exhaled from the lungs; where the lungs perform their office imperfectly, the temperature of the skin is often high; in all febrile diseases it should be kept moist. The absorbent powers of the skin are noticed under ABSORPTION.

**SKIN, Diseases of the.** See p. 880.

**SKINK,** the common name of the *scincidæ*, a family of lepidosaurian, slender-tongued lizards, with elongated cylindrical body, covered above and below by imbricated fish-like scales, arranged in quincunx and held in membranous sacs; they have no lateral folds. The family, by such forms as the seps and orvet, constitutes a connecting link between the saurians and ophidians. The head is covered with large angular plates, joined by their borders; the neck is of the same size as the chest; the tongue free, without sheath, slightly notched in front, with the surface mostly covered with papillæ; the scales are smooth. They creep with a lateral sinuous motion like serpents; they have no crests nor fringes on the neck, back, sides, or tail, the last being conical, and generally long and without spines; the feet (absent in some) are short and clumsy, with well developed digits and claws. The jaws are short and united at the symphysis, so that the opening of the mouth is always the same; the teeth are sharp and slender, suited for seizing insects and worms; in the snake-like forms only one lung is largely developed; the ears are exposed. They are generally small, and live in holes and under stones in dry sandy places; they are usually of an earthy gray color. They inhabit the torrid zone and the driest portions of temperate regions. Duméril makes three great divisions according to the differences in the covering of the eyes: 1, *saurophthalmes*, with lizard-like eyes, protected by two lids moving vertically; 2, *ophiophthalmes*, with a rudimentary lid, as in serpents; and 3, *typhlophthalmes*, in which the eyes are concealed under the skin. Most of the more than 30 genera, comprising more than 100 species, belong to the first division, the only one that need be treated here; some of them have four limbs, others two, others none. Dr. Gray divides them into *scincinæ*, with smooth scales, and *tropidophorinæ*, with

Common Skink (Scincus officinalis).

keeled scales.—In the genus *scincus* (Fitz.) the snout is wedge-shaped, the upper jaw the longer, the teeth simple, conical, and obtuse, with a row on the palate; the limbs are four, with five nearly equal digits, flattened, and with serrated borders; the tail is conical and pointed. The common skink (*S. officinalis*, Laur.) is 8 or 9 in. long, with stout body, short thick limbs, and a proportionally short tail, very thick at the base; the eyes are small, high up and far back. The colors vary considerably, from silvery yellow to brownish, with seven or eight black transverse bands. It is a native of Egypt, Nubia, Arabia, and N. and W. Africa.—There are several American species of this family, most of which are popularly called "galliwasps," one of the best known of which belongs to the genus *diploglossus* (Wieg.), characterized by a tongue with scaly papillæ in front and filiform behind, toothless palate, flat head, obtuse muzzle, and flattened body; the feet have five unequal toes, compressed, without lateral edgings, and with tuberculose palms and soles; the scales are striated, and ridged in the middle; the tail is rounded, long and pointed, with a very large anal operculum. The great galliwasp (*D. occiduus*, Wieg.) is about 21 in. long, of which the tail is one half; it is one of the largest of the skinks. The color above is generally light brown, with a dozen or more transverse bands, sometimes darker and sometimes lighter, and yellowish white below with brownish tints. It is found in Jamaica, where it is very much dreaded, though it is perfectly harmless; it forms the type of Gray's genus *celestus*. The five-lined skink (*euprepes quinquelineatus*, Wagl.) is 10 to 11 in. long, the head pale red with six obscure white lines, the two internal confluent at the back part; the body above is olive brown, with five pale white longitudinal lines and a black lateral band; the tail brown, tinged with blue, and the lower surface white. There are no teeth on the palate, otherwise the characters are as in the last genus. It lives in the stumps of old trees in thick woods, not far from the ground, and is found from lat. 35° N. to the gulf of Mexico and west to the Mississippi river.

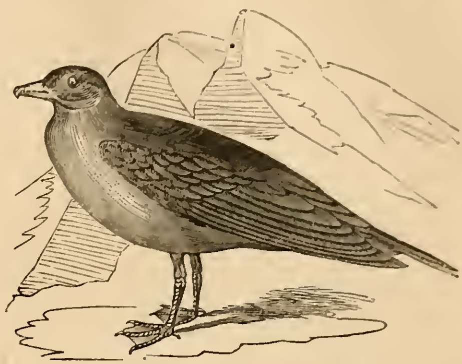
**SKINNER, Thomas Harvey,** an American clergyman, born at Harvey's Neck, N. C., March 7, 1791, died in New York, Feb. 1, 1871. He graduated at Princeton college in 1809, was licensed to preach in December, 1812, and was a pastor in Philadelphia from 1813 to 1832, when he became professor of sacred rhetoric in Andover theological seminary. In 1835 he became pastor of the Mercer street Presbyterian church, New York, and in 1848 professor of sacred rhetoric and pastoral theology in the Union theological seminary. He published "Religion of the Bible" (1839); "Aids in Preaching and Hearing" (1839); "Hints to Christians" (1841); "Thoughts on Evangelizing the World;" "Religious Life of Francis Markoe;" "Vinet's Pastoral Theology," and "Vinet's Homiletics," translated from the French (1854); and "Discussions in Theology" (1868).

**SKIPJACK.** See Bluefish, and Bonito.

**SKOBELEFF, Mikhail Dimitriyevitch.** See p. 890.

**SKRZYNECKI, Jan Boncza,** a Polish soldier, born in Galicia in February, 1786, died in Cracow, Jan. 12, 1860. His military career began in 1806, and he distinguished himself in the Napoleonic wars, and after the Polish revolution of 1830 as brigadier general, especially at Dobre, Wawer, and Grochów (February and March, 1831). He then succeeded Radziwill as commander-in-chief; but waiting in vain for assistance from foreign powers, he failed to follow up his great advantages, and lost the battle of Ostrolenka, May 26. On Aug. 10 he was deposed, and after the fall of Warsaw (Sept. 8) he fled to Austria and next to Belgium. In the latter country he was appointed to a high command in the army, which however, owing to the protests of the eastern powers and the peace of 1839 with Holland, was of short duration. He remained in Brussels until shortly before his death, when he was permitted to return to Poland.

**SKUA,** the common name of the web-footed birds of the gull family, subfamily *lestridinæ*, and genus *stercorarius* (Briss.). The bill is strong, the basal half with a membranous or corneous cere distinct from the tip, the nostrils opening under it in advance of the middle of the bill; the tip is abruptly and strongly curved; the wings very long, the first quill the longest; the tail wedge-shaped, the two central feathers projecting; tarsi strong, with prominent scales; claws sharp and curved, and feet fully webbed, with the hind toe short and but little elevated; body full and stout. They inhabit the high latitudes of both the northern and southern hemispheres; they chase gulls and other marine birds, even the albatross, forcing them to disgorge a part of their food, and are hence called jagers or yagers; they feed also on the carcasses of cetaceans, the eggs and young of sea birds, and the smaller petrels. Their flight is elevated, rapid, long sustained, and generally in circles, as in birds of prey, which they represent among the *natatores;* the nests are made in company, of coarse grass, and are placed on rocks or sand, or in desolate heaths; the eggs are one or two. —The common skua (*S. catarractes*, Temm.), the largest species, is about 2 ft. long, with an alar extent of about 4½ ft.; the bill is 2½ in.; the color above is dark brown, the feathers tipped with gray; wings chocolate brown with the shafts and basal parts white; tail dark brown, white at the base; lower parts dark grayish brown; legs, feet, and bill black, the latter with a tinge of bluish; the central tail feathers project only an inch beyond the others. The favorite haunts of this species are the seas of northern Europe, especially about the Orkney and Shetland islands, where great numbers are killed for their feathers; it has been obtained on the California coast, and either this or a nearly allied species occurs about Cape Horn, the cape of Good Hope, and in the antarctic seas. The arctic skua (*S.* [*lestris*] *parasiticus*, Temm.) is 21 in. long and 44 in. in extent of wings; the central tail feathers extend about 3 in. beyond the others, and are pointed at the end. This species breeds in arctic America, coming down as



Common Skua (Stercorarius catarractes).

far as New York in summer and to the gulf of Mexico in winter; it breeds also in the Orkney and Shetland islands.

**SKULL.** See COMPARATIVE ANATOMY, and SKELETON.

**SKULLCAP,** the common name for plants of the labiate family of the genus *scutellaria*, the botanical name being derived from Lat. *scutella*, a dish, as the fruiting calyx has an appendage which closes it; this appendage has also suggested the popular name skullcap. The skullcaps are perennial herbs, destitute of the aromatic qualities usually found in the order; they are widely distributed over the temperate and subtropical countries, and some of the Mexican and South American species are sometimes met with as greenhouse plants. Eight or ten species are found in our northern states. The common skullcap (*S. galericulata*), common also in Europe, is very frequent in wet and shady places, and is quite showy; it has had a medicinal reputation, as has a still more common species, *S. lateriflora*, which under the name of mad-dog skullcap was some years ago used as a pretended remedy for hydrophobia. The plants are of interest to the botanist, but of no medicinal value.

Common Skullcap (Scutellaria galericulata).

**SKUNK,** an American carnivorous mammal of the weasel family, badger subfamily, and genus *mephitis* (Cuv.). It may be distinguished from its congeners by a more slender and elongated body, pointed nose, feet adapted for digging, with the anterior claws the longest and the soles usually naked, and a long bushy tail. The cheek teeth are $\frac{4-4}{5-5}$, the upper posterior being very large and nearly square; the head is small, with a projecting naked nose, small and piercing eyes, and short and rounded ears; the feet are short, with five closely united toes; the palms naked and the soles mostly so; they are essentially plantigrade, and walk with the back much arched and the tail erect; they are nocturnal, and feed on animal substances. Though weak, timid, and slow in their motions, they are effectually armed against the most ferocious enemies in an acrid and exceedingly offensive fluid secreted by glands whose ducts open near the anus; these glands are surrounded by a thick muscular covering, the contractions of which are sufficient to eject the fluid to a distance of 14 ft.—The common skunk (*M. mephitica*, Shaw; *M. chinga*, Tiedm.) is from 16½ to 20 in. long, the tail being 13 or 14 in. additional; the prevailing color is black, with a narrow line on the forehead, broad triangular patch on nape continuous with a narrow line on each side of the back, and tail tuft, white; the variation is considerable, the white markings being wider in some specimens, and in others wanting; the posterior third of the soles is hairy. When about to use its natural means of defence, it raises its tail over the back, and ejects the secretion in two thread-like streams with great force and accuracy; it can also diffuse it in a fine spray on near objects; it is almost impossible to remove the odor from clothes impregnated with it, and a dog which has been touched by it is a nuisance for weeks; it is said to be phosphorescent at night. It is a very cleanly animal, and never allows its own

Common Skunk (Mephitis mephitica).

fur to be soiled with its secretion. It sometimes commits havoc among hens, chickens, and eggs, but is far less injurious than the mink and weasels, and from its clumsiness is more easily detected; it feeds on small quadrupeds and birds, reptiles, insects, nuts, and fruits. It has from six to nine young at a time, and would prove exceedingly annoying were not great numbers killed by dogs and carnivorous mammals and birds, and caught in traps at the mouths of their burrows, which are generally near the surface, in level ground, and 6 to 8 ft. in extent. They remain in their burrows in the northern states from December to the middle of February, laying up no winter stores, but retiring in a very fat condition, and remaining dull and inactive, though not properly hibernating. This species is abundant in the northern and middle states, and found from lat. 57° N. to Florida and Louisiana, and west to the Mississippi river. Its flesh is white and fat, and if properly skinned in no way tainted by its secretion; it is highly esteemed by the Indians, and is eaten by the whites in various parts of the country; the oil, nearly pure oleine, is excellent for leather, but is of no special use in medicine; the fur is rather coarse, but is sometimes used for common purposes, and of late years thousands of skins have been annually carried to Europe, where they make their appearance in various disguises. The secretion has been successfully employed in some forms of asthma, in the dose of a drop three times a day, though it so taints the patient's excretions that the remedy is generally considered worse than the disease; it has also been used as a powerful antispasmodic in asthma, hysteria, and other nervous disorders, applied to the nostrils.—There are several other species in the United States, especially in Texas and California. In an article in the "American Journal of Science" for May, 1874, Mr. Hovey says that this animal is very dangerous in the western states. It is often affected by a disease which renders its saliva so poisonous that its bite is more to be feared than that of the rattlesnake. He gives many instances in which persons sleeping on the ground have been bitten, generally with fatal, and always with dangerous consequences.

**SKUNK CABBAGE,** a plant the peculiar odor and the large clusters of luxuriant leaves of which readily suggested the common name. Botanically it has received the names *pothos*, *ictodes*, *dracontium*, and others, but botanists have finally settled upon *symplocarpus* (Gr. *συμπλοκή*, connection, and *καρπός*, fruit, in reference to the manner in which the ovaries form a connected or compound fruit). In all the different genera in which it has been placed, it retained the descriptive specific name *fœtidus*. It belongs to the arum family, which is well known through its handsome exotic representative *Richardia*, the calla lily, or lily of the Nile. The skunk cabbage is one of our very earliest spring flowers, and appears in wet places from New England to North Carolina; the flowers come long before the leaves in the latitude of New York, often as early as February, and they are very abundant in March and

April. The plant is an endogen, and its perfect flowers have four petals each, with as many opposite stamens, and a simple pistil with a one-ovuled ovary, which has a four-angled style.

Skunk Cabbage (Symplocarpus fœtidus).

These flowers are crowded in a dense globular cluster upon a short stem or spadix, and the cluster is surrounded by a peculiar, shell-formed hood or spathe, with an incurved point and of the shape shown in the engraving; this hood is sometimes of a dark lurid purple color, but is more frequently striped and spotted with yellow and purple, and sometimes varied with blotches of green and red. The hoods may be found long before the leaves appear, as these seem to require warm weather for their luxuriant growth; but they grow very rapidly when they start, and are heart-shaped, on short petioles and 1 to 2 ft. long; they form large clusters, which disappear very suddenly after midsummer, the spathe around the flowers having decayed much earlier. The fruit is a large oval fleshy mass, consisting of the purplish and green, berry-like seeds immersed in the enlarged spadix. All parts of the plant have a strong and strikingly skunk-like odor, which has been likened to a combination of garlic and asafœtida; the seeds are odorless when whole, but very strong when bruised. The root has been used as a stimulant and expectorant, but it rapidly deteriorates when dried. The leaves are sometimes used to dress blisters to keep up the discharge.

**SKYE,** the largest island of the inner Hebrides, off the W. coast of Scotland, forming part of Inverness-shire, from the mainland of which it is separated by the narrow strait of Loch Alsh; area, 535 sq. m.; pop. in 1871, 17,330. The surface is mountainous. In the centre of the island the Cuchullin or Coolin hills and other summits rise to the height of 2,000 and 3,000 ft. above the sea. The shores, especially in the north, are very bold and picturesque, and are indented by many inlets or lochs. In the northeast are basaltic columns equal to those at Staffa, and caves, some of which abound with stalactites of great beauty. Soapstone, manganese, jet, and some coal are found, but none of them are productively worked. White and variegated marble is quarried. The climate is variable; on the higher portions the snow lies long, and when it melts there are heavy rains. The soil is poor and the productions scanty. The greater part of it is in pasture, and devoted to the rearing of cattle and sheep. Large plantations of trees have lately been made. Red deer and game are abundant. The well known Skye terrier is raised here. The fisheries, especially in the sounds between the island and the mainland, furnish employment and subsistence to a large proportion of the inhabitants. The manufacture of kelp, once extensive, is now nearly extinct; there are no other manufactures, and very little trade. The people are of Gaelic origin; they are peaceable and moral, but indolent and generally poor. The island contains many Danish antiquities. The greater part of the land belongs to Lord Macdonald and the Macleod family. Skye was the home of Flora Macdonald, who died here in 1790. The principal port is Portree, which has an excellent harbor.

**SKYLARK.** See Lark.

**SLANDER,** in law, defamatory words falsely and maliciously spoken, and injurious either in fact or in legal presumption. It is actionable slander: 1, to speak of one thus falsely and maliciously words importing his guiltiness of an offence involving moral turpitude or punishable by law; 2, to charge him with having such an infectious, or perhaps disgusting disease as, if known, would probably cause his exclusion from society; 3, to use in regard to one in office, or of a person in reference to his profession, trade, or business, such language as has a natural tendency to cause him damage or loss, either because the language implies the lack of some requisite qualification for the occupation or profession, or because it implies insolvency or some positive misconduct or dishonest practice in the business or calling; 4, to speak words which, though not naturally or presumptively productive of loss, have nevertheless caused actual damage to the person slandered. Of these four classes of slanderous words, the first, second, and third include those that are actionable *per se*, or of themselves; that is to say, if the plaintiff proves that the words were spoken, he recovers damages without proving any particular loss. An action lies for words of the fourth class only when the plaintiff can prove express and special damage.—Of the form of slander which imputes guiltiness of crime, it is to be observed that the immediate ground on which the law founds the action is that injury to the party's reputation and his consequent degradation in society which is the natural and immediate incident of criminal guilt.

The words must therefore suggest an offence which subjects the party to a criminal prosecution and to infamous punishment. If the penalty for an offence is merely pecuniary, it does not appear that an action will lie for charging it, even though in default of payment imprisonment should be prescribed by the statute, the imprisonment not being the primary and immediate punishment of the offence. But the words will be actionable in themselves in case the charge, if true, will make the party charged liable to an indictment for a crime involving moral turpitude or subjecting him to an infamous punishment. Thus, to charge forgery or counterfeiting, keeping a bawdy house, bribery at an election, and the soliciting one to commit murder, are all actionable slanders *per se*, for they suggest both moral turpitude and an indictable offence. For the same reason it is actionable *per se* not only to say that one has done enough to send him to the penitentiary, but to say that he has already been there. But to allege that one lives by imposture imputes indeed moral turpitude, but not an indictable offence, and is consequently not slanderous *per se*, or without proof of actual damage. Words alleging perjury are actionable of themselves. The language must of course either express or imply all that is essential to constitute the crime, to wit, a judicial proceeding, material testimony, and the other essential elements of perjury. A charge of false swearing which does not expressly or impliedly comprehend all these points is not slanderous. Theft is an indictable and infamous offence, and the false and malicious imputation of it is actionable without proof of damage. One may sometimes call another a thief, just as he calls him scoundrel, liar, or cheat, by way of general abuse, and without any intention of charging the crime of larceny to him. If the defendant can show this clearly, he may defeat the presumption which the law always makes of a slanderous quality and intent in the word. Where fornication is made punishable by statute, as in most of the states, it is slanderous *per se* to charge unchastity. It was not so at the common law, but the hardship, and indeed the absurdity of this rule, when the consequences to a woman are considered, are so manifest that it has quite generally been changed by statutes in the several states. Words charging disease are actionable only when they imply that the disease now exists.—The third class of slanderous words includes those imputations which affect one's official, professional, or business character. To be actionable of themselves, the words must immediately contemplate and touch these relations; for it is invariably held that where the words complained of, though calculated in every respect to cause the forfeiture of an office or the loss of the income of a profession or business, are nevertheless not in fact applied to the conduct of the plaintiff in his office or business, the action for slander fails. But words which necessarily, even if not in terms, refer to and affect one's business relations, may be held slanderous; as to say, for example, in reply to an inquiry about failures, "I understand there is trouble with the Smiths," or "B owes more money than he is worth, and is broken." So it is slanderous *per se* to say that a trader is insolvent, that X keeps none but rotten goods, that Y uses filthy water in making his beer, or that Z keeps false books, where keeping books is a necessary incident to the business. It is slander to charge an attorney or physician with general ignorance or unskilfulness in his profession; and words which of themselves allege ignorance or unskilfulness in a particular case may be actionable if they fairly imply general disqualification in these respects.—The fourth class includes those words for which an action lies if special damage be proved. Thus, to say of another that he is a knave, a blackleg, a liar, a cheat, or a scoundrel, is generally not actionable. If, however, the speaking of these or the like defamatory words has wrought the plaintiff particular pecuniary loss, he can recover damages.—In all cases in which an action for slander lies, an essential principle on which the action rests is that the speaking of words false in fact and injurious to the reputation of another is malicious. By malice in this place is to be understood, not that disposition of ill will, spite, or revenge which in common parlance the word implies, but that legal malice which is the presumption and conclusion of the law from the fact of the deliberate and unqualified statement of false and defamatory matter, without cause or justification. Where these elements coincide, the law implies the malice, and the slander is complete. It is the corollary of this conception of slander that a defendant cannot justify the speaking of the slanderous words by the plea that he merely repeated the language of another. Formerly, indeed, it was held, on the authority of an old case in Coke, that if the defendant, at the time of uttering the words complained of, named his informant and gave his precise language, so as to furnish the plaintiff with a good cause of action against him, these facts might be pleaded as presumptive proof that the defendant did not utter the slanderous words maliciously. But the latest English cases hold that the defendant's plea must go further, and must show in addition to the facts just mentioned that he believed the charge to be true, and repeated it with a justifiable intent and on a justifiable occasion. The American rule is at least equally strict, and until the legal presumption of malice is rebutted by showing a justifiable intent and justifiable occasion, the uttering or repeating of slanderous words is actionable. To refrain altogether from the repetition of such words is the only way to be entirely safe. The presumption of legal malice is defeated when the otherwise slanderous language is employed upon a just occasion, in the discharge of a duty or in the protection of an

interest. Such communications as these are said to be privileged, and the burden of showing express malice is thrown upon the plaintiff. In a leading case upon this subject in the supreme court of the United States, privileged communications were divided into four classes, viz.: 1, publications duly made in the ordinary mode of parliamentary proceedings; 2, words used in the course of legal or judicial proceedings; 3, anything said or written by a master in giving the character of a servant who has been in his employment; 4, words used by any one in good faith in the discharge of any public or private duty, legal or moral, or in the prosecution of his own rights or interests. With reference to the first of these classes, the exemption from liability for any words spoken in debate is expressly provided by the constitution of the United States, and is probably repeated in the declaration of rights in the constitution of every state in the Union. The exemption extends to everything said or done by a representative in the discharge of his office, whether in debate in open session of the house, or more privately out of the house in committee, or even during the ordinary adjournment of the sessions. On the same principle, namely, the public interest in the prompt, unembarrassed, and efficient administration of the laws, all language spoken in good faith in the course of legal proceedings before a competent jurisdiction, pertinent in any wise to the matter in question, enjoys perfect immunity. The benefit of the privilege is secured alike to the parties, the counsel, the witnesses, the judges, and the jury. As to statements made by masters in reference to the character of their servants, good faith will be presumed, and it is for the servant to negative the presumption. Malice will be implied if he shows the falsehood of the charge; and there may be a *prima facie* presumption of malice if a master volunteered the unfavorable statement respecting his discarded servant.—In a civil action for slander, the truth of the facts imputed may be pleaded by the defendant in justification. If the plea is maintained by proof, the action is defeated; for the principle is, that if the plaintiff is guilty of the whole matter charged to him, he has sustained no injury and has therefore no valid claim for damages. The amount of the damages lies almost entirely within the discretion of the jury. They may give punitory or vindictive damages in cases of wanton and unqualified malice; and even though the amount may seem excessive, yet the court will not generally set the verdict aside, unless it shall be plain that the jury was influenced by improper motives or was misled by some gross error.

**SLANG**, a burlesque or colloquial form of expression, the language of low humor, or the jargon of thieves and vagrants. Slang is probably as old as human speech. We find traces of it in many of the early writers, particularly the Greek and Roman dramatists; and the works of Aristophanes, Plautus, Terence, and Martial abound with words which the purists of their day would not have recognized. All modern European languages have their vulgar or slang dialects, and some of them more than one; and in several countries the thieves' jargon has been reduced to grammatical rules and has a literature of its own. The language used by the English criminal classes is called more properly cant, but slang and cant have borrowed so many terms from each other that it is almost impossible to distinguish them. It is equally difficult to draw the line between slang and pure language, for very many words, illegitimate in origin, have become classical by prescription. The word slang is supposed to be of gypsy origin, and to have been used as a synonyme of Romany or Bohemian, the Zingari or gypsy tongue. Gibberish was used in nearly the same sense. The gypsies probably entered England in the beginning of the 16th century. They came as conjurers and jugglers, professing the gifts of palmistry and second sight, and speaking a secret language. They met with favor among the lower classes, and speedily found many imitators, who adopted their habits and many words of their language, while the gypsies added to their own vocabulary numerous terms and phrases of English vagabondage. Thus between them was formed a kind of slang compromise, out of which eventually grew the conglomerate jargon called variously the canting language, peddlers' French, thieves' Latin, and St. Giles's Greek. The earliest collection of English cant words is contained in "A Caueat for commen Cvrsetors vulgarely called Vagabones," by Thomas Harman (4to, London, 1567). Harman fell into such disrepute with thieves and vagrants for his exposure of their secret tricks, words, and signs, that his name became the cant synonyme for a constable and the stocks. "The Belman of London, bringing to Light the most notorious Villanies now practised in the Kingdome," by Thomas Decker (4to, London, 1608), professes to give an account of the cant of thieves and vagabonds, and contains much curious information. The civil wars brought into common use many slang and cant terms, but it was reserved for the court of Charles II., in which coarse wit was the fashion, to bring slang to a perfection before unknown. Lords and ladies talked slang, and much of the literature of the time is filled with it. Butler's "Hudibras," according to a contemporary writer, was the chief entertainment of Charles II., who often quoted it. In the time of George III. and the regency, the current slang was known as "flash," and sometimes as the language of "gig." The most important of the early collections of slang and cant words, and that on which almost all later works have been founded, is Francis Grose's "Classical Dictionary of the Vulgar Tongue" (8vo, London, 1785), containing all the cant and slang of the earlier glossaries, and

all the vulgar, flash, and indecent terms of the author's time. It has been several times reprinted; the best edition is by Pierce Egan, with additions (8vo, 1823). A "Slang Dictionary" was published in London in 1860, and a revised edition of it in 1875. The earliest work on American vulgarisms is the Rev. Dr. John Witherspoon's "Essays on Americanisms, Perversions of Language in the United States, Cant Phrases," &c. (Philadelphia, 1801), originally published in a periodical called "The Druid" in 1761.—Slang, considered as the generic term for all illegitimate words and phrases, consists partly of words derived directly from thieves' cant and foreign languages, partly of old words with new adaptations, and partly of new words and expressions coined to meet new conditions. Many of the most common slang words were originally thieves' cant, and have been in use for centuries. Among these are "cove" or "covey," a boy or man; "darbies," handcuffs; "doxy," a strumpet, a tramp's female companion; "duds," clothes; "fence," a receiver of stolen goods; "glim," a light; "mug," the mouth or face; "nob," the head; "swag," booty or property; "tog," a coat; and "wipe," a pocket handkerchief. Of words derived from the gypsies are "bosh," nonsense; "cheese," anything good or genuine; "pal," a friend or accomplice; "rum," good (man or thing); and "snack," a share of plunder. Besides what English slang has drawn from the Celtic, Gaelic, Saxon, and Norman French, it derives many words from other European tongues, including the ancient Greek and Latin, and from several of the eastern languages, notably the various East Indian dialects, the Persian, and the Chinese. Among the words borrowed from the French are: "cahoot" (*cohorte*), to keep company; "spree" (*esprit*), a carousal; and "feele" (*fille*), a girl; from the Spanish: "savvey" (*sabe*), to know; "vamose" and "mosey" (*vamos*), to go; and "cavort" (*cavar*), to caper; from the German: "loafer" (*Läufer*), an idle fellow; "frow" (*Frau*), a wife; and "bower" (*Bauer*), used in right and left bower in cards; and from the Dutch: "boosey" (*buizen*), drunk; "logy" (*log*), dull, heavy; "boss" (*baas*), a master or head; and "landlubber" (*landlooper*), a vagabond. The East Indian tongues contribute "tiffin," breakfast or lunch; "dungaree," poor, motley; and "chit," a letter; and the Chinese, "chop," used in such expressions as "first chop," "second chop"; "kootoo" or "kotow," to cringe to, to flatter; and "pigeon," the Chinese pronunciation of business, used in the expression "pigeon English." The *lingua Franca*, or bastard Italian, spoken in the Mediterranean seaports, which is a barbarous compound of most of the languages used along the shores of that sea, has also contributed largely to English slang. Of old words invested with new meanings, some of the most common are: "bleed," to pay or lose money; "blow," to vaunt or boast; "bolt," to leave, to run away; "do," to cheat, as "to do one out of his money," &c. The verb "to go" furnishes numerous slang phrases, as "go it strong," "go back on," "go ahead," "go for one," "go through," "go by," "go the whole hog," "great go," "little go," "rum go," "pretty go," a "go" of liquor, &c.; and "let" almost as many, as "let slide," "let rip," "let up," "let on," "let out," "let in," "let drive," "let alone," "let the cat out," &c. Many of these, although properly slang, have acquired through constant use a right to a place in the language, and may be regarded as good "dialect" English. To this class also belong many of the words usually called Americanisms, which had their origin in this country and have a flavor of our institutions, such as "log-rolling," "wire-pulling," "axe-grinding," "pipe-laying," "filibustering," "mudsill," "mean white," "doughface," "jayhawker," "bushwhacker," "copperhead," "carpet-bagger," "shinplaster," "stamp," "greenback," "copper," "nickel," &c. The fashionable affectation too of using French words, with meanings which would not be recognized in Paris, as "on the *tapis*," "to *chaperon*," "*beau monde*," "*thé dansant*," may be relegated to this department of slang. America is responsible also for very many of the new words coined to meet new conditions, such as "caboodle," "calithumps," "contraptions," "highfalutin," "hunkydory," "shenanigan," "spondulicks," "skedaddle," "scalawag," and such corruptions as "slantindicular," "rambumptious," and "splendiferous." (See AMERICANISMS.) Every business, vocation, and profession has its slang, and every notable civil event and political convulsion furnishes new phrases and words, most of which are ephemeral. The press and the theatre are prolific coiners, and the university, the army, the exchange (see STOCK EXCHANGE), politics, fashion, the prize ring (see PUGILISM), and the turf are all responsible for a large share of the current slang of the day. The sea too is no less profuse in illegitimate expressions than the land, and sailors' slang is proverbial.—In France the jargon of the thieves and vagrants, which is called *argot*, is a comprehensive language, with a grammar and literature of its own. Argot has been traced as far back as the 14th century according to some authors, but others believe that it originated with the gypsies, who appeared in Paris in the first half of the 15th century. One of the earliest works on it is *Le jargon, ou langage de l'argot réformé*, &c. (Troyes, 1660). In 1827 a dictionary of argot was published in Paris; but the prosperity of argot literature dates rather from the publication in 1837 of Vidocq's work on thieves, containing the argot dictionary, which he began in 1819. Since then many other works have appeared, of which one of the most valuable is Michel's *Études de philologie comparée sur l'argot*, &c. (Paris, 1856). Argot has found a conspicuous place in modern

French novels, especially in Sue's *Mystères de Paris;* indeed, the language of some of the characters in that work was so difficult to understand that it was found necessary to publish a *Dictionnaire complet de l'argot employé dans les Mystères de Paris.* Some of the argot words are very expressive: thus, God is *Mec des mecs* (*Maître des maîtres*, Master of masters); the devil, *boulanger* (baker); prison, *collége* or *abbaye de sots* (college, fools' abbey); the gibbet, *veuve* (widow); to suffer capital punishment, *épouser la veuve* (to marry the widow); a café, *bocard* (stamping mill); to eat, *jouer des dominos* (to play dominoes); an omnibus, *four banal* or *face à face* (parish oven, face to face); the sea, *la grande tasse* (the big cup); rain, *bouillon de chien* (dog soup); the moon, *moucharde* or *cafarde* (female spy, hypocrite); an Englishman, *goddem*, *rosbif*, &c.—In Spain the slang language is called *germania* (Lat. *germanus*, a full brother, hence faithful, true), from the brotherhoods or associations of thieves who make use of it. Some, with less probability, refer the name to the German origin of the earliest associations in Spain. Cervantes used some of its terms in "Don Quixote" and others of his works, and some are also to be found in the writings of Quevedo. In 1609 Juan Hidalgo compiled a book on the subject entitled *Romances de germania de varios autores, con su vocabulario*, &c. In germania a highway robber is called picturesquely *ermitano de camino* (hermit of the road); death, *cierta* (the certain); suspicion, *espino* (a thorn); a person hanged, *racimo* (bunch of grapes). In Portugal thieves' slang is called *calão*, perhaps from *calar*, to conceal. The slang of the Italian vagrants and thieves is called *furbesco* (from *furbo*, a quack, knave, rogue), and sometimes *gergo*, jargon. Some of its expressions are very suggestive: thus, hell is *calda casa* (hot house); a stone, *artone di calcosa* (earth bread); the mouth, *caverna* (cavern); the nose, *flauto* (flute); the tongue, *ingegnosa* (cunning); the stomach, *fagiana* (bean box); the beard, *bosco di berlo* (face forest).—The thieves' slang of Germany is called *Rothwälsch*, from *roth*, a cant term for vagrant, and *wälsch*, foreign. It is called also *Kokamloschen*, from the Hebrew *'hakham*, adroit, ingenious, and *lashon*, language. It is composed of Low, High, Jew, and gypsy German, has a grammar and almost a literature of its own, and two dialects, one in North and one in South Germany. Among its words are: custom house officer, *Auskätscher* (one who rummages everything); lawyer, *Diftler* (one who finesses); night, *schwarz* (black); priest, *Schwarzfärber* (black dyer); gold, *Fuchs* (fox); sword, *Kehrum* (face about). One of the earliest and most curious books on *Rothwälsch*, entitled *Von den falschen Bettlern und ihrer Büberey* (Wittenberg, 1528), has a preface by Martin Luther. A vocabulary of it was published in 1661, and since that time many other works have appeared.—In Jutland a slang allied to German cant is much spoken. The Czech thieves' cant is called *hantyrka*. The slang language of Holland is the *bargoens* or *dieventael*. In Norway, Sweden, and Denmark, besides the *fantasprog*, spoken of in Sund's work, *Om Fante eller Landstrygerfolket y Norge* (Christiania, 1850), are used the *tatersproget*, or gypsy gibberish, and the *sköiersproget*, the jargon of thieves and vagabonds. Russian thieves make use of different slang dialects, and several of the dissenting religious sects have languages peculiar to themselves. In Albania a slang language made up of a mixture of modern Greek, Wallachian, Italian, and Latin, with a few words of oriental invention, is spoken chiefly by quack doctors. In it the verbs signifying to practise medicine and to cheat are synonymous. Asiatic criminals speak the *balaibalan*, an artificial language made from the Arab, Persian, and Turkish vocabularies. The Indian Thugs speak the *ramaseena* language, a vocabulary and history of which appeared in Calcutta in 1836.

**SLATE,** a rock of no definite composition, distinguished by its structure, which is of parallel sheets or laminæ, easily separated. The term is in common use also applied to various rocks which do not possess the fissile character in so eminent a degree, and which are sometimes distinguished from the true slates by the name of schists; such are the mica, talcose, hornblende, and chlorite schists or slates. Shale differs from slate in its more earthy texture and less tenacity, as well as want of the perfect slaty structure. But its composition is like that of the argillaceous or clay slate, which is the well known roofing and writing slate. This variety, which is the only slate of economical importance, is found among the metamorphic rocks passing into mica slate, and with the strata of the Silurian period, and sometimes with those of still later origin. It is eminently characterized by splitting with ease into large smooth plates, which have a uniform degree of hardness, possess a dull or feeble lustre, and are blackish gray, bluish black, bluish or reddish brown, purplish, or greenish. The rock is often traversed by thin seams of quartz, but the prepared slates should be entirely free from foreign minerals, and especially from iron pyrites, which are too often seen in yellow cubical crystals scattered over the surface of what would otherwise be excellent roofing slates. Such are unfit for writing or school slates; and for roofing slates they are objectionable on account of the pyrites weakening the slates, and also being liable to decompose after exposure for some time, and cause unsightly stains of oxide of iron. Carbonate of lime is also sometimes present, and is likewise injurious. The best slates are distinguished by an appearance of compactness and solidity in the blocks, with nothing to suggest their fissile character; and yet this should be so perfect, that when fresh from the quarry these blocks may be split with greater ease than

pine timber, and into sheets of any desired thinness.. The faces should be perfectly smooth and parallel, without any curvatures or irregularities. There should be no lines of cross fracture that should prevent their breaking in any one direction more than another. When one is balanced on the finger and struck with a hammer, it should give a clear ringing sound; and after being dried in an oven and immersed in water, it should absorb but little, as may be ascertained by weighing it before and after immersion. This is an excellent test of the comparative values of different slates. The powder of slates is light gray, and when a pointed piece is rubbed upon a smooth slate surface a portion of the powder remains behind, leaving a plain mark that is easily wiped or washed off. It is this property which renders the slates serviceable for drawing and writing upon. Argillaceous slates, like the clays which they originally were, are essentially composed of silex and alumina, and the following is the result of the analysis of a common Scotch variety: silex, 50 parts in 100; alumina, 27; oxide and sulphate of iron, 11; potash, 4; magnesia, 1; water, 7; carbon, a trace. The slates are found often in beds of great extent, associated with other beds of similar character; and this singular feature is observed in the structure of the rocks, that the cleavage, or lines along which the slates naturally separate, has no relation to the lines of stratification. However much the beds themselves may be contorted and follow irregular waving planes, each system of cleavage lines, in case there are more than one, as sometimes occurs, maintains its own direction and rarely coincides with the plane of dip. It is evident that the cleavage seams must have been produced subsequently to the time when the beds acquired their final position. This structure is what is known as slaty cleavage; and sometimes when the strata are themselves thinly bedded and the stratification is regular over extended areas, it is not easy to distinguish immediately the two sets of planes one from the other.—Slates are quarried either by blasting out large slabs, or, when practicable, splitting them off with gads and large wedges. The slabs from a foot to a foot and a half thick, and it may be 8 or 10 ft. long and 1 or 2 ft. wide, are set on edge, and grooves are cut across the top and down the sides to determine the lines of fracture for separating them into rectangular blocks, which is done by blows from a wooden beetle directed upon the top near the furrow. The splitting is effected by driving wide, thin chisels between the laminæ, and the sizes of the slates are reduced whenever desirable by cutting cross grooves and then breaking the pieces with the chisel. When reduced to the required thinness, the slates are roughly dressed over the edge of a block of wood by the blows of a sort of chopping knife called a sack, sax, or zax. On the back of this tool is a sharp tapering steel point, with which the workman when preparing roofing slates pecks two holes through the slates near what is to be the head or upper edge, for the nails which are to hold it down to the roof. In Vermont machines have been applied to cutting grooves in the slate in the ledge to facilitate the quarrying, and the cutting and trimming are also done by machinery. It is important that all this work should be done while the blocks are fresh from the quarry, as in drying they are apt to lose their property of splitting freely, though freezing may restore this; but a succession of frosts and thaws has the effect of thorough seasoning. Slabs for internal decoration, as mantelpieces, and for articles of furniture, as table tops, billiard tables, sinks, &c., are cut by circular saws which are made to revolve slowly. The sheets when thus squared to suitable sizes are planed in machines similar to those used for planing metals; and pieces for mouldings are shaped by tools of the desired figure. Various ornamental articles are prepared of slate in imitation of marbles, granites, and other stones, by the application of colors, which are baked in, varnished, and polished, the applications being several times repeated. (See Enamelling, vol. vi., p. 591.)—Slate Pencils are made from argillaceous slate rock, sometimes from talcose slate, and sometimes from various materials ground together and compressed. Near the town of Castleton, and near one extremity of the western Vermont slate belt, is found an argillaceous slate from which the finest pencils are made. The stone is sawed into blocks 7 in. long by 6 in. wide, and split into slabs a little more than a quarter of an inch thick. These are then planed and placed in a machine, in which a series of grooved knives cut through one half the thickness of the slab, when it is placed in a second machine having a bed with grooves corresponding to the sides of the pencils cut, and a cutter like the one in the first machine completes the operation. The pencils are then counted and put up in boxes of 100 each, and packed in cases of 10,000. There are three sizes, 6, 5, and 4 in. in length. The waste of this slate has been utilized by grinding it into flour and making it into artificial pencils.

**SLATER, Samuel,** an American manufacturer, born at Belper, Derbyshire, England, June 9, 1768, died at Webster, Mass., April 21, 1835. He was apprenticed to cotton spinning under Jedidiah Strutt, partner of Arkwright, and was a favorite with his master. He aided Mr. Strutt in making improvements in his mills, and gained a thorough mastery of the theory and practice of the new manufacture. In 1789 congress passed its first act for the encouragement of manufactures, and the Pennsylvania legislature offered a bounty for the introduction of the Arkwright patents. These laws met the eye of young Slater in an English journal, and he believed himself able to carry the Arkwright cotton manufacture across the Atlantic without drawings or models, the export being forbidden under severe penalties. He arrived

in New York in November, 1789, and learned accidentally that Moses Brown had made some attempts at cotton spinning by machinery in Rhode Island. He wrote to Mr. Brown informing him of what he could do, and received a reply stating that these attempts had not been successful, and adding: "If thou canst do this thing, I invite thee to come to Rhode Island and have the credit and the profit of introducing cotton manufacture into America." Slater proceeded thither, and immediately entered into articles of agreement with William Almy and Smith Brown to construct and operate the new cotton-spinning machinery. On Dec. 21, 1790, he started at Pawtucket three 18-inch carding machines, the necessary drawing heads with two rolls and four processes, the roving cases and winders for the same, and throstle spinning frames of 72 spindles. Reels were soon after made for putting the yarn into skeins, in which form it was then exclusively marketed. The first yarns made on this machinery were equal in quality to the best made at that time in England. The growth of cotton manufacture was for some time necessarily slow, as the cotton was picked by hand in families. Further progress was made some years later when yarn was dyed and distributed in families for weaving. In 1812 Slater began the erection of mills in Oxford (now Webster), Mass., adding in 1815–'16 the manufacture of woollen cloths; and here has grown up the large establishment which still bears his name. He established in 1796, for the improvement of his workpeople, a Sunday school, which was the first or among the first in the United States.

**SLAVE COAST,** a part of the coast of Upper Guinea, W. Africa, between the rivers Volta and Cameroons, comprising a small part of the British Gold Coast protectorate, the coast of Dahomey, the British colony of Lagos, and the coast of Benin and Calabar. It derived its name from the trade in slaves, formerly the chief traffic of the coast. (See Guinea.)

**SLAVERY,** the condition of absolute bondage, in which one person is the unconditional property or chattel of another, and obliged to labor for his master's benefit, without his own consent. It has existed in some form in all nations, and still exists in many countries, though modern slavery differs in several respects from ancient slavery. It was in perfect existence at the dawn of history, and allusions to it are found in some of the earliest extant writings. Kidnapping was a common mode of obtaining slaves for commerce, and it was extensively followed by the Phœnicians as much as 3,000 years ago, and the slave trade was then in full vigor. Slavery first appears in Chinese records about 13 centuries B. C. In India the number of slaves was small, and it has even been asserted that slavery was there prohibited by positive law; but the lower castes could be enslaved for debt. Slavery existed among the Assyrians, the Babylonians, and the Persians after they had become conquerors. The conquering races who established their rule, in succession, in that quarter of the globe, found slavery there existing, and in some instances they increased its extent; but the general tendency of extensive conquests was to lessen the number of slaves, for when different races became subject to the same royal line, and peace prevailed, as in the Persian empire, which extended from the borders of Ethiopia to India, the supplies of slaves were largely cut off, as those supplies were principally obtained through war. The Hebrews had some form of slavery from the time of Abraham. The Mosaic legislation concerning servitude was very mild, and contained numerous important limitations of the rights of masters. In Phœnicia slaves were very numerous, and were extensively employed in all the branches of industry that were pursued by that enterprising people. They formed much the larger part of the populations of such cities as Tyre and Sidon.—Slavery was a firmly established institution of the Hellenic heroic age. It was the consequence of invasion and conquest, and it led to further wars that were waged in order to procure more slaves. Piracy and kidnapping were resorted to for the same object, and no degree of life was exempt from the effects of this state of things. Yet in the heroic age Grecian slavery was mild. "In Homer," it has been truly said, "the condition of the slave seems everywhere tempered by the kindness and indulgence of the master." The condition of women, however, was worse than that of men. The female slaves performed the principal work in the interior of the house. Not only do they seem to have been more harshly treated than the males, but they were charged with the hardest and most exhausting labor which the establishment of a Greek chief required. The treatment of slaves was very different by the different Greek communities. The Athenians were very kind toward them, and throughout Attica prevailed the mildest form of servitude known to the world of antiquity. Athenian legislation protected the personal rights of the slave, and promoted his efforts to obtain freedom. There were both public and private slaves at Athens, the former being the property of the state, some of whom were educated and filled important offices, such as those of secretaries of the commanders and treasurers of the armies. Sparta was regarded by Greece as furnishing the practical antithesis to Athens in the treatment of slaves. The helots of Sparta furnish the type of all that is calamitous among the oppressed, and there is much in Spartan history that justifies this view of their condition. They were slaves of the state, and those by whom they were held could neither liberate them nor sell them out of Laconia. They appear to have occupied some such position as the serfs of the middle ages, but the central authority had more power over them. (See Helots.) The supplies of slaves were obtained

in most parts of Greece through war, commerce, piracy, and kidnapping. There were regular markets for their sale, the principal of which were held at Athens, Samos, and Chios. Negroes were among the slaves imported, Egypt furnishing the larger number of them; and they were valued for their complexion, and considered as luxuries. Most of the domestic and personal slaves were barbarians, that is, persons who were not of Greek blood, for it was the Grecian custom to allow prisoners of their own race to be ransomed. The number of slaves in Greece was very large, and it is even estimated to have been three or four times as great as that of the free population. Unlike the Romans, the Greeks did not seek to possess many slaves from motives of luxury and ostentation, but of profit. Fifty slaves were a large number for a wealthy Athenian to own, while some Romans owned 20,000 each. There were many slaves employed in the mines, but they were of the least valuable kind, and their labor was destructive of life. Most of the slave insurrections in Attica were brought about by the mining slaves, and on one occasion they took possession of Sunium, and held it for some time. The Athenian slaves were not, save on extraordinary occasions, employed as soldiers, like those of the Dorian Greeks. They fought at Marathon and at the Arginusæ, but these were remarkable exceptions. Manumitted slaves in Greece could not become citizens, but became metics, and were still under certain obligations to their former masters, neglect of which made them liable to be sold into slavery again.—In Italy slavery prevailed even more extensively than in Greece, though in the early times, it has been contended, and before the foundation of the Roman dominion, the number of slaves was so small, and they were so well treated, as hardly to deserve the name; but as there is evidence that the Etruscans had negro slaves, the slave trade must have been extensively carried on between Italy and Africa at a remote period. The Romans had slaves at the earliest dates of their annals, and far earlier than that time which is recognized as the beginning of their authentic history; but there was a great difference between the institution as it existed in the opening years of the republic and as it became several generations before the establishment of the imperial rule. As the kingdom of Rome is believed to have been far more powerful than was the Roman republic during the first two centuries of its existence, and had commercial relations with the Carthaginians, the principal slave traders of the time, the just conclusion is that slavery was more extensive under the later kings than it was under the prætors and early consuls. In the early times nearly all the domestics of the Romans were slaves, and so were the majority of the operatives in town; but that excess of agricultural slaves which in later times became a marked feature of Roman industrial life was then unknown. Agriculture was considered an honorable pursuit, and the haughtiest of the patricians often cultivated their fields with their own hands; for they were not all rich, as the story of Cincinnatus shows. The first slaves of the Romans were exclusively prisoners of war made from the peoples in their immediate vicinity, and sold at auction by the state as booty; they strongly resembled their masters, so that their condition was probably not hard; but there was a constant change for the worse as the circle of Roman conquest extended. So long as the wars of the Romans were confined to their own immediate part of the world, the numbers obtained by war could not have been very large; but when their armies began to contend with distant peoples, and to conquer them, they were counted by myriads. They acted on the principle of sparing the humble and subduing the proud, granting both life and liberty to those who surrendered, but taking captive all those who resisted their arms, and consigning such of them to slavery as were not reserved for a fate more immediately severe. The Romans were not sparing in the infliction of this rule of war, and the consequence was, not only that the slave population was rapidly increased, but that it was made to include the most cultivated classes of the most cultivated period of antiquity, as the Roman conquests did not begin until after the highest of ancient races had completed their development. Roman slavery began to assume its great proportions in the same age that saw the beginning of its long quarrel with Carthage, which opened in 264 B. C. When the Romans made their first invasion of Africa, 256 B. C., under Regulus, they landed in a portion of the Carthaginian territory lying between the Hermæan headland and the Lesser Syrtis. This fine country was given up to all the horrors of ancient warfare, "and 20,000 persons, many of them doubtless of the highest condition, and bred up in all the enjoyments of domestic peace and affluence, were carried away as slaves." Most of the captives taken at the conquest of Carthage, who had surrendered, were sold into slavery. This treatment of the Carthaginians, a high-bred and refined people, shows the character of Roman slavery, which was not confined to the barbarous races, or to any peculiar people, but swept all within its nets who could be conquered or purchased. Corinth, one of the richest and most luxurious cities of Greece, was destroyed at the same time with Carthage, and the Corinthians were all sold into slavery; and nothing but the influence of Polybius with the younger Scipio Africanus prevented the entire population of the Peloponnesus from sharing their fate. Two generations earlier, Capua, a city not inferior to Carthage or Corinth in culture, the wealth and magnificence of which were proverbial, had many of its best citizens sold into slavery, their wives and

children being also thus sold; "and it was especially ordered that they should be sold at Rome, lest some of their countrymen or neighbors should purchase them for the purpose of restoring their liberty." After the close of the second Punic war, the conquests of Rome went on with great rapidity, and the numbers of the slave population increased at the same rate, so that in 70 years even the free agricultural population of Italy had mostly disappeared. The absorption of small freeholds in large estates, along with war, led to the decrease of that population, and the places thus made vacant were filled by the purchase of slaves, the latter being taken in war to a considerable extent, though the slave traders were by no means idle. One of the consequences of the successes of Æmilius Paulus in Macedonia was the sale of 150,000 Epirotes, who had been seized because their country was friendly to Perseus. The demand for slaves became very great full two centuries B. C. in Sicily, which had then fallen completely under the Roman dominion, and because corn was much wanted in Italy, then beginning to recover from the effect of the Carthaginian invasion and occupation; and the state of things in Sicily was so favorable to the aggregation of wealth, that it soon extended to Italy, where the land passed into the hands of the few. Great estates succeeding to the many small farms that had been known in the preceding generations, the soil was now cultivated or attended to by great masses of slaves, the property chiefly of the leading members of the *optimates*, or the high aristocratical party. The wars in Spain, Illyria, Greece, Syria, and Macedonia furnished large numbers of slaves, the common sorts of whom were sold at low rates, and were employed in the country. The invasion of the Roman territories by the Teutones and Cimbri, which ended in the total defeat of those barbarians by Marius, added considerably to the number of slaves, 60,000 of the Cimbri alone being taken captive in the last great battle of the war. The conquests of Sulla, Lucullus, and Pompey in Greece and the East, actually flooded the slave markets, so that in the camp of Lucullus, in Pontus, men were sold for four drachmæ each, or about 62 cents of our money. Cicero sold about 10,000 of the inhabitants of the Cilician town of Pindenissus. The Gallic wars of Julius Cæsar furnished almost half a million slaves; and Augustus sold 36,000 of the Salassi, nearly a fourth of whom were men of military age. In the Jewish war which ended in the destruction of Jerusalem, 90,000 persons were made captives. But Roman slavery would not have been so comprehensive if the Romans had been compelled to rely solely upon war for slaves. Commerce has been a chief means of feeding slavery from the beginning of the world. Before the Romans had obtained dominion over Italy, they were slave purchasers from the Carthaginians, who drew their principal supplies of men from the interior of Africa, the slave trade of that region, like that of Asia and Greece, being much older than history. Many slaves were obtained by commerce from the East, and the cities on the shores of the Euxine were among the chief slave marts of antiquity far down into the days of the empire. Barbarians of whom the Romans otherwise knew nothing found their way to the imperial city as slaves. At the height of her power Rome had slaves from Britain, Gaul, Scandinavia, Germany, Sarmatia, Dacia, Spain, the different countries of Africa, from Egypt to the Troglodytes of Ethiopia, the western Mediterranean islands, Sicily, Greece, Illyria, Thrace, Macedonia, Bithynia, Phrygia, Cappadocia, Syria, Media, and almost every other country to which ambition or avarice could lead the soldier or the trader to penetrate. All races furnished their contributions to the greatest population of slaves that ever existed under one dominion. Unlike the Greeks, the Romans "acknowledged the general equality of the human species, and confessed the dominion of masters to flow entirely from the will of society;" but this did not prevent them from enslaving all men upon whom they could lay their hands, while they were much harsher toward their slaves than the Greeks were. Not a few slaves were procured by kidnapping persons, and it was notorious that even Roman freemen were seized and shut up in the *ergastula* of the great proprietors, which invasion of personal rights the whole power of the government was unable to prevent. Children were sometimes sold into slavery by their parents, either from love of gain or to save them from starvation; and the number of these sales was large in times of general distress. Men were also sold for debts due to the imperial treasury. Under a variety of circumstances poor people could sell themselves into slavery, but such sales were not irrevocable until the second century of the empire, and then the law was somewhat limited, the object being to punish those who had sold themselves with the intention of reclaiming their freedom, the purchaser in such cases having no redress. Romans who had committed crimes that were ignominiously punished became slaves through that fact, and were known as *servi pœnæ*, or slaves of punishment, and were public property. They remained slaves even if pardoned, unless specially restored to citizenship; and it was not until the reign of Justinian that this form of slavery was abolished. In early times, persons who did not give in their names for enrolment in the public force were sold into slavery, after being beaten; and incorrect returns to the censors led to the same punishment. Poor thieves, who could not make a fourfold return of the amount of their booty, became slaves to the party stolen from; and a father could give up a child who had stolen to the prosecutor. Poor debtors were sold as slaves.—The em-

ployments of Roman slaves, both public and private, were very various, and were minutely subdivided. Besides filling all the more menial offices, many of them occupied the positions of librarians, readers, reciters, story tellers, journal keepers, amanuenses, physicians and surgeons, architects, diviners, grammarians, penmen, musicians and singers, players, builders, engravers, antiquaries, illuminators, painters, silversmiths, gladiators, charioteers of the circus, &c. Before a slave could become a soldier he was emancipated, and into the Roman armies of the early republic not even freedmen were allowed to enter; but the demand for soldiers did away with this delicacy, and slaves were regularly enlisted in the second Punic war, and did good service to the state. Many of the Roman slaves were on the most intimate terms with their masters, and must have been well treated, or the state of society would have been intolerable; and we read of not a few instances in which the lives of masters were saved by their slaves, in the times of the proscriptions and massacres of Marius and Sulla, and of the triumvirs, and on other occasions. But the masses of the slaves were treated harshly, and the laws and regulations affecting them were mostly severe. The Romans were generally hard masters; and "the original condition of slaves, in relation to freemen, was as low as can be conceived. They were not considered members of the community, in which they had no station nor place. They possessed no rights, and were not deemed persons in law; so that they could neither sue nor be sued in any court of civil judicature, and they could not invoke the protection of the tribunes. So far were these notions carried, that when an alleged slave claimed his freedom on the ground of unjust detention in servitude, he was under the necessity of having a free protector to sue for him, till Justinian dispensed with that formality." Slaves were allowed only a special kind of marriage (*contubernium*), and they had no power over their children. Few of the ties of blood were recognized among them; and they could hold property only by the sanction or tolerance of their masters. The criminal law was equally harsh, slaves being treated under it as things, but it was gradually meliorated. The severest and most ignominious punishments were shared by slaves with the vilest malefactors, as crucifixion and hanging, and later they were burned alive. Under the empire the condition of the slaves was better than it had been under the republic. The emperors were, however, far from pursuing a uniform policy toward the servile class, and some of them even restored cruel laws that had been abolished. In theory Roman slavery was perpetual, and to this theory the practice conformed, inasmuch as by no act of his own could the slave become free. Freedom could proceed only from the action of the master. Manumission was not uncommon, and there were numerous freedmen who exercised much influence, as well in public life as in families. Freedom was the reward of good conduct, and the ease with which the places of freed slaves could be filled up by new purchases made manumission much more frequent than it would have been under other circumstances. Dying masters freed slaves by the hundred, in order that they might swell their funeral processions. On joyful occasions a wealthy master would manumit many of his slaves. Sometimes slaves were liberated in the article of death, in order that they might die in freedom. Manumission was often the result of agreement between masters and slaves, the latter either purchasing freedom with money, or binding themselves to pursue certain courses that should be for their former owner's interest. The republican period was favorable to emancipation, and freedmen were so numerous at the formation of the empire that some of the early emperors sought to restrict manumission, less however to promote the interest of slaveholders, or to increase the number of slaves, than for the purpose of increasing the numbers of the ingenuous class, an object much thought of and aimed at by several generations of Roman statesmen, but always without success. The later emperors favored emancipation, particularly after they had become Christian; and Justinian removed nearly every obstacle to it. Augustus labored strenuously to limit emancipation, but even he had recourse to the society of freedmen, in accordance with a custom of the great men of his country; and in 30 years after his death the Roman world was governed by members of that class of persons. Julius Cæsar employed no freedmen, and Tiberius employed but few, and gave them none of his confidence, thus imitating Cæsar rather than Augustus; and even Caligula used them but little. Claudius they ruled, and through him the empire.—It is impossible to estimate with an approach to accuracy the number of Roman slaves. Gibbon thought it was equal to that of the free population, which Zumpt pronounces a "gross error;" and Blair estimates that during the 14 generations that followed the conquest of Greece, there were three slaves to one freeman. Gibbon's estimate, which applies to the reign of Claudius, would give 60,000,000, and probably it is not far from the truth, though we may agree with Blair that it seems much too low for those places which were inhabited by Romans properly so called. Many individuals owned immense numbers, though the figures in some of these cases are perhaps exaggerated, or the results of the mistakes of copyists. The prices of slaves were not fixed. Good doctors, actors, cooks, beautiful women, and skilled artists brought heavy sums, and "ruled high;" and so did handsome boys, eunuchs, and fools. Learned men, grammarians, and rhetoricians also sold at high rates. Some descriptions of artisans and laborers

would sell at good prices, upward of $300 of our money each; but $100 was a fair average price for a common slave, and when a slave could be bought for about half that sum the price was held to be low. Insurrections and servile wars were not uncommon. Two such wars broke out in Sicily after the conquest of that island by the Romans, and were extinguished only in the blood of myriads of men, and through the exertions of consular armies. Toward the close of the 7th century of Rome the war of the gladiators, waged on the one side by slaves alone, from general to camp servants, brought the republic to the verge of ruin. The war was commenced by a few gladiators from the schools of Capua, under the lead of Spartacus, a Thracian, 73 B. C., and lasted for more than two years. Several Roman armies, commanded by prætors and consuls, were defeated, and for a time the revolted slaves had the peninsula more at their command than it was at the command of the Romans. The country was horribly ravaged, and it was not until Crassus took the field, and 200,000 men were employed, that the insurrection was subdued; and the final battle was won by the Romans more as the consequence of the death of Spartacus before it was half fought than from their superior generalship. Six thousand of the slaves were hanged or crucified after their defeat. The punishment of rebellious slaves was always very severe. Many slaves had enlisted under Sextus Pompey, and thousands of them who fell into the hands of Octavius were sent to the horrible death of the cross, with the general approbation of the citizens. They were crucified solely as fugitives, as all whose masters could be found were restored to them; and the cruel act was perpetrated in violation of plighted faith. It more than once happened that Roman leaders in the civil wars either called upon slaves to rebel, or availed themselves of the services of slaves. Marius, on his return from Africa to Italy, and just before his death, proclaimed liberty to all slaves who would join him, and at least 4,000 enlisted under his banner. Before his exile he had tried the same plan, but without success. The Cornelians of Sulla were 10,000 freed slaves, who had belonged to members of the Marian party that had been proscribed by the conqueror, and who took their appellation from the gentile name of their patron.—The slave trade of antiquity comprehended the whole hemisphere in its circle. Its origin is unknown, for it was practised in all its parts at the earliest period of which any knowledge is to be obtained. The Phœnician slave trade was very extensive, and supplied in part by piracy. They stole Greeks and sold them 12 centuries before Christ, and they also sold stolen people to the Greeks. They had a land traffic in slaves, obtaining them in the countries between the Black and Caspian seas; and they exchanged Hebrew slaves for the productions of Arabia with the Sabæans and Edomites. The Greeks were also great slave traders, and were as skilful in kidnapping persons as were the Phœnicians. Their slave traffic extended to Egypt, Thrace, Phrygia, Lydia, Syria, and other countries. From Egypt they obtained blacks, then regarded as slaves of luxury. Their slaves came mostly from the north and the east. The chief Grecian slave marts were Athens, Samos, Chios, Ephesus, Cyprus, and Corinth. The Carthaginians, who were the Phœnicians of the west, rivalled their progenitors in the extent and comprehensiveness of their slave traffic. They had an immense traffic with the interior of Africa, a caravan trade, like that of the Egyptians and of the Cyrenæans. Women were preferred to men in the trade with the African slave dealers, as they sold for much higher prices in some northern countries. There was a large demand for negroes in the Balearic islands, and especially for women. Corsica also furnished many valuable slaves to the Carthaginians. The Roman slave trade as much exceeded that of any other country of antiquity as the institution of Roman slavery exceeded slavery in other countries. In remoter times the Romans were no better than robbers in their treatment of foreigners, imitating the Etruscans in this respect, who were the worst pirates of antiquity. Corinth had been the chief slave mart of Greece toward the close of its independence, before it fell into the hands of the Romans, and at the time when slavery was beginning to increase rapidly in Italy; and it is supposed, its situation being favorable to trade of the kind, that many slaves were sent thence from the East to the cities on the eastern Italian coast. But the destruction of Corinth by the Romans, 146 B. C., transferred the slave trade to Delos, which became the most noted slave market of that age, though the trade in slaves was but one branch of the immense commerce that centred there. The importance of the slave trade in that island was owing to the Roman demand, as it was most favorably situated to minister to the desire for slaves from eastern countries—Greeks, Syrians, Phrygians, Bithynians, and others. According to Strabo, it was possible, so complete were the arrangements, to import 10,000 slaves in one day, and to export them on the same day. But all this prosperity came to an end when the forces of Mithridates entered Greece. They landed on Delos, and devastated the island, so that it never recovered from their ravages. The Mediterranean pirates had supplied Delos with many slaves; and at Side, in Pamphylia, they had a great market of their own, at which they disposed of their captives, many of whom were captured far inland, even Italy itself not being safe from their ravages, and its villas and highroads furnishing victims to the marauders, who became very powerful during that disturbed period of Roman history in which occurred the social war and the contest between Marius and Sulla. From Alexandria the Romans obtained

slaves, Egyptians and Ethiopians, that city having a great trade in men. Others were drawn from Thrace, which continued to be a slave-breeding country long after the fall of Greece. After the devastation of Delos, the slave trade fell back nearer to its sources, and the Romans obtained slaves direct from the marts on the Euxine, where the trade had existed from time immemorial, being fed by the constant warfare that was waged by the neighboring tribes. Many came from Scythia, and Scythian and slave were all but convertible terms. The Galatians carried on an extensive slave trade; and between Italy and Illyria this commerce was considerable in the first days of the empire. The Roman wars fed the slave trade, and enabled those who carried it on to accumulate immense fortunes. So long as those wars were fought near home, the victors could sell their captives easily, without much aid from traders; but as soon as they extended to any distance from Italy, the trader's aid became necessary. The trader followed the camp, and in the camp the human booty was sold, and often at prices so low as to appear incredible. The Romans neither encouraged nor discouraged the slave trade. They held the slave trader in contempt, and deemed his business utterly unworthy of merchants. Special names were given to such traders, implying that they were necessarily cheats; but their enormous wealth made them powerful.—Slavery is regarded as one of the chief causes of the decline of Rome. The institution existed in all parts of the Roman empire, and prevailed in the countries which were formed from its fragments, though essentially modified by a variety of circumstances. The influence of Christianity upon it was very great. It had indeed existed before the extension of the Roman dominion, and was known to most of the peoples who invaded and overthrew the empire, and on its ruins established the feudal system and serfdom. (See SERF.) The rise of the Saracens tended to increase the number of slaves, and to feed the trade in them, as Christians felt no scruples about enslaving Mussulmans, and the Mussulmans were quite as unscrupulous toward Christians. The wars between the Germans and Slavs furnished so many of the latter race for the market, that the word slave is derived from them. The great commercial republics of Italy were much engaged in slave trading. The Venetians had many slaves, and the history of their commerce shows that they pursued the slave trade with vigor and profit. In spite of the efforts of the popes, they sold Christians to Moslems. Slavery also existed in Florence, though the slaves were almost exclusively Moslems and other unransomed prisoners of war. In England, under the Saxons, the slave trade flourished, Bristol being the chief mart, whence many slaves were exported to Ireland. But in this island slaveholding was never very popular, and the Irish early emancipated their bondmen.—At the close of the middle ages two peculiar forms of slavery and the slave trade began to be known, one of which has but recently ceased to exist, while the other is not yet entirely extinguished. The new phase of Mohammedanism that came up with the rapid development of the power of the Turks, in the 14th and 15th centuries, nearly synchronizes with the origin and progress of what is known specifically as negro slavery. The Turks completed the establishment of their power in Europe by the conquest of Constantinople in 1453; and not quite 40 years later the last Mussulman state in Spain, Granada, was conquered by the Christians. These two events had a remarkable effect on slavery. The fears of Christendom were excited by the rapid and sweeping successes of the Turks, and the anger of the Mussulmans was roused by the overthrow and enslavement of their brethren in Spain; and from these feelings the system of slavery received an impetus and acquired forms that under other conditions it never could have known. We have seen that the church, at a much earlier period, did not object so much to the traffic in men as to the traffic in Christians, and that lay legislators took the same view of human duties; and it was also the case that the selling of Christians to Moslems was more strictly forbidden than was the selling of Christians to other Christians. The sentiment that prevailed while the Saracens were so strong as to excite fears throughout all Christendom for its safety, was revived in the 15th century, and did not become altogether extinct until after the middle of the 17th. In the East, and for the greater part of the time in most of N. Africa, the Mohammedans were in the ascendant, they having become masters of Barbary and lords of the Levant. Between the Turks on the one side and the Italians and Spaniards on the other the long struggle was principally carried on in the south, the English being too remote from the scene to take much part in it, while the French, though occasionally furnishing some gallant volunteers, were as a nation the friends and sometimes the allies of the infidels. The knights of St. John of Jerusalem, first in Palestine, then at Rhodes, and afterward at Malta, carried on perpetual warfare with the Mussulmans. The contending parties divided between them the whole of the sea dominion of the Romans, and the compound rivalry of religion and race doomed multitudes of civilized people to slavery. Men who were taken in war did not alone compose these slaves, but among them were many women and children, the victims of *razzias* that were undertaken by the parties to the bitter and prolonged contest. The light, low vessels of the Mussulmans often ran into the ports of the Spaniards and Italians by night, and plundered and burned them, while the inhabitants were either murdered or carried into captivity. Watch towers were built along the coasts, that the approach of the corsairs might be detected. So marked

a feature of the war then waged was this form of slavery, that it furnished much matter for the romantic literature of southern Europe, in which nothing is more common than incidents connected with bondage in Barbary. Cervantes himself was for five years an Algerine captive, and he formed a project for a slave insurrection, there being 25,000 enslaved Christians at that time in Algiers alone. Enormous numbers of captives were employed as rowers of galleys, Christians on board those of the Mussulmans and Mussulmans on board Christian vessels. When the Turks lost the battle of Lepanto, in 1571, 12,000 Christian captives, galley slaves, were released from the prizes made by the allied fleet. When Charles V. took Tunis, in 1535, 20,000 Christians were released from slavery. Great numbers of women were taken as slaves, and sold in the markets of Turkey and Barbary. The corsairs passed out of the Mediterranean, sailed far to the north, and seized people on the coast of Ireland. This brought upon them punishment from the English, but that did not put an end to their Atlantic cruising. There were some places in Barbary on the Atlantic from which corsairs sailed, and those of Salé were among the most famous of the brotherhood. The European powers made frequent war on the Barbary states; and of the early contests in which the American Union was engaged none were more brilliant than those which it carried on with some of those states, in defence of the liberty and commerce of its citizens. But the jealousies of the European powers prevented them from putting an end to the piracy and slavery of Barbary long after the Turks had ceased to be able to protect the corsairs, and tribute was paid to the petty powers down to the beginning of the 19th century. The successful bombardment of Algiers in 1816, by an English fleet commanded by Lord Exmouth, put an end to white slavery in Barbary, it having previously ceased to exist in the other countries of N. Africa, to which the exploits of the American navy had much contributed, though at first the government of the United States had paid tribute to the pirate chiefs.—At the same time that slavery was acquiring its peculiar form in the countries on the Mediterranean, negro or African slavery came into existence. This form of slavery belongs entirely to modern times. As we know, the slave trade in negroes existed 3,000 years ago at least, and the Carthaginians brought numbers of black slaves from central and southern Africa, by means of their caravan commerce, a mode of traffic that was common long before the Carthaginians had a political existence; but in trading in negroes, the slave traders of antiquity only did that which they did with all other descriptions of men, and as the slave traders of the East have always done until now. The fact that the ancients regarded black slaves as luxuries, proves that their number could not have been large in the European countries to which they were taken, either by the way of Egypt or that of Carthage. Such details as we have concerning the black slaves of antiquity all serve to show that they were not numerous, far less so indeed than were slaves belonging to some of the highest of the white races. They were probably more numerous in the East than in Greece and Italy, and most numerous of all in Egypt and other parts of N. Africa, because of the comparative ease of acquiring them in those countries. The Venetians, who carried on a large trade with Africa, no doubt distributed some negro slaves over the various European nations which they visited. In the Mohammedan countries there have been black slaves from the time of the prophet, and they have often risen very high, as well in the state as in the household. But in all these cases the negro has but shared the common lot, and might have been sold on the same day with the Greek or the Arab, and by the same trader. The negro was then sold, not because he was a negro, but because he was a man whose services could be turned to profitable account. Negro slavery, in its special form, is one of the consequences of that grand movement in behalf of maritime discovery and commerce which began in the 15th century. Portugal took the lead in this movement, which was already prominent more than four centuries ago; and it was headed in that country by Prince Henry, son of John I. In 1441 two of Prince Henry's captains seized some Moors, who were taken to Portugal. The next year these Moors were allowed to ransom themselves, and among the goods given in exchange for them were ten black slaves, whose appearance in Portugal excited general astonishment, and who led the van of the African slave trade. This was openly commenced in 1444, by a company formed at Lagos; and though it is doubtful whether that company was formed expressly to trade in men, and it is by no means certain that the 200 persons whom its agents seized and brought to Europe were negroes, it is from that time that the negro trade is generally dated. The first negroes taken by the Portuguese in the negro country were but four in number, in 1445, and they were rather taken accidentally than of set purpose to make them slaves; but the trade in negroes as slaves was quickly regulated, and a Portuguese factory was established in one of the Arguin islands, where the slave trade had been commenced. Every year 700 or 800 black slaves were sent from this factory to Portugal, while other slaves of the same description from the countries that furnished those sent to Portugal were sold to other traders, who took them to Tunis and to Sicily. But Prince Henry and those who followed in his path did not regard the trade in slaves as a thing to be encouraged. They thought rather of the conversion of the Africans to Christianity, both the Portuguese and Spanish discoverers being enthusiastic propa-

gandists. Had it not been for the discovery of America in 1492, it is altogether probable that the African slave trade would never have exceeded the dimensions it had known in antiquity; and it is believed that between 1455 and 1492 that trade had fallen off considerably, and that the number of negroes taken by the Portuguese for exportation did not exceed 300 or 400 a year. In fact, Europe presented no field for the labor of black slaves, the employment of which must have been confined to the houses of the great, as in the classic times, with rare exceptions. The negro trade was verging to extinction, when the success of the great enterprise of Columbus imparted to it new life, and made it one of the most lucrative branches of commerce.—Soon after the discovery of America the Spaniards began to enslave the natives, large numbers of whom were sent to Spain as slaves in 1495. The system of *repartimientos* (slave distributions) was begun in 1496. Columbus appears to have had no scruples on the subject, and had indeed been engaged in the Portuguese slave trade. He strongly recommended the trade in the cannibal Indians; and the Spanish sovereigns, though in general their legislation was kindly toward the natives, did not discourage his proposition. At a later period Isabella sought to make a distinction between Indians who had been sold into slavery after being taken in war, and others who had been seized in consequence of failure to pay tribute; and she was very angry with "the admiral" for making the seizure, and ordered the sufferers to be released and returned to America. Under the Spanish rule the Indians perished in immense numbers, until they became extinct in the islands, or were absorbed by the other races. Slavery itself was not unknown in America, and had a well defined system in Mexico. The desire of the Spaniards to have laborers, and the inability of the natives to perform the labors required of them, soon led to the sending of negroes to the new world. Interest and humanity promoted their rapid increase in the Spanish colonies. They could perform the work to which the Indians were unequal, and throve under it. The government of Ferdinand feared that the sending of many negroes to America would prove injurious, but Charles V. granted a license to a Fleming to import negroes into the West Indies. Thenceforth the trade went on vigorously. The demand of the colonists for negroes was supported by the benevolent Las Casas, and by other leaders in the Roman Catholic church, who were desirous of preventing the extinction of the Indians. One negro was counted as worth four natives. There was a negro insurrection in Hispaniola as early as 1522. The African slave trade, under such stimulus as was afforded by the American demand, rapidly increased, and England took part in the work of supplying the Spaniards in 1562, previously to which negroes had been landed in England, and there sold, in 1553. Queen Elizabeth is charged with sharing the profits made by Sir John Hawkins, the first Englishman who commanded a regular slave trader. The English were far more cruel traders than the Portuguese. In the times of the Stuarts four English companies were chartered for carrying on the African slave trade, and Charles II. and James II. were members of the fourth company. While duke of York, James II. was at the head of the last company. After the revolution the trade was thrown open to all; and at later periods the royal African company received aid from parliament. These companies furnished negroes to America; and in 1713 the privilege of supplying them to the Spanish colonies was secured to Englishmen for 30 years, during which 144,000 were to be landed. The French, the Dutch, and other European nations engaged in the traffic; and the first slaves brought to the old territory of the United States were sold from a Dutch vessel, which landed 20 at Jamestown, Virginia, in 1619. The culture of cotton began the next year. Slavery soon came into existence in nearly every part of North America, and Indians were enslaved as well as negroes. The son of King Philip was sold as a slave. The trade between North America and Africa was carried on with considerable vigor. Some of the colonies remonstrated against the trade, but without success, as the mother country encouraged it. In 1776 it was resolved by the continental congress that no more slaves should be imported; but when the American constitution was formed, in 1788, congress was prohibited from interdicting the traffic before 1808, at which time it was abolished. The state of Georgia prohibited the slave trade in 1798. America was thus in advance of other countries in fixing a time for the cessation of a traffic which has been as generally condemned as it has been persistently pursued for four centuries. In England the slave trade was early denounced by individuals, but it was regarded by most men as a perfectly legitimate branch of commerce. The last act of the British legislature regulating the slave trade was passed in 1788, the same year that the first parliamentary movement for the abolition of the trade was made. The Quakers were opposed to slavery and the slave trade from the beginning of their existence as a body, but neither their influence nor their numbers were large. English lawyers were nearly unanimous in their support of the legality of slavery, and the trade in negroes was in various ways encouraged by law. In the 18th century a sentiment of hostility to the system of slavery, never altogether unknown since the Christian era, became very common, and was shared by many literary men, philosophers, and statesmen, who labored with zeal for the suppression of the system. Of these, the most noted was Granville Sharp, who exerted himself for half a century in the emancipation cause; and it was chiefly through his labors

that the decision of Lord Mansfield, in the case of Somerset, was given in 1772, that decision being that the master of a slave could not by force compel him to go out of the kingdom. "The power of a master over his slave," the English chief justice of the court of king's bench observed, "has been extremely different in different countries. The state of slavery is of such a nature that it is incapable of being introduced on any reasons, moral or political, but only positive law, which preserves its force long after the reasons, occasions, and time itself from whence it was created are erased from memory. It is so odious that nothing can be suffered to support it but positive law. Whatever inconveniences, therefore, may follow from a decision, I cannot say this case is allowed or approved by the law of England, and therefore the black must be discharged." Lord Mansfield's decision has been greatly overrated as to the importance of its terms, and it is incorrect to say that it was the first in the order of time. More than ten years earlier, the admiralty court of Glasgow liberated a negro slave who had been imported into Scotland; and 70 years before, Chief Justice Holt ruled that "as soon as a negro comes into England he is free; one may be a villein in England, but not a slave;" and later: "In England there is no such thing as a slave, and a human being never was considered a chattel to be sold for a price." The decision of Lord Mansfield was made almost under compulsion, so strong was the feeling in England against slavery at that time; and immediately the enemies of both the trade and the institution went to work, and began those exertions which were not to cease until their country had abolished, first the commerce in negroes, and then the practice of enslaving them. The Quakers presented to parliament the first petition for the abolition of the slave trade. Mr. Clarkson began his anti-slavery labors in 1786, and Mr. Wilberforce joined him soon after. In June, 1787, a committee, composed of 12 members, all Quakers save Clarkson, Sharp, and another, was instituted for "effecting the abolition of the slave trade." In spite of the care they took to define their object and to conciliate popular prejudice, they encountered the violent opposition of the most eminent men of the country. The duke of Clarence denounced them in the house of lords as fanatics and hypocrites, including Wilberforce by name. The subject was brought before parliament, May 9, 1788, but the abolitionists were beaten, as they also were in 1789. Mr. Pitt, chief of the ministry, and Mr. Fox, chief of the opposition, joined them in 1790; and soon nearly all the leading members of the house of commons, of both parties, became abolitionists; but still defeat met every proposition for abolition till 1793, when the commons passed an act for the gradual abolition of the trade, which failed in the house of peers. The commons changed their mind in 1794, but passed another bill the next year, which the peers threw out. The agitation was continued, but the abolitionists failed in parliament till 1804, when another act passed by the commons was lost in the upper house. Another failure in the commons was experienced in 1805. In 1806, when the Fox and Grenville ministry ruled England, abolition was brought forward as a government measure, and was carried in 1807, after the death of Mr. Fox. The abolitionists then began to labor for the removal of slavery itself, but not with much effect till 1823, when a society was formed "for the mitigation and gradual abolition of slavery throughout the British dominions." The principal leaders in this new movement were Clarkson, Wilberforce, and Buxton. About this time appeared a pamphlet, written by Elizabeth Heyrick, a Quaker, and entitled "Immediate, not Gradual, Abolition." Her views did not at first command the assent of those who controlled the operations of the society, but subsequent reflection and discussion, and the resistance of the colonial authorities to every scheme of amelioration proposed by parliament, finally led them almost unanimously to the conclusion that she was right, and they abandoned the doctrines and measures of gradualism for those of immediate and unqualified emancipation on the soil. The cause from this time advanced with great rapidity. The question exerted a controlling influence in the election of the reformed parliament in 1832, and when, near the close of the year, that body assembled, the government avowed its purpose to bring in a bill for the abolition of slavery. The anxiety of the abolitionists as to the character of the proposed measure led to a conference, composed of 369 delegates from every part of the kingdom. A deputation of more than 300 members of this conference had an audience with leading members of the cabinet, to urge the necessity of total and immediate emancipation. The government measure was brought forward April 23, 1833. It proposed an apprenticeship of 12 years for the slaves, and to pay out of their earnings to the masters the sum of £15,000,000. The friends of emancipation remonstrated against these features of the plan, and it was finally modified by a reduction of the term of apprenticeship to six years, and a provision to pay the masters £20,000,000 out of the national treasury. The bill passed the house of commons Aug. 7, the house of lords Aug. 20, and received the royal assent Aug. 28, 1833. The day fixed for emancipation was Aug. 1, 1834, and it was left optional with the local legislatures respectively to adopt or reject the system of apprenticeship. Antigua and Bermuda rejected, while the other islands adopted the system. The apprenticeship system did not work well. In some instances the local legislatures voluntarily abolished it, and in 1838, two years before the time of its appointed expiration, it was brought to an end by act of parliament. In

1843 Great Britain emancipated more than 12,000,000 slaves in her East Indian possessions.—France had been as much committed to negro slavery as England, but moved sooner for its abolition. The national assembly, May 15, 1791, virtually granted equal political privileges to all free men without regard to color, and this led to those struggles in Santo Domingo which put an end to slavery there. Napoleon I. succeeded in restoring slavery in most of the French colonies, but failed in Hayti. In 1815, during the hundred days, he issued an order for the immediate abolition of the slave trade, which the government of Louis XVIII. reënacted, and the French slave trade ceased in 1819. The congress of Vienna denounced the slave trade. After much discussion in the reign of Louis Philippe, slavery in the French colonies was abolished by the provisional government in 1848, without indemnity to the masters. Sweden abolished slavery in 1846–'7, Denmark in 1848, and the Netherlands in 1862. Spain agreed in 1814 to abolish the slave trade in 1820. The Netherlands abolished it in 1818, and Brazil in 1826, but the Brazilians continued to prosecute it notwithstanding. In the United States it was prohibited by law from 1808. In 1820 a law was enacted declaring it piracy, but no conviction was obtained under this statute till November, 1861, when Nathaniel Gordon, master of a vessel called the Erie, was convicted at New York and executed. A similar statute was passed by the British parliament in 1825. But the trade by no means ceased because of these vigorous efforts for its abolition, which Great Britain and the United States supported by the presence of powerful fleets on the coast of Africa. The demand for slaves continued to be great, and the profits on the cargoes of slaves that were landed in various parts of America were so heavy that the traders could afford to lose many of their vessels. Not until the breaking out of the American civil war did the trade cease to be profitable, but that and the agitation for emancipation in Brazil nearly put an end to the slave trade across the Atlantic. In the interior of Africa it still has considerable vigor and constant activity, although it is much shorn of its profits by the loss of foreign markets.—Except in Cuba, slavery in Spanish America has disappeared. In Brazil it continued to flourish with considerable vigor till 1871. For several years preceding that date a strong agitation for its gradual abolition had existed, in which the emperor was understood to sympathize. The speech from the throne at the opening of the chamber on May 3, 1871, announced the belief of the government that the time had arrived for the final solution of the slavery controversy, and that a bill would be introduced for that purpose. The bill was finally acted upon Sept. 27, when it was adopted by a considerable majority. The children born of slaves from that date were to be considered free-born, but were to remain with the masters of the mothers until reaching the age of eight, when the master had the option to retain their services until they should be 21 years of age, or to receive from the government a compensation of 600 milreis. If he should accept the compensation, the government was to take charge of the minor and of his education. Every minor was to be at liberty to free himself from service by making compensation to the master proportioned to the period for which the service was to continue. Ill treatment or neglect of support or education was to entitle a child to his discharge from service. Children ceded or given to the government or taken from their masters by it might be delivered to privileged societies to be kept until they were 21, under an obligation securing them support and education. An emancipation fund, to be made up of certain taxes, the proceeds of certain lotteries, and other specified resources, together with donations, was to be employed annually in manumitting slaves, and they were to be entitled to purchase their freedom. The following classes were to be free: slaves of the nation; slaves given to the crown in usufruct; slaves of the religious orders (within seven years); slaves belonging to vacant inheritances; slaves who saved the lives of their masters, or the parents or children of their masters, and slaves given up by their masters. The law was received with general satisfaction. —The whole number of Africans taken for slaves is estimated at 40,000,000, or nearly 100,000 per annum since the beginning of the traffic; but for 80 years after the trade began their exportation was very limited, and probably not 30,000 were taken by the Portuguese between 1444 and 1493. The greatest part of the exportation was during the years that elapsed after movements for the abolition of the trade were commenced, the demand for tropical produce having immensely increased in the present century. Some of the slaves were sold in European countries, and it was supposed that there were 15,000 in the British islands at the time of the decision of the Somerset case. African slaves were said to be "dispersed all over Europe." Spain and France took some of them, as well as England. The number of slaves imported into those British colonies which became the United States in 1776 is computed at 300,000 down to that year. At the first census, in 1790, the slaves in the United States numbered 697,897, all the states but Massachusetts (which then included Maine) having some servile inhabitants, though Vermont had but 17, and New Hampshire only 158. In 1800 their number was 893,041, slavery having ceased in Vermont, and but 8 slaves being left in New Hampshire. The census of 1810 showed 1,191,364 slaves, there being none in Massachusetts, New Hampshire, Vermont, and Ohio, the last a new state, created out of territory that was a wilderness in 1776.

In 1820 the slaves numbered 1,538,022; in 1830, 2,009,043; in 1840, 2,487,455; in 1850, 3,204,313; and in 1860, 3,953,760.—The feeling in the United States was generally averse to slavery at the time their national existence began, and in some of the southern states that feeling was stronger than it was in most of the northern ones. The ordinance of 1787, excluding it from the N. W. territory, was supported by southern men, and some southern states abolished the slave trade with Africa while northern states continued to carry it on. Vermont abolished slavery in 1777, before she had joined the Union. Pennsylvania in 1780 provided for the gradual emancipation of her slaves, of whom 64 were still living as such in 1840, the relics of her 3,737 in 1790. In Massachusetts the supreme court declared that slavery was abolished by the act of adopting the state constitution of 1780, which had been so framed in one part as to provide for such a decision. Rhode Island gradually emancipated her slaves, and had but 5 left in 1840; and Connecticut did the same, having 17 in that year, and having had 2,759 in 1790. New York adopted a gradual emancipation act in 1799, at which date she had upward of 20,000 slaves; and in 1817 she passed another act declaring all slaves free on the 4th of July, 1827. New Jersey pursued the same course in 1804, her slaves in 1790 numbering 11,423, of whom 236 were living in 1850. That the southern states did not imitate the emancipation policy of those of the northern part of the American Union, is to be attributed to a variety of circumstances, the principal of which were the difference of climate and the difference of social life, which made slavery far more profitable in the south than it could ever be made in the north, where it never flourished, and where in some instances the young of slaves were given away. The invention of the cotton gin made slavery very profitable, and so helped to change that opinion which had existed in the south, both in the colonial and in the revolutionary times, and which, as expressed by such men as Washington, Jefferson, and Patrick Henry, looked to the extinction of slavery. That opinion passed away, and slavery was upheld in the southern states as an institution excellent in itself, and to be in every way promoted and extended, some of its more ardent friends advocating the resumption of the slave trade with Africa. The system of American slavery, unlike that of Greece or of Rome, was based on the alleged inferiority of the African race. The Greeks and the Romans enslaved white men of all races with whom they came in contact. So did the Barbary states, in which, notwithstanding their proximity to the country of the blacks, there were probably as many white as colored slaves. In America the idea of holding white men in slavery was always abhorrent to the most devoted supporters of slavery. But owing to the illicit amalgamation of the white and black races which is a concomitant of slavery, there was no inconsiderable number of American slaves in whom the proportion of African blood was so slight as to be almost or quite imperceptible. The aversion to color was so far shared in the non-slaveholding states, that before the late civil war in only one of their number (Vermont) were negroes entirely the equals of the whites before the law; and socially they were everywhere treated as an inferior caste. —Slavery was opposed by eminent men in the United States from the beginning. Washington, Franklin, Jefferson, Madison, Jay, Hamilton, and many more of those who took a conspicuous part in laying the foundations of the government, regarded slavery as a great evil, inconsistent with the principles of the declaration of independence and the spirit of Christianity. They confidently expected that it would gradually pass away before the advancing power of civilization and freedom; and, shrinking from what they regarded as insurmountable obstacles to emancipation in their own time, they consented, in forming the constitution, to give the system certain advantages which they hoped would be temporary, and therefore not dangerous to the stability of the government. Societies to promote the gradual abolition of slavery were formed in many of the states. The "Pennsylvania Abolition Society," founded in 1775, continued in existence until slavery was destroyed. Its first president was Benjamin Franklin, its first secretary Benjamin Rush. In 1790 it sent a memorial to congress, bearing the official signature of "Benjamin Franklin, president," asking that body to "devise means for removing the inconsistency of slavery from the American people," and to "step to the very verge of its power for discouraging every species of traffic in the persons of our fellow men." The "New York Manumission Society" was formed in 1785, John Jay being the first president, and Alexander Hamilton his successor. Similar associations were formed in Connecticut, Rhode Island, Delaware, Maryland, and Virginia. These societies exerted a strong influence in favor of the abolition of slavery in several northern states. In 1819–'20 the opponents of slavery made a stern resistance to the admission of Missouri to the Union as a slave state, and were defeated. (For particulars on the compromises which ended this and a similar struggle in 1850, and the whole of the political conflicts in regard to slaveholding in the territories of the United States, and the laws regulating the rendition of fugitive slaves, see United States and the notices of the presidents and the principal party leaders, such as Calhoun, Henry Clay, and Stephen A. Douglas.) The Missouri conflict was followed by a period of profound repose in regard to the whole subject. The publication, by Benjamin Lundy, a Quaker, of a small journal at Baltimore entitled "Genius of Universal Emancipation," was almost the

only visible sign of opposition to slavery until William Lloyd Garrison established "The Liberator" in Boston, Jan. 1, 1831. Accepting the definition of American slavery furnished by the statutes of the slave states, which declare the slaves to be "chattels personal, in the hands of their owners and possessors, to all intents, constructions, and purposes whatsoever," he asserted that slaveholding was a sin against God and a crime against humanity; that immediate emancipation was the right of every slave and the duty of every master. On Jan. 1, 1832, the first society on this basis was organized in Boston by 12 men, Arnold Buffum, a Quaker, being president. The "American Anti-Slavery Society" was formed in Philadelphia in December, 1833, Arthur Tappan being its first president. This society and its auxiliaries expressly affirmed that congress had no right to abolish slavery in the slave states, and they asked for no action on the part of the national government that had not, up to that time, been held to be constitutional by leading men of all parties in every portion of the country. They pronounced all laws admitting the right of slavery to be "before God utterly null and void." They declared that their principles led them "to reject, and to entreat the oppressed to reject, the use of all carnal weapons for deliverance from bondage;" their measures, they said, would be "such only as the opposition of moral purity to moral corruption, the destruction of error by the potency of truth, and the abolition of slavery by the spirit of repentance." By means of lectures, newspapers, tracts, public meetings, and petitions to congress, they produced an intense excitement throughout the country, the effects of which were soon manifest in the religious sects and political parties. The American anti-slavery society and those affiliated with it were opposed to the formation of a distinct anti-slavery political party, deeming it wiser to attempt to diffuse their principles among the members of all parties. In 1840, on account of differences upon this and other matters affecting the policy of the movement, a portion of the members seceded and formed the "American and Foreign Anti-Slavery Society." The "liberty party" was organized in the same year, mainly by the seceders and those in sympathy with them. This party was mostly absorbed by the "free-soil party" in the presidential election of 1848, though a small number of persons, holding the opinion that the national government had constitutional power to abolish slavery in every part of the country, continued under the name of liberty party for several years. The free-soil party was in its turn absorbed by the republican party, which in the presidential election of 1856 first exhibited great strength and commanded a popular vote of upward of 1,300,000, though it failed to elect its candidates. In 1860 it elected Abraham Lincoln president and Hannibal Hamlin vice president by the vote of all the free states except New Jersey. In 1844 the American anti-slavery society openly avowed its conviction that the so-called "compromises of the constitution" were immoral; that, consequently, it was wrong to swear to support that instrument, or to hold office or vote under it. From that time until the secession of the slave states, the abolitionists of this school avowed it to be their object to effect a dissolution of the American Union and the organization of a northern republic where no slavery should exist. The "American Abolition Society" was formed in Boston in 1855, to promote the views of those who held that the national government had constitutional power to abolish slavery in every part of the Union. The "Church Anti-Slavery Society" was organized in 1859, for the purpose of convincing the American churches and ministers that slavery was a sin, and inducing them to take the lead in the work of abolition. There have been few slave conspiracies or insurrections in the United States, and the servile population never produced any band of men to be compared with the Maroons of the West Indies, who so long baffled the exertions of the whites to subdue them. It is estimated that more than 30,000 American slaves, after escaping from bondage, found an asylum in Canada. They were aided in their flight by opponents of slavery in the free states. An attempt, in 1859, at subverting the slave institutions of the United States by an insurrection ended in speedy defeat, and was followed by the execution of the leader, John Brown, and some of his associates. The secession of the states which formed the government of the Confederate States in 1861 wholly changed the relations of the government of the United States to the institution of slavery. Although President Lincoln hastened to make strong assurances of the purpose of the government to abide faithfully by all the compromises of the constitution relating to slavery, and in all the military orders endeavored to provide for so conducting the war as to avoid disturbing the relation of master and slave as it then existed under state laws, it soon became evident that a vigorous prosecution of the war must of necessity make serious inroads upon the institution, if not wholly destroy it in those districts which the federal army should occupy. In May, 1861, Maj. Gen. Butler, commanding the department of Eastern Virginia, declared slaves who had been employed for military purposes of the confederacy to be contraband of war, and appropriated them to the purposes of his own army. In August following Gen. Fremont, commanding in Missouri, issued a general order wherein, among other things, he proclaimed free all the slaves of those who should take up arms against the United States, or take active part with their enemies in the field. In the particular specified this order was modified by direction of the president, but slaves who had performed any service for the confederate army, whether as servants

or as day laborers, were in general treated as "contrabands" by all the military leaders. In the annual report of the secretary of war, Dec. 1, 1861, the following passage occurs: "It is already a grave question what shall be done with those slaves who were abandoned by their owners on the advance of our troops into southern territory, as at Beaufort district in South Carolina. The number left within our control at that point is very considerable; and similar cases will probably recur. What shall be done with them? Can we afford to send them forward to their masters, to be by them armed against us, or used in producing supplies to sustain the rebellion? Their labor may be useful to us; withheld from the enemy, it lessens his military resources; and withholding them has no tendency to induce the horrors of insurrection, even in the rebel communities. They constitute a military resource; and being such, that they should not be turned over to the enemy is too plain to discuss. Why deprive him of supplies by a blockade, and voluntarily give him men to produce them?" Nevertheless several of the commanders of Union armies allowed masters to appear within their lines and carry off into slavery fugitives found therein. An order of Gen. David Hunter, commanding the department of the South, dated May 9, 1862, declaring the states of Georgia, Florida, and South Carolina under martial law and the slaves therein free, was annulled by proclamation of the president ten days later. On Aug. 22, 1862, the president in a public telegraphic despatch addressed to Horace Greeley, in response to a letter from that gentleman, gave utterance to his views as follows: "If there be those who would not save the Union unless they could at the same time save slavery, I do not agree with them. If there be those who would not save the Union unless they could at the same time destroy slavery, I do not agree with them. My paramount object is to save the Union, and not either to save or destroy slavery. If I could save the Union without freeing any slave, I would do it; if I could save it by freeing all the slaves, I would do it; and if I could save it by freeing some and leaving others alone, I would also do that. What I do about slavery and the colored race, I do because I believe it helps to save this Union; and what I forbear, I forbear because I do not believe it would help to save the Union. I shall do less whenever I shall believe what I am doing hurts the cause, and I shall do more whenever I believe doing more will help the cause." Meantime, on March 2, 1862, the president had recommended to congress that a resolution be adopted "that the United States, in order to coöperate with any state which may adopt gradual abolition of slavery, give to such state pecuniary aid, to be used by such state in its discretion, to compensate it for the inconvenience, public and private, produced by such change of system." The resolution was adopted, but produced no effect. Immediately after the battle of Antietam the president issued a proclamation (Sept. 22, 1862), in which, after declaring his determination to prosecute the war for the object of practically restoring the constitutional relation between the Union and the several states, and that it was his purpose at the next meeting of congress to recommend some practical measure of assistance in emancipation to those states which would voluntarily accept it, he proceeded to announce that on the first day of January, 1863, all persons held as slaves within any state or designated part of a state, the people whereof should then be in rebellion, should be then, thenceforward, and for ever free, and the executive government, including the military and naval authority thereof, would maintain such freedom. He further proclaimed that on the said first day of January he would by proclamation designate the states and parts of states then in rebellion, but that any state which should then be represented in congress by members chosen thereto at elections wherein a majority of the qualified voters participated, should in the absence of strong countervailing testimony be conclusively deemed not in rebellion. After then calling attention to legislation of congress bearing date March 13, 1862, forbidding the employment of military force to return fugitives to slavery, and that of July 16, 1862, for the confiscation of property of rebels, including slaves, and enjoining the observance thereof, he closed with the assurance that in due time, on the restoration of constitutional relations between the Union and the respective states, he should recommend compensation to loyal persons for all losses, including that of slaves. The final proclamation of freedom was issued on Jan. 1, 1863. It designated the following states and parts of states as then in rebellion: Arkansas, Texas, Louisiana (except the parishes of St. Bernard, Plaquemine, Jefferson, St. John, St. Charles, St. James, Ascension, Assumption, Terre Bonne, Lafourche, St. Mary, St. Martin, and Orleans, including the city of New Orleans), Mississippi, Alabama, Florida, Georgia, South Carolina, North Carolina, and Virginia (except the 48 counties designated as West Virginia, and the counties of Berkeley, Accomac, Northampton, Elizabeth City, York, Princess Anne, and Norfolk, including the cities of Norfolk and Portsmouth). The president enjoined upon the freedmen to abstain from all violence unless in necessary self-defence, and recommended to them in all cases, when allowed to do so, to labor faithfully for reasonable wages; but gave notice also that suitable persons would be received into the armed service of the United States. This proclamation had no very marked effect upon the relation of slavery beyond the lines of the federal army, but it gave consistency and unity to the action of the federal commanders, and it facilitated and hastened the incorporation of freedmen and other colored persons into the federal armies. On June 9, 1862, a law had

been enacted which terminated for ever the long and bitter agitation beginning with the contest about the admission of Missouri to the Union. This declared that "from and after the passage of this act there shall be neither slavery nor involuntary servitude in any of the territories of the United States now existing, or which may at any time hereafter be formed or acquired by the United States, otherwise than in the punishment of crime whereof the party shall have been duly convicted." On June 23, 1864, all laws for the rendition of fugitive slaves to their masters were repealed. On Jan. 31, 1865, the final vote was taken in congress submitting to the states for their approval and ratification the following amendment to the constitution: "Article XIII. Neither slavery nor involuntary servitude, except as a punishment for crime, whereof the party shall have been duly convicted, shall exist within the United States or any place subject to their jurisdiction." On Dec. 18, 1865, the secretary of state issued his proclamation declaring that this amendment had been approved by the legislatures of Illinois, Rhode Island, Michigan, Maryland, New York, West Virginia, Maine, Kansas, Massachusetts, Pennsylvania, Virginia, Ohio, Missouri, Nevada, Indiana, Louisiana, Minnesota, Wisconsin, Vermont, Tennessee, Arkansas, Connecticut, New Hampshire, South Carolina, Alabama, North Carolina, and Georgia—in all, 27 of the 36 states—and was consequently adopted. The assassination of President Lincoln put an end to any very serious thoughts of making provision for compensation for losses of slaves; and the fourteenth amendment to the constitution, ratified by a majority of the states in 1867–'8, absolutely forbade compensation being made either by the United States or by any state. Thus terminated for ever in the United States the system of bondage which had been its chief reproach in the eyes of the world and of its own people; which from the outset had been the principal source of solicitude to its statesmen; and the southern defenders of which finally assailed the life of the nation with a power and persistency from which it barely escaped, after losses and sacrifices such as few peoples in modern times have been called upon to suffer.—The abolition of slavery has rendered the laws of the several states concerning it of little practical interest, but a few points may be mentioned. The slave was a chattel, for an injury to whom the master might recover damages as for an injury to a beast. Nevertheless he was recognized as a person, so far as to be made amenable to the criminal code, and was punishable as such. The master had a power of discipline over him which did not extend to life or limb, and for any excess in punishment he might be criminally responsible, as he might for excessive violence to a child or apprentice. The police laws of the state were at the master's service for disciplinary purposes, and stringent regulations were made in his interest. The slave had no legal family relations, and any that should be voluntarily formed might be changed at the will of the master, by sale or otherwise. Slaves might be emancipated by the master, by deed or will, under state regulations; but in some of the states the laws were adverse to emancipation, and interposed various obstacles. Whatever was acquired by the slave belonged to his master, and it was therefore legally impossible for the slave to purchase his freedom; nevertheless masters frequently received from their slaves sums which they had accumulated by extra services, and gave them freedom in return. The general doctrine of the courts was that the master by voluntarily taking his slave into a free state gave him his freedom, and this rule was supposed to be applicable to the free territories of the United States until the decision of the supreme court in the case of Dred Scott in 1857, which denied the constitutional power of congress to prohibit the holding of persons in slavery in the territories. Near the same time the doctrine that a master might lawfully hold his slaves in passing through the free states found able advocates among lawyers. Slaves were not allowed legal rights in courts, though persons held as slaves but claiming to be free might bring actions to recover their freedom. Slaves might be witnesses for or against each other where crimes were charged, but were not allowed to be witnesses against white persons. In general the teaching of slaves to read and write was prohibited, as tending to render them discontented with their condition. *Prima facie* in slave states all colored persons were slaves. Since the abolition of slavery persons living together as husband and wife, and continuing to do so, have been recognized in law as being legally married; but until they had voluntarily assumed that relation after becoming free, they were at liberty to marry others without incurring legal penalty.—The colonization of emancipated American slaves in Africa was undertaken in 1820, when the colony of Liberia was founded. (See COLONIZATION SOCIETY.) The colony of Sierra Leone was founded by England in 1787, being composed of American slaves who had joined her flag under promises of freedom. (See SIERRA LEONE.)—The following are some of the most important modern works on the subject of slavery: Thomas Clarkson, "History of the Abolition of the Slave Trade" (London, 1808); George Stroud, "Laws relative to Slavery" (Philadelphia, 1827); William Blair, "An Inquiry into the State of Slavery among the Romans" (Edinburgh, 1832); L. M. Child, "Appeal in behalf of that Class of Americans called Africans" (Boston, 1833); Theodore Weld, "American Slavery as It Is" (New York, 1835); William Jay, "A View of the Action of the Federal Government on Slavery" (New York, 1838); David Trumbull, "Cuba, with Notices of Porto Rico and the Slave Trade" (London, 1840); Richard Hildreth, "Despotism in America"

(Boston, 1840); W. Adam, "The Law and Custom of Slavery in British India" (Boston, 1840); William Goodell, "Slavery and Anti-Slavery" (New York, 1843); Wallon, *Histoire de l'esclavage dans l'antiquité* (Paris, 1847); Fuller and Wayland, "Domestic Slavery" (New York, 1847); Copley, "A History of Slavery" (London, 1852); Horace Mann, "Slavery, Letters and Speeches" (Boston, 1851); John Fletcher, "Studies on Slavery" (Natchez, 1852); "The Pro-Slavery Argument" (Charleston, 1853); F. L. Olmsted, "A Journey in the Seaboard Slave States," "A Journey through Texas," "A Journey in the Back Country," and "The Cotton Kingdom" (New York, 1856–'61); the Rev. Albert Barnes, "An Inquiry into the Scriptural Views of Slavery" (Philadelphia, 1855); Theodore Parker, "Trial for the Misdemeanor of a Speech against Kidnapping" (Boston, 1855); the Rev. Nehemiah Adams, "A South Side View of Slavery" (Boston, 1855); George Fitzhugh, "Sociology for the South" (Richmond, 1855); Arthur Helps, "The Spanish Conquest in America, and its Relation to the History of Slavery," &c. Gurowski, "Slavery in History" (New York, 1860); Horace Greeley, "The American Conflict" (2 vols., Hartford, 1864–'6); E. M'Pherson, "History of the Rebellion" (Washington, 1865), and "History of Reconstruction" (Washington, 1868); A. H. Stephens, "The War between the States" (2 vols., Philadelphia, 1868–'70); S. J. May, "Recollections of the Anti-Slavery Conflict" (Boston, 1868); and Henry Wilson, "Rise and Fall of the Slave Power in America" (3 vols., Boston, 1871–'6).

**SLAVIC RACE AND LANGUAGES.** The Slavs or Slavi (in the Slavic languages, *Slovene*, *Słowianie*, &c., names now commonly derived from *slovo* or *słowo*, word; hence, "peoples of one tongue") are one of the most numerous and powerful groups of nations of the Indo-European or Aryan race, occupying at present nearly the whole of eastern Europe and parts of northern Asia. They seem to have anciently been included in the names of the Scythians and Sarmatians. Roman writers refer to the Slavs under the name of the Venedi (Winds, Wends), and later writers under that of Serbs, both of which still designate branches of the race. In the most ancient times to which the history of the Slavs as such can be traced, their seats were around and near the Carpathian mountains, whence they spread N. toward the Baltic, W. toward the Elbe and Saale, and finally, after the destruction of the empire of the Huns, S. across the Danube over the territories of modern Turkey and Greece. With this extension the unity of the race ceased, and they split into a number of tribes, separated from each other by political organization and different dialects. The eminent Slavic scholars Dobrovsky, Kopitar, and Schafarik divide the Slavs into the eastern and western or southeastern and northwestern stems. The former of these contains three branches: 1, the Russians, who are subdivided into Russians and Rusniaks or Ruthenians (in W. Russia, E. Galicia, and N. E. Hungary); 2, the Illyrico-Servian branch, comprising the Serbs proper, the Rascians or Hungarian Serbs, the Bosnians, Herzegovinians, Montenegrins, Slavonians, Dalmatians, Croats, and Slovens or Winds; 3, the Bulgarian branch. The western or northwestern stem comprises: 1, the Lechian or Polish branch, to which belong the Poles, the Slavic Silesians, and an isolated tribe in the Prussian province of Pomerania called Kassubs; 2, the Czecho-Slovak branch, which embraces the Bohemians, Moravians, and Slovaks in N. W. Hungary; and 3, the Sorabo-Wendic or Lusatian branch, containing the remnants of the Slavs of N. Germany. A number of Slavic realms have perished in succession, as those of Bohemia, Moravia, and Poland; and at the beginning of the present century only one, Russia, was left, besides which Servia and Montenegro maintain a semi-independent position.—In modern times a Panslavic movement, aiming at a closer union of all Slavic tribes, has arisen and gained considerable political importance. One of the first publicly to advocate it was the Czecho-Slovak poet Kollar, who published an address to all the Slavs, urging them to drop their numerous family feuds, to consider themselves as one great nation, and their related languages essentially as one. The idea was seized upon with eagerness by the Bohemians and other Slavs of Austria, who by a Slavic union hoped to prevent their being absorbed by the German and Hungarian races. It has since gained great strength in Austria by the endeavors of Schafarik, Palacky, Gaj, and other eminent Slavists, and has also found many distinguished advocates in Poland and Russia, in literary as well as in political circles. From a federative union of all Slavs under a democratic form of government to a union under the sceptre of the czar, every possible form of future organization has found advocates, the movement being principally fostered by Russian, and according to circumstances also by Austrian, influence. In the Slavic congress of Prague, assembled in the spring of 1848, the revolutionary element prevailed, leading to a bloody conflict with the Austrian troops under Windischgrätz, and the severe persecution of various members of the congress. The opening of the Austrian provincial diets and central Reichsrath in 1861 was productive of new Panslavic manifestations. An important Panslavic gathering took

place in Moscow on occasion of the ethnographic exhibition opened in May, 1867. The aggregate number of the Slavs was estimated by Schafarik about 35 years ago at about 80,000,000, of whom about 39,000,000 were Russians, 13,000,000 Rusniaks or Ruthenians (in a wider sense, including the Little Russians), 10,000,000 Poles (including Silesians and Kassubs), 4,500,000 Bohemians and Moravians, 3,500,000 Bulgarians, 2,800,000 Slovaks, &c. More recent estimates place the aggregate number of the Slavs nearer to 90,000,000. (See Europe, vol. vi., p. 787.)—The Old or Church Slavic (so called because it is still used in divine service) is the oldest branch of the Slavic languages. The Bible or parts of it were translated into it by Cyril and Methodius in the 9th century, the former of whom also invented an alphabet for it, which was called after him the Cyrillic, and is still used by the Serbs belonging to the Greek church, and in a modified form by the Russians, while the Poles, Bohemians, and others use the Roman alphabet. (See Glagolitic.) The church books written in Old Slavic are still used by the Serbs and Russians. Among the most important documents of this language are old gospels. The oldest works of the Servian and Russian literature, as the works of Nestor, were also written in this language. There is a grammar of it by Miklosich (Vienna, 2d ed., 1854). Formerly this was regarded as the common language of the ancient Slavs and as the mother of all the present Slavic idioms, but modern investigations have clearly shown that it was only their elder sister. Where this idiom was spoken is a controversy not yet settled; but the best authorities favor the claims of Bulgaria, regarding the present Bulgarian as its direct descendant. It is no longer a living tongue, but its treasures are still an inexhaustible mine for its younger sisters. Of the living Slavic languages, the Russian, Polish, Bohemian, and Servian have considerable literature. These languages, as well as their literatures, are treated separately under their respective heads. Among the peculiarities of the Slavic languages are the following. They have three genders. Like the Latin, they have no articles, with the exception of the Bulgarian, which suffixes one to the noun. The nouns, pronouns, and adjectives have seven cases. Some dialects have a dual. The verbs are divided into perfect and imperfect, whose relation to each other is about the same as that of the perfect and imperfect tenses in the conjugation of the Latin verb. All the dialects are comparatively poor in vowels and deficient in diphthongs. There is a great variety of consonants, and especially of sibilants, but no *f* proper is to be found in any genuine Slavic word. Slavic words very seldom begin with *a*, and hardly ever with *e*. The letters *l* and *r* have in some Slavic languages the value of vowels, and words like *twrdy*, *vjtr*, are in metre used as words of two syllables.—The primitive religion of the ancient Slavs seems to have been a kind of monotheism, which gradually passed into polytheism, and lastly into pantheism. Yet the idea of one divine essence was never completely lost, at least among the priests. All Slavs worshipped as their highest god Sviatovist, beside whom the other divinities were accounted as mere demigods. Among these Perun and Radegast received the highest honors. In addition to their gods, they believed in good and evil spirits and demons of different kinds, in the immortality of the soul, and in a retribution after death. Worship was held by their priests in forests and temples, and sacrifices of cattle and fruit were offered. The dead were burned, and their ashes preserved in urns.—See Schafarik, *Slawische Alterthümer* (2 vols., Leipsic, 1843); Talvi, "Historical View of the Languages and Literature of the Slavic Nations" (New York, 1850); Miklosich, *Vergleichende Grammatik der slawischen Sprachen* (Vienna, 1852–'71), and *Beiträge zur Kenntniss der slawischen Volkspoesie* (1870); and Naaké, "Slavonic Fairy Tales" (London, 1874).

**SLAVONIA**, or **Sclavonia** (Hun. *Tótország*), a province of the Austro-Hungarian monarchy, forming with Croatia a kingdom united with that of Hungary, bounded N. and E. by Hungary proper, W. by Croatia, and S. by Turkey; area, inclusive of the recently annexed portions of the former Military Frontier, about 6,600 sq. m.; pop. about 600,000, chiefly belonging to the Greek church. It is divided into the counties of Pozsega, Verőcze, and Szerém (Sirmia). Capital, Eszék. The Danube and the Drave separate Slavonia from Hungary, and the Save from Turkey. A branch of the Carnic Alps traverses its whole length. The mountains abound in coal and marble and in mineral springs, and the forests yield valuable timber. There are many extensive plains covered with vineyards, which produce large quantities of excellent red and white wines. Cattle are largely exported to Cisleithan Austria and Turkey, along with many other products, among which are grain, hemp, flax, tobacco, and silk. The chief manufacture is glass. Among the principal towns are Peterwardein, Carlovitz, and Semlin on the Danube, and Mitrovitz (anc. *Sirmium*), Brod, and Old Gradiska on the Save, all formerly included in the Military Frontier. The inhabitants belong to the Illyrico-Servian branch of the Slavs. (See Servian Language and Literature.)—Under the Romans Slavonia formed part of the province of Pannonia, and was called Pannonia Savia. Later it belonged to the Byzantine empire, until it was occupied by the Avars and Slavs. In the time of Louis le Débonnaire it had its own prince, who submitted to the sovereignty of the Franks. In the 11th century it was incorporated with Hungary. It was conquered by the Turks in 1524, and was formally ceded to them in 1562; but in 1699, by the peace of Carlovitz, it was

retroceded to Austria, resuming also its relation to Hungary. Separated from Hungary in 1849, it was reunited with it in 1867–'8 as a part of the kingdom of Croatia and Slavonia. (See Croatia, and Hungary.)

**SLAVS,** or **Sclaves.** See Slavic Race and Languages.

**SLEEP,** a period of repose in the animal system, in which there is a partial suspension of nervous and muscular activity, necessary for the reparation of the vital powers. In sleep there is more or less complete unconsciousness of external impressions, which may be dissipated by any extraordinary excitement, in this respect differing from the torpor of coma produced by abnormal conditions within the cranium or the action of narcotic poisons. In the deep sleep after extreme fatigue there may possibly be a complete suspension of the activity of the cerebrum and the sensory ganglia; some consider dreams a proof of imperfect sleep, while others maintain that there are always dreams during sleep, though they may not be remembered. The refreshing power of sleep depends on the nutritive renovation effected during its continuance; it is a necessity of the system, and must be periodically indulged in. After 12 to 16 hours of waking a sense of fatigue is experienced under ordinary circumstances, showing that the brain needs rest, and this cannot be shaken off unless by some strong physical or moral stimulus; more sleep is required by the young, and less by the aged, in proportion to the rapidity of waste of the tissues. When the sense of fatigue has reached its maximum, sleep will supervene, even under the most unfavorable circumstances. It may be retarded by uncommon mental concentration, excitement, suspense, or the exercise of a strong will, but always with an exhaustion of nervous power which requires a proportionally long period of repose. Stillness, the absence of light, and monotonous low noises, like the buzzing of insects, the murmur of the wind in the trees, the purling sound of running water, the rippling on a beach, the suppressed hum of a distant town, the droning voice of a dull reader, or the mother's lullaby, promote sleep; gentle movements, like the swinging of a hammock or the rocking of a cradle or boat, are also conducive to sleep; in reading a dull book the eyes wander fatigued from page to page, and the excitement of the mind is not enough to overcome the tendency to sleep. Persons may become so accustomed to continuous loud noises, as in the vicinity of mills, forges, and factories, that they cannot readily fall asleep in their absence. The transition from sleep to the waking state, and *vice versa*, is generally gradual, but sometimes sudden. The fœtus may be said to be in a continued sleep, and the excess of the sleeping over the waking hours prevails during infancy and childhood, or while growth is greater than the decay of the tissues, and this sleep is more profound as well as longer. Persons of plethoric habit, with good appetite and powers of digestion, are usually sound sleepers; the nervous sleep comparatively little; lymphatic, passionless individuals, who vegetate rather than live, are generally long sleepers. The amount of sleep required depends much on constitution and habit, and the smallest sleepers have sometimes been men of the greatest mental activity. Most men require from six to eight hours of sleep daily, and this amount cannot be materially diminished without injury to the health. As a general rule, the amount necessary to refresh the system is in proportion to the amount of bodily and mental exertion of the individual. —In natural sleep, during the repose of the voluntary muscles, the senses, and the perceptive and intellectual faculties, the functions of respiration, circulation, nutrition, secretion, and absorption continue. The respiration and the pulse, however, are both diminished in frequency; and the temperature of the body is somewhat reduced from its usual standard. Hence the chilliness generally felt during a nap in the daytime, and the propriety of throwing some covering over the body during sleep, even in summer, to avoid taking cold; in this state there is also less power of resisting diseases, especially malarious ones. Nothing is so refreshing during sickness, or so conducive to rapid convalescence, as quiet sleep; and few symptoms are more unfavorable than continued sleeplessness. A habitual deficiency of sleep, from excitement or excessive study, produces sooner or later headache, cerebral disturbance, restlessness and feverishness, and, if the warning be not seasonably heeded, a serious impairment of the vital powers. (See Coma, Dream, and Somnambulism.)

**SLEIDAN,** or **Sleidanus, Johann,** a German author, whose real name was Philipson, born at Schleiden, near Cologne, in 1506, died in Strasburg, Oct. 31, 1556. After studying in many universities, he was employed in diplomacy by King Francis I. of France. Having secretly adopted Lutheranism, he went to Strasburg, where in 1542 he was appointed by the Protestant princes historian of the Smalcald league, and by the town council professor of law. Subsequently he conducted negotiations with France and England, and attended the council of Trent as deputy from Strasburg. His reputation rests on his great work entitled *De Statu Religionis et Reipublicæ, Carolo Quinto Cæsare, Commentarii* (1555; best ed., 3 vols., Frankfort, 1785–'6), in 25 books, to which a 26th was added from a manuscript found among his papers. It embraces a history of the reformation from 1517 to 1556, and is remarkable for impartiality and for its simple and elegant Latin. The best English version is that of E. Bohun, with a continuation to 1562, entitled "General History of the Reformation begun in Germany by M. Luther" (fol., London, 1689).

**SLIDELL, John,** an American politician, born in the city of New York in 1793, died in Lon-

don, July 29, 1871. He graduated at Columbia college in 1810 and entered commercial life, but was not successful, and removed to New Orleans, where he became a prominent member of the Louisiana bar, and was United States district attorney from 1829 to 1833. He was frequently elected to the state legislature, and was a representative in congress from 1843 to 1845. In the latter year he was sent as envoy extraordinary and minister plenipotentiary to Mexico. In 1853 he was chosen United States senator for the unexpired term of Senator Soulé, and was afterward reëlected for six years. He was a supporter of the southern rights party, and when Louisiana had passed the ordinance of secession, in January, 1861, he withdrew on Feb. 4 from the senate, after delivering a menacing and defiant speech. In the autumn he was sent as commissioner to France, together with Mr. Mason of Virginia, who was appointed in the same capacity to England. Sailing from Charleston, they ran the blockade, and embarked at Havana on board the English mail steamer Trent. On Nov. 8 Capt. Wilkes, of the United States steam frigate San Jacinto, boarded this vessel, and arrested the commissioners, who were confined in Fort Warren, Boston harbor. But as their capture was informal, they were released on the reclamation of the British government, and on Jan. 2, 1862, sailed for England. Mr. Slidell proceeded to Paris, where through the banker Erlanger (who became his son-in-law) he secured some aid in money and ships for the confederates, and after the close of the war settled in London.

**SLIGO. I.** A county of Ireland, in the province of Connaught, on the N. W. coast, bordering on Leitrim, Roscommon, Mayo, and the Atlantic ocean; area, 721 sq. m.; pop. in 1871, 115,311. The chief towns are Sligo, Dromore, and Tobercurry. The coast line is generally rugged, and is deeply indented by the bays of Sligo and Killala. Sligo bay is about 6 m. wide at the mouth, and extends inland 10 m. to the town of Sligo. The principal rivers are the Sligo, Moy, Arrow, Awinmore, and Easky. Lough Gill, the chief lake, is about 5 m. long and 1½ broad, and is remarkable for the beauty of its scenery. A great deal of the surface is mountainous or boggy. Iron ore is found, and copper and lead mines were formerly worked. Coarse woollens are manufactured. There are many remains of antiquity. **II.** A town, capital of the county, at the head of an arm of the bay of the same name, 107 m. N. W. of Dublin; pop. in 1871, 9,340. It has considerable commerce, but vessels drawing more than 13 ft. are obliged to anchor a mile below the town. In 1870 Sligo was disfranchised as a parliamentary borough.

**SLOANE,** Sir **Hans,** a British naturalist, born at Killyleagh, county Down, Ireland, April 16, 1660, died in Chelsea, near London, Jan. 11, 1753. He studied medicine, natural history, and chemistry in London, where he became acquainted with Ray and Boyle. After a tour on the continent, he settled in 1684 in London, and was soon after elected a fellow of the royal society. In 1687 he accompanied the duke of Albemarle to Jamaica in the capacity of physician, and during a residence of 15 months made large collections of natural curiosities, particularly of plants. Returning to London, he was chosen physician of Christ's hospital in 1694, a post which he filled for 36 years. Being shortly before this time elected secretary of the royal society, he revived the "Philosophical Transactions," and until 1712 was editor of the work. Meanwhile he had formed the nucleus of a comprehensive cabinet of curiosities, which it became one of the chief objects of his life to enrich and enlarge, and which in 1702 received a very considerable augmentation by the bequest of the collection of William Courten. In 1716 he was created a baronet, and was appointed physician general to the army, which office he held till 1727, when he became physician in ordinary to the king. In 1719 he was elected president of the college of physicians, and in 1727 president of the royal society. In 1741 he removed his library and collections to an estate in Chelsea, purchased in 1720, where he spent the rest of his life in retirement. His collections, amounting to 200 volumes of dried plants and over 30,000 other specimens of natural history, besides a library of 50,000 volumes and 3,566 manuscripts, were by the direction of his will offered to the nation for £20,000, less than a quarter of their real value. The legacy was accepted by parliament, and in its purchase originated the British museum. Among many important benevolent schemes he was engaged in the establishment of a dispensary for providing the poor with medical services and medicines, and of the foundling hospital. He also presented the apothecaries' company with the freehold of their botanic garden, which formed part of his estate at Chelsea. His writings comprise "The Natural History of Jamaica" (2 vols. fol., 1707-'25), a Latin catalogue of the plants of Jamaica, a treatise on sore eyes (once highly esteemed), and contributions to the "Philosophical Transactions." He aided in the introduction of the use of Peruvian bark and other new remedies, and gave a considerable impulse to the practice of inoculation by performing that operation on several of the royal family.

**SLOE** (A. S. *sla*), a wild plum, *prunus spinosa*, native in Europe and Russian and central Asia, and sparingly naturalized in the New England and some others of the older states. It is a shrub or low tree, with its smaller branches ending in sharp thorns, which, with the blackish color of the bark, give it the name of blackthorn by which it is frequently called in England; the leaves are ovate or oblong; the small, white flowers are succeeded by a small, globular, black fruit, with a fine bloom; stone turgid; pulp greenish and astringent.

As stated under PLUM, this is thought to be the original of all the cultivated European varieties of that fruit. The sloe is sometimes used as a hedge plant in Europe, and is planted

Sloe or Blackthorn (Prunus spinosa).

around trees in parks to protect them while young from injury by animals; it is sometimes seen in this country in collections of shrubs, its chief merit as an ornament being its early flowering. The wood is hard, heavy, and dark-colored, takes a fine polish, and is used for handles to tools, flails, teeth to rakes, and the like; upright shoots make favorite walking sticks. The leaves when dried are regarded as more like tea than any other substitute; they were at one time largely collected for the adulteration of tea in England, but this is now forbidden under a heavy penalty. The fruit when mellowed by frost is eaten in some parts of Europe, and is made into a conserve; its expressed juice is used in Germany to mark clothing, it being nearly indelible, and in England it forms the basis of "British port."

**SLOTH**, the name of the edentate mammals of the family *tardigrada* (Ill.) and genus *bradypus* (Linn.); both the family and generic names are derived from the extreme slowness of the gait; it is *le paresseux* of the French. The skull is small, rounded, flat, and truncated in front; the jaws very short and the face very little projecting beyond the line of the cranium; the malar bone gives off a zygomatic process which runs backward and passes above the corresponding one of the temporal bone without touching it, a second process descending outside the lower jaw, which is very strong. The fore legs are much longer than the hind, and all the toes end in long curved claws, channelled underneath, the bones firmly united together and the claws naturally turned in against the soles; the fore feet have either three or two toes, and the hind feet three toes; the latter are articulated obliquely on the leg, so that only the exterior edge touches the ground, of course making progression on a level surface very awkward; the pelvis is so wide and the thighs so laterally directed that the knees cannot be brought together. The ears are very short, and concealed under the hair, which is dry, harsh, and coarse. The axillary and iliac arteries, instead of pursuing their usual course down the limbs as single vessels, suddenly subdivide into from 40 to 60 small trunks of equal size, freely anastomosing with each other, looking somewhat like a mass of varicose veins, and distributed chiefly to the muscles; the arrest of the circulation by pressure on a single trunk is thus prevented, and its retardation permits slow and long continued contraction of the muscles of the arms and legs. The stomach is divided into four cavities without folds, the intestine is short, and the cæcum absent; the mammæ are two, and pectoral; there is a common cloaca, as in birds, for the expulsion of the urine and fæces. The dental formula is $\frac{5}{4}-\frac{5}{4}$, the teeth being simple, separated, nearly cylindrical, without roots, with an undivided hollow base continually growing as they are worn by use, and composed of dentine and cement without enamel; there are no incisors; the anterior molars are very small in the three-toed sloth, but in the two-toed are long, pointed, resembling canines, and the lower placed behind the upper. The tail is very short, or absent. The sloths were considered by the early naturalists as imperfect and deformed creatures; but in the trees, their natural home, their peculiarities of structure are as admirably adapted for their convenience and enjoyment as in any other animal; the fore limbs have great freedom of motion, and all are so constructed that by means of the claws they suspend themselves to the branches and hang for a long time, and even sleep, back downward. They are rarely seen on the ground, for the reason that they can pass from one tree to another by the interlocking branches for miles in the thick forests of South America, which they inhabit from Guiana to Paraguay, some species extending to Peru, and according to some authors into Central America. They are rarely more than 2 ft. long, and their hair resembles in color the bark of the trees upon which they live; the food is entirely vegetable, the leaves and twigs of trees. They have one young one at a time, which clings to the mother's back, hiding among the hair; the native name is *ai*, from their feeble plaintive cry; they are remarkably tenacious of life, and apparently unconscious of pain.—Linnæus gave the name of *B. tridactylus* to a three-toed sloth, under the impression that there was only one species thus characterized, whereas Wagner describes several in the *Archiv für Naturgeschichte* for 1850. The animal referred to by Linnæus is grayish, with the body 14 in. long, the head about 3, the tail 1, the fore limb 11, the hind 6, and the claws 2 to 2½; it has 9 cervical vertebræ, and 14 ribs on each side, of which 9 are true; the thumb and little finger are rudimentary and hidden under the skin; there is a ru-

dimentary clavicle attached to the acromion; the hair is reversed on the forearm. It has been calculated that it can take only 50 steps a day, consuming a month in traversing a mile;

Three-toed Sloth (Bradypus tridactylus).

if by chance it ascends a tree too remote from another to admit of a passage across, the natives say that it rolls itself in a ball and drops to the ground, and the thick wiry hair would render such a fall comparatively harmless; from its habits it can rarely if ever drink; its flesh and skin are useless; in captivity it is exceedingly stupid and uninteresting. The unau or two-toed sloth (*B. didactylus*, Linn.; genus

Unau or Two-toed Sloth (Bradypus didactylus).

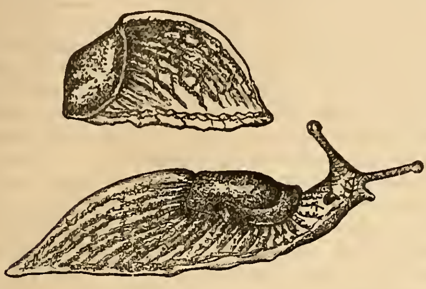
*cholœpus*, Illig.) is mixed brown and white, paler below; it is about 2 ft. long, with, according to Daubenton, 23 ribs on each side, of which 12 are true; the clavicles are complete, and the tail is wanting; it has a longer muzzle and shorter fore legs than the three-toed species, and is more active, especially at night; it inhabits the same region, and is sometimes eaten by Indians and negroes.—For the fossil edentates, see MEGALONYX, MEGATHERIUM, and MYLODON; for anatomical details, see COMPARATIVE ANATOMY, and EDENTATA.

**SLOVAKS**, a Slavic people, belonging to the western stem of the race, and inhabiting chiefly the mountainous regions of N. W. Hungary and the adjoining portions of Moravia. Their number is estimated at nearly 3,000,000, more than two thirds of whom are Catholics, and the remainder Lutherans. They are of medium stature, have blue eyes, straight and long hair, a yellowish skin, and generally coarse features. They are chiefly engaged in agriculture and mining. Numbers of them spend their lives wandering through various countries of Europe, selling linen, mouse traps, and other articles of wire work. The language of the Slovaks is a sub-dialect of the Bohemian or Czech, which latter is generally used by them as a literary medium, as by Kollar, Schafarik, Holly, and other writers, and is also the language of their church services.—The Slovaks occupied their present abodes early in the middle ages, and in the 9th century they formed the nucleus of the Moravian empire until its destruction by the Magyars.

**SLOVENS**, or **Sloventzi**. See WINDS.

**SLUG** (*limax*, Lam.), a genus of mollusks, belonging to the air-breathing gasteropods. The form is elongated, tapering, snail-like, the head having two long and two short tentacles which can be extended and drawn in like the finger of a glove by being turned inside and out; the naked body is covered anteriorly by a coriaceous mantle, under which is the branchial cavity, the respiratory orifice and vent opening on the right side of it, and the generative orifice beneath the right tentacles; the mantle in some contains a calcareous grit, and in others a small, thin, nail-like shell; the head can be partly drawn under the mantle; at the posterior end of the body is a small aperture whence proceed the adhesive threads by which they let themselves down from plants which they ascend in search of food. Their motion is proverbially slow, and effected by the contractions of the flat disk or foot on the ventral surface. The upper jaw is in the form of a toothed crescent, by which they gnaw plants with great voracity; the stomach is elongated; the skin secretes a great quantity of mucosity, which serves to attach them to the surfaces on which they creep; the eyes are small black disks at the end of the posterior tentacles; the sense of touch is delicate. The reproductive season is in spring and summer; they are hermaphrodite, and mutually impregnate each other; the eggs, to the number of 700 or 800, are laid in moist and shady places; at the approach of winter they burrow into the ground, where they hibernate; they hide under decaying logs and stones in damp places, and are seen in gardens and orchards in evening and early morning, especially after gentle and warm showers. They are found in the northern temperate zones of both hemispheres. The common slug of New England, *L. tunicata* (Gould), is nearly an inch long, varying in color from dark drab to blackish brown; the

back is wrinkled, and the upper tentacles granulated and black at the tips; the foot is very narrow; it is found almost always with the isopod crustaceans commonly called sow bugs. Other species are described; they are comparatively rare in the United States, and by no means so troublesome as in Europe. The common European slug, *L. agrestis* (Linn.), is small and unspotted, and very abundant and destruc-



Slug (Limax agrestis).

tive; they are killed by solutions of tobacco, salt, or other irritants, or by covering a spot infested by them with ashes, lime, fine sand, or any powder which attaches itself to the body and prevents their walking, or they may be arrested by some sticky substance; many are devoured by mammals, birds, and reptiles.

**SLUG WORM**, the common name of the larvæ of the sawflies, or the hymenopterous insects of the family *tenthredinidæ*. The slug worm described by Prof. Peck in his prize essay (Boston, 1799), and called by him *tenthredo cerasi* (Linn.), has been placed by Harris in the genus *selandria* (*blennocampa*). The fly is black, with the first pair of legs yellowish clay-colored; the body of the female is about a fifth of an inch long, that of the male a little smaller. They usually appear in Massachusetts on the cherry and plum trees toward the end of May, disappearing in three weeks after laying their eggs singly in incisions on the lower surface of the leaves; the young are hatched in two weeks, coming out from June 5 to July 20, according to season; they have 20 short legs, a pair under every segment except the fourth and the last, and are half an inch long when fully grown; in form they resemble small tadpoles, and are covered with a thick slimy matter which has given them the name of slugs; they also emit a disagreeable odor. They come to their full size in 26 days, casting their skin five times, after which they enter the ground, change to chrysalids, and come out flies in 16 days; they then lay eggs for a second brood, which enter the ground in autumn, and appear as flies in the ensuing spring, some remaining unchanged for a year longer. They feed on leaves, and in some seasons have been so numerous as to strip trees entirely of their foliage and even cause their destruction; they are eaten by small mammals and birds, and the eggs are destroyed by the larvæ of a tiny ichneumon fly (*encyrtus*). The trees may be best preserved against their attacks by showering them with a mixture of whale-oil soap and water, or powdering with ashes or quicklime.

**SMALCALD** (Ger. *Schmalkalden*), a town of Prussia, in the province of Hesse-Nassau (before 1866 of Hesse-Cassel), 34 m. E. N. E. of Fulda; pop. in 1871, 5,792. It manufactures iron, steel, and salt.—The Smalcald league was concluded here in 1531, by various Protestant princes and free cities, for mutual defence of their religious and political independence against Charles V. and the Catholic states of the empire. It was limited at first to six years, but in 1535 new members were admitted at a second convention in Smalcald, and the term was extended ten years, with a resolution to maintain an army of 12,000 men. The elector John Frederick of Saxony and the landgrave Philip of Hesse became the leaders of the league, whose war against the emperor (1546-'7) was terminated by the victory of the latter at Mühlberg, April 24, 1547. In 1537 a confession of faith was drawn up in several articles by Luther, known subsequently as the "Articles of Smalcald," which became one of the symbolical books of the Lutheran church.

**SMALLPOX** (*variola*), a contagious fever, characterized by a pustular eruption having a depressed centre. The terms *variola* and *pacce* first occur in the Bertinian chronicle of the date 961. Variola is derived from the Latin *varus*, a blotch or pimple, while pox is of Saxon origin and signifies a bag or pouch; the prefix small was added in the 15th century. The era commonly assigned for the first appearance of smallpox is A. D. 569; it seems then to have begun in Arabia, and the raising of the siege of Mecca by an Abyssinian army is attributed to the ravages made by smallpox among the troops. The new part which Arabia under Mohammed and his followers was made to play in history contributed to the rapid propagation of the disease throughout the world. Rhazes, an Arabian physician who practised at Bagdad about the beginning of the 10th century, is the first medical author whose writings have come down to us who treats expressly of the disease; he however quotes several of his predecessors, one of whom is believed to have flourished about the year of the Hegira, A. D. 622. Measles and scarlet fever were at first confounded with smallpox, or considered as varieties of it; and this error seems to have prevailed more or less until Sydenham finally showed the essential differences between them. Boerhaave was the first to insist that contagion is essential to the propagation of the disease.—The period of incubation, that is, the time that elapses from the moment the patient receives the contagion until it begins to manifest its effect in the initiatory fever, is usually 14 days, though it sometimes varies. During this time there is usually no disturbance of the ordinary health.

The invasion of the disease is announced by chills followed by fever; this is apt to be attended with pain in the back, particularly in the loins, and with nausea and vomiting. If the fever runs high, with violent pain in the back and much delirium, the disease commonly assumes a severe form. In children the invasion is often announced by an attack of convulsions. The eruption begins to show itself on the third day of the fever. As a rule, it appears first on the face, then on the neck and wrists, then on the trunk, and finally on the extremities. On the fifth day the eruption is complete, and after this few or no new spots appear. It at first consists of minute rounded papules or pimples of a characteristic solid consistency, feeling like small shot beneath the skin. It is by this peculiar solidity of the spots that smallpox at this period is distinguished from other papular eruptions. By the fourth day from their first appearance the papules are converted into vesicles filled with a thin lymph and having a depressed centre, whence they are termed umbilicated. The vesicles begin now to be surrounded by an areola, or circular flush upon the skin, which soon becomes dark crimson; the lymph, at first colorless and transparent, is gradually converted into pus, which increases in quantity and distends the vesicles until they become hemispherical. About the eighth day of the eruption a dark spot makes its appearance at the centre of the pustule, and gradually dries up and is converted into a scab. When this scab falls it leaves either an indelible cicatrix or a purplish red mark which fades very slowly, and which long exposure to a cool atmosphere renders very distinct. In passing away, the eruption follows the course which it took on its first appearance, the scabs first falling from the face, then from the trunk, and last from the extremities.—When the pustules are comparatively few, they are separated, sometimes widely, from each other, and the disease is termed discrete (*variola discreta*); when they are very numerous, they touch each other and run together, and then it is termed confluent (*variola confluens*); and between the two a third variety, the semi-confluent or coherent, is often spoken of. In the discrete form the fever commonly subsides on the appearance of the eruption, and when the pustules are few it may not return; but where they are at all numerous, their maturation is commonly attended with more or less fever. With the appearance of the eruption on the surface, more or less sore throat is complained of; the fauces and tonsils are red and swollen, and pustules make their appearance upon them, upon the roof of the mouth, and the inside of the cheeks; the patient at the same time is commonly troubled with salivation. When smallpox is confluent, the subcutaneous cellular tissue seems involved in the disease, the swelling is very great, and by the fifth day the patient is commonly unable to open his eyes. The eruption on the face sometimes coalesces into one huge sore; it is attended with a tormenting itching, and the fever is of the typhoid kind, the debility being extreme, and the patient restless, sleepless, and often delirious, while the pulse is small, frequent, and feeble. In such cases the accompanying inflammation of the mouth, nasal passages, pharynx, and larynx adds greatly to the distress of the patient and the danger of the disease, sometimes even producing suffocation. The disease is always attended by a peculiar odor, but in confluent cases this is nauseous and offensive to an excessive degree. In this form the fever, which commonly abates on the coming out of the eruption, is aggravated as the eruption approaches maturation. The eighth day of the eruption or the eleventh of the disease is commonly the most fatal day, while more patients die during the second week of the disease than either earlier or later. A second attack, even after free exposure to the contagion, is very rare. Only widely separated instances have been known.—When patients recover from severe attacks of smallpox, blindness from an intercurrent inflammation of the conjunctiva is an occasional result, and before the general introduction of vaccination blindness from smallpox was common. Besides inflammation of the eyes, glandular swellings and abscesses, bed sores, and phlebitis are occasional complications. It is also sometimes complicated with a diseased condition of the blood, producing hæmorrhage from various organs, together with petechiæ. These cases are always attended with great debility; the accompanying fever is typhoid, and the eruption itself does not come out freely. They are almost invariably fatal. Pregnancy is a serious complication. Abortion or premature delivery with the death of the child is commonly produced, but the mother frequently recovers. Sometimes the child presents the characteristic eruption of the disease, but this is rare. Still more rarely a mother whose system has been protected by vaccination or a previous attack of the disease, communicates it, after exposure, to the *fœtus in utero*, while she herself escapes. Confluent smallpox is always dangerous, and the danger is aggravated if the patient be still in infancy or over 45 years of age, or of a feeble or strumous constitution.—The mortality from smallpox is estimated at one fourth or one fifth of all who are attacked; that of the London smallpox hospital has long averaged 30 per cent. Like many other contagious diseases, it is subject to epidemic influence, and when it prevails epidemically it seems to be severer and more fatal. It is remarkable that when it is communicated by a minute portion of the virus being inserted under the cuticle by inoculation, as it is termed, the disease is far less violent than if communicated through the atmosphere; and yet a second attack in such a case is as improbable as in any other. When patients are inoculated the mortality is rarely greater than 1 in 600 or 700. Inoculation was

introduced into civilized Europe from Constantinople through the sense and courage of Lady Mary Wortley Montagu, but since the discovery of vaccination by Dr. Jenner has been discontinued. (See VACCINATION.)—For a long time the dangers of smallpox were aggravated by the means used for its cure; in accordance with the theories of the time, which still have their influence among the vulgar, the eruption was looked upon as an effort made by nature to free the system of morbid matter; the more abundant it was, the better for the patient. The eruption was accordingly encouraged by warm drinks and a heated atmosphere. Sydenham was the first to inculcate the necessity of free ventilation and a cooling regimen. Mild cases require little except attention to hygienic measures; the disease is attended with little danger, and should run its course uninfluenced by art. When it is severe, attention should be early directed to supporting the strength of the patient. The diet should be as nutritious as he can bear, and, when indicated by the pulse, wine and stimulants should be freely administered. The troublesome itching, which causes great suffering, may be alleviated by the application of sweet oil, cold cream, or lard; opiates may be useful to procure sleep, and the bowels should be occasionally moved by mild laxatives or enemata.

**SMART, Christopher**, an English author, born at Shipborne, Kent, April 11, 1722, died in the king's bench prison, London, May 18, 1770. He was educated at Cambridge, and elected a fellow of Pembroke hall in 1745, and gained the Seatonian prize for poems on the Supreme Being for five years consecutively. In 1753 he married, removed to London, and supported himself by writing. Through intemperance and extreme poverty he lost his reason, and was confined in a lunatic asylum for two years. He made a prose translation of Horace, and metrical versions of Horace and Phædrus, and of the Psalms. Among his other works is "The Hilliad, an Epic Poem," a satire on Sir John Hill, who had criticised him. In 1752 he published a collection of his poems. A posthumous edition appeared in 1791 with a memoir (2 vols. 12mo). His Horace has had several editions in the present century.

**SMART, John.** See p. 890.

**SMARTWEED.** See POLYGONUM.

**SMEATON, John**, an English civil engineer, born at Austhorpe, near Leeds, May 28, 1724, died there, Oct. 28, 1792. Before his 15th year he had made mechanical inventions and discoveries. In 1750 he became a mathematical instrument maker, and in 1751 invented a machine for measuring a ship's way at sea. He made valuable improvements in hydraulic machinery, and in 1759 read a paper on this subject before the royal society, for which he received the Copley gold medal. The Eddystone lighthouse being destroyed by fire in 1755, Smeaton rebuilt it. (See LIGHTHOUSE.) He afterward built canals and locks on the Derwentwater estate, constructed the great canal from the Forth to the Clyde, improved the Calder navigation, supplied Greenwich and Deptford with water, erected the Spurn lighthouse, preserved the old London bridge, and erected several bridges in Scotland. About 1783 he withdrew from business. He published a volume on the Eddystone lighthouse (1791), and his professional reports were published by the institution of civil engineers (3 vols. 4to, 1812-'14).—See Smiles's "Lives of the Engineers."

**SMELL**, the special sense by which we take cognizance of the odoriferous qualities of foreign bodies. The main peculiarity of this sense is that it gives us intelligence of the physical properties of substances in a gaseous or vaporous condition. An odoriferous body gives off emanations which diffuse themselves through the atmosphere, and we thus perceive its existence at a distance and when it may be concealed from sight. The actual quantity of vaporous material necessary for making an impression upon the olfactory organ is very small; and a substance like musk or attar of roses may fill an entire apartment or even a house for days or weeks with its peculiar odor, readily perceptible by all the occupants, without suffering any appreciable loss of weight.—The organ of smell is the mucous membrane of the upper part of the nasal passages, supplied by the filaments of the olfactory or first pair of cranial nerves. These nerves are endowed with the special sense of smell, but are destitute of ordinary or general sensibility. Thus they can perceive the odors of foreign substances, but not the physical contact of a solid body. On the other hand, the lower portion of the nasal passages is supplied by filaments from the fifth pair of cranial nerves, which are nerves of general sensibility, but not susceptible to the impression of odors. Not all vapors are odoriferous; some are simply irritating or stimulating to the mucous membrane. The odors proper are generally of an organic origin, such as those of musk, asafœtida, the leaves and blossoms of plants, and the exhalations of living or decomposing animal bodies. Other gaseous emanations are simply irritating, like those of ammonia, chlorine, and acetic acid. Sometimes the two kinds of exhalations are mingled; thus pure alcohol is nearly or quite destitute of odor, but in cologne water we have the stimulating properties of the alcohol, mingled with odoriferous ingredients of a vegetable origin. Ammonia is irritating to the mucous membrane of the nose for the same reason that it is irritating to the skin when brought in contact with it; but the skin is incapable of perceiving a true odor. The dissemination of odors is favored by the movement of the atmosphere; and when a disagreeable or noxious odor is contained in the air of an apartment, a free ventilation is the readiest method of expelling it. When we wish to perceive more distinctly a

faint or a delicate odor, we direct the air forcibly upward, by a peculiar inspiratory effort of the nostrils, through the superior part of the nasal passages. This movement is especially observable in many of the inferior animals, in whom the sense of smell is remarkably acute, and the olfactory mucous membrane unusually extensive and sensible. The dog, for instance, will not only distinguish different kinds of animals by their odor, but will recognize different individuals of the human species, or particular articles of dress belonging to them. He will even follow the track of wild game by the minute quantity of animal odor left by their footsteps upon the grass or dried leaves.—The sense of smell, like the other senses, becomes habituated to particular impressions when long continued; even disagreeable odors gradually lose in this way their offensiveness, and we become after a time more or less insensible to their presence. A disagreeable odor is not invariably injurious in itself; but it is almost always the indication or accompaniment of a gaseous emanation which is in reality noxious, or will become so if allowed to accumulate. The offensive odor is a warning to the senses that the atmosphere is no longer pure and should be renovated; and if this warning be neglected, it at last ceases to make itself felt, and the exhalations may then imperceptibly increase until they produce serious injury.

**SMELT,** a soft-rayed fish of the salmon family, and genus *osmerus* (Artedi). The body is elongated and covered with small scales; there are two dorsals, the first with rays and the second adipose and rayless; ventrals under the anterior rays of dorsal; teeth on the jaws and tongue very long, and on the premaxillaries small and hooked; gill openings wide; air bladder silvery within. The common American smelt (*O. viridescens*, Les.) is about 10 in. long; the upper parts with the dorsal and caudal fins are yellowish green with coppery reflections, with very minute black dots; sides silvery white; abdomen and lower fins milky white; gill covers golden. It is found from

American Smelt (Osmerus viridescens).

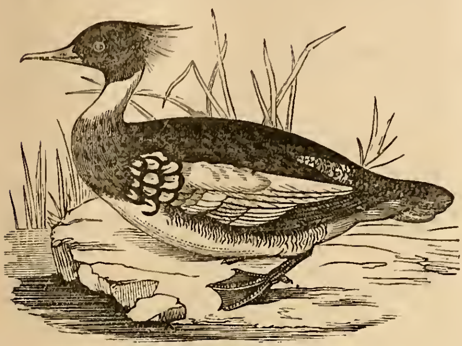
New York to Labrador, going up rivers in early spring and returning to the sea late in autumn, at which times immense quantities are taken by hook and nets; the flavor is very delicate. They bear transfer from salt into fresh water, and have become permanent residents in Champlain, Squam, and Winnipiseogee lakes, and in Jamaica pond near Boston; these are smaller and more slender than the marine smelt. The European smelt (*O. eperlanus*, Art.) is from 7 to 9 in. long, lighter colored above, with thicker body and narrower head. They are found in all the rivers opening into northern seas; they are the *éperlans* of the French and the spirling or sparling of the English; when recently taken from the water, they have a sweetish, not disagreeable, and cucumber-like odor, from which the generic and the common names are derived. Smelts eat small fish, crustaceans, and mollusks.

**SMELTING.** See Copper Smelting, Iron Manufacture, Lead, and Silver.

**SMET, Peter John de,** an American missionary, born in Dendermonde, Belgium, Dec. 31, 1801, died in St. Louis, May 23, 1873. He arrived in Philadelphia in August, 1821, entered the Jesuit novitiate at Whitemarsh, Md., went to Missouri in 1823, and aided in founding the university of St. Louis, in which he labored till 1838, when he was sent to found a mission among the Pottawattamies. His success caused him to be sent to the Flatheads in 1840, and to the Blackfeet soon afterward. He then planned a regular system of missionary establishments, which were taken charge of by his brother Jesuits, reserving to himself a general superintendence over them and the duty of providing funds for their support. He published several papers in the United States and in Europe for the purpose of creating public interest in favor of these missions, repeatedly visited Belgium and other Catholic countries to collect alms and obtain missionaries, and established several new missionary centres on both sides of the Rocky mountains. During a last voyage undertaken for the missions he sustained injuries which resulted in his death. His principal works are: "Letters and Sketches, and Residence in the Rocky Mountains" (Philadelphia, 1843); "Oregon Missions, and Travels over the Rocky Mountains" (New York, 1847); "Western Missions and Missionaries" and "New Indian Sketches" (New York, 1863); and *Reisen zu den Felsengebirgen und ein Jahr unter den wilden Indianerstämmen des Oregon-Gebietes* (St. Louis, 1865).

**SMEW** (*mergellus albellus*, Selby), a web-footed bird differing from the typical mergansers, to which subfamily it belongs, in having the bill much shorter than the head and elevated at the base, and the mandibles with short and closely set lamellæ. It is about 17½ in. long and 27 in. in alar extent; the general color is white, whence its common name of white nun; around the eyes, a patch on each side of the nape, semi-collar on each side of lower neck, middle of back, tail, and wings black; scapulars, middle wing coverts, tertials, and secondary tips white; in the female the head is reddish brown. It is found in the northern parts of the old world, in winter coming down to central Europe, frequenting the sea coast, lakes, and rivers; it is an expert swimmer and diver, and feeds on fish and crustaceans; the nest is made near the water,

and the eggs are 8 to 12; like other mergansers it hybridizes with the ducks, especially with the genus *clangula* (Flem.). It is generally



Smew (Mergellus albellus).

believed to be accidental in America, only a single female specimen having been obtained by Audubon, near New Orleans.

**SMIBERT, or Smybert, John,** a Scottish painter, born in Edinburgh about 1684, died in Boston, Mass., in 1751. He studied in Italy for three years, and attained a respectable standing as a portrait painter in London. In 1728 he accompanied Dean Berkeley to America, after whose return he settled in Boston. He painted most of the contemporary worthies of New England and New York. His most celebrated picture is a large portrait piece representing Berkeley and several members of his family, together with the artist himself, on their first landing in America. It is now in the possession of Yale college.

**SMILAX,** a genus of endogenous, mostly shrubby, often prickly plants, which climb by tendrils. They are abundant in warm climates, and are represented in the Atlantic states by several species, some of which are popularly known as greenbrier, catbrier, or brier. The genus is the only one in the flora of the northernmost states which affords an example of a woody endogenous stem; the general aspect of the plants is that of the exogens, as their leaves are netted-veined, while in the great majority of endogens they are parallel-veined; the petioles are furnished with a tendril upon each side. The flowers, in axillary umbels, are small, diœcious, with the greenish or yellowish regular perianth in six parts; the sterile flower has six stamens; the fertile has a free ovary of three or more cells and as many thick and spreading stigmas; fruit a small berry with one to three seeds. The best known species is the common greenbrier (*smilax rotundifolia*), which extends from Canada through the southern states; it often forms, by spreading over the shrubs and trees, impenetrable thickets, its stems extending from one tree to another for 30 or 40 ft., and very slender and strong; the smooth leaves are nearly orbicular, often broader than long, and somewhat heart-shaped at base, of a pleasing soft green color, which turns to deep yellow in autumn, and later to a rusty brown, though in the southern states they are nearly evergreen; the small clusters of berries are black, with a bloom, and have a tempting appearance, but are very nauseous to the taste. The plant is variable, and forms of it have been described as distinct species. It is a handsome ornamental climber, which has received no attention because it is common. There are about a dozen other species, from New Jersey southward, with variously shaped leaves, some of them evergreen, and differing in their fruit clusters. The most important of these is popularly known in the southern states as China brier (*S. pseudo-China*), which extends northward to New Jersey; its stems, especially near the base, have weak blackish prickles; the leaves are ovate heart-shaped, often with a fringe of rough hairs on the margins and a

Greenbrier (Smilax rotundifolia).

slender point. The young and tender shoots of this are eaten as asparagus; the mature stems have a reputation as an alterative; the rootstocks, which are tuberous, brownish red, and sometimes as large as the two fists, contain considerable starch, which the Seminoles formerly used in times of scarcity, both by separating the starch and by cooking the whole root; a kind of beer has been made from them, with molasses, parched corn, and sassafras; the root is light, porous, easily worked, and is largely used for tobacco pipes. A few species are herbaceous, the most common being the variable *S. herbacea*, 1 to 6 ft. high, with mostly heart-shaped leaves; the flowers are in large umbels, upon stalks 3 to 8 in. long, the fertile ones succeeded by a showy, nearly globular cluster of berries. This is sometimes a troublesome weed in pastures; when in bloom its presence is readily detected from the odor of its flowers, which has given the plant the well merited name of carrion flower. Two

other species belong to this section, which Torrey at one time regarded as a distinct genus, to which he gave the appropriate name of *coprosmanthus*. Nearly 200 species of *smilax* are enumerated as growing in various parts of the world, but, judging from the confusion of names existing among our own, the number of real species is much less. The most important exotic species are those which furnish the drug sarsaparilla. (See SARSAPARILLA.) Another medicinal product is the China root, the rhizome of *S. China* and several other eastern species, which, under the name of *radix Chinæ*, came into use about A. D. 1535 as a remedy for syphilis, gout, and rheumatism; it is now little used except in the East. The fresh rootstocks of this and other species are cooked and eaten by the Chinese.—Under the name of smilax florists cultivate in greenhouses large quantities of *myrsiphyllum asparagoides*, a liliaceous plant from the Cape of Good Hope, closely allied to asparagus; it has small tuberous roots, and very slender, strong, branching stems, which climb by twining to the height of 20 ft. or more; its proper leaves are minute scales, from the axils of which, as in asparagus, appear small branches, so modified that they look like true leaves, the functions of which they perform; the flowers are small, whitish, and inconspicuous, and are followed by green berries about the size of those of asparagus. It is raised from seeds, the roots being kept from year to year. This plant is one of the most valuable and popular of all greens used for decorations, as it does not readily fade, and its thread-like stems allow it to be used in the most delicate work. It is a very useful window plant if the atmosphere of the room is not excessively dry.

Smilax Vine (Myrsiphyllum asparagoides).

**SMILES, Samuel,** a British author, born at Haddington, Scotland, in 1816. After practising as a surgeon for some time at Leeds, he became editor of the Leeds "Times" in 1845, secretary of the Leeds and Thirsk railway, and in 1852 secretary of the Southeastern railway, from which post he retired in 1866. He has published "Physical Education, or Nature of Children" (Edinburgh, 1837); "History of Ireland and the Irish People under the Government of England" (London, 1844); "Life of George Stephenson" (1857); "Self-Help, with Illustrations of Character and Conduct" (1859); "Brief Biographies" (Boston, 1860); "Workmen's Earnings, Strikes, and Savings" (London, 1861); "Lives of the Engineers, with an Account of their Principal Works" (4 vols. 8vo, 1861–'5; new ed., 5 vols., 1875, including Stephenson); "Industrial Biography" (1863); "The Huguenots, their Settlements, Churches, and Industries in England and Ireland" (1867); "Character," a companion volume to "Self-Help" (1871); "The Huguenots in France after the Revocation of the Edict of Nantes" (1874); and "Thrift" (1875).

**SMILLIE, James, James D., and George H.** See p. 891.

**SMIRKE. I. Sir Robert,** an English architect, born in London in 1780, died at Cheltenham, April 18, 1867. He was the oldest son of Robert Smirke, a popular genre painter. After a tour through Germany and southern Europe, he settled in London in 1805 as an architect. He brought himself early into notice by his design for Covent Garden theatre (1808–'9), which was destroyed by fire in March, 1856. Subsequently he was employed in designing many public buildings in the metropolis, the most considerable being the mint, a Grecian Doric edifice erected in 1811; the post office (1823–'9); the college of physicians; King's college, as the eastern wing of Somerset house (1831); and the British museum (1823–'47). These were all in the classical style. His chief Gothic works are the restorations of York minster and the improvements and extensions of the Inner Temple. He also erected buildings for the United Service, Carlton, and Oxford and Cambridge clubs, the last in conjunction with his brother Sydney. He was elected a royal academician in 1812, and in 1831 was knighted. He published "Specimens of Continental Architecture" (fol., London, 1806). **II. Sydney,** younger brother of the preceding, also an architect, died Dec. 11, 1877. His style was more ornate and florid than that of his brother, and was employed with effect upon several of the London club houses, especially the Carlton in Pall Mall. He also directed the restorations of the Temple church and Lichfield cathedral, and in 1847 succeeded his brother as architect of the British museum. He was elected a member of the royal academy in 1860, professor of architecture in 1861, and treasurer in 1862. He published "Suggestions on the Architectural Improvements of the West of London" (1834), and "Architecture of the Temple Church" (4to, 1842).

**SMITH,** the name of four counties in the United States. **I.** A central county of Mississippi, intersected by Strong river and drained by the head streams of Leaf river; area, 620 sq. m.; pop. in 1870, 7,126, of whom 1,711 were colored. The surface is generally level and the soil poor. The chief productions in 1870 were 144,688 bushels of Indian corn, 28,286 of sweet potatoes, 45,040 lbs. of rice, 5,666 of wool, and 2,411 bales of cotton. There were 1,065 horses, 2,027 milch cows, 4,308 other cattle, 3,694 sheep, and 11,254

swine. Capital, Raleigh. **II.** A N. E. county of Texas, bounded N. by the Sabine river and W. by the Neches, and drained by the sources of the Angelina; area, 900 sq. m.; pop. in 1870, 16,532, of whom 7,131 were colored. The greater portion of the surface is prairie land, and the soil is fertile. It is traversed by the International and Great Northern railroad. The chief productions in 1870 were 420,646 bushels of Indian corn, 22,017 of barley, 54,987 of sweet potatoes, 100,856 lbs. of butter, 1,878 gallons of molasses, and 9,322 bales of cotton. There were 1,988 horses, 1,189 mules and asses, 4,975 milch cows, 9,954 other cattle, 2,726 sheep, and 22,658 swine. Capital, Tyler. **III.** A N. county of Tennessee, intersected by the Cumberland river and drained by Caney fork; area, about 300 sq. m.; pop. in 1870, 15,994, of whom 3,536 were colored. The surface is rough, but the soil is generally fertile. The chief productions in 1870 were 126,837 bushels of wheat, 888,078 of Indian corn, 72,528 of oats, 17,996 of Irish and 15,163 of sweet potatoes, 2,250,202 lbs. of tobacco, 32,674 of wool, 255,723 of butter, 39,061 of honey, and 40,344 gallons of sorghum molasses. There were 4,857 horses, 3,715 milch cows, 6,117 other cattle, 17,591 sheep, and 33,687 swine. Capital, Carthage. **IV.** A N. county of Kansas, bordering on Nebraska, and intersected by the N. fork of Solomon river; area, 900 sq. m.; pop. in 1870, 66; in 1875, 3,876. The surface is undulating and fertile. Capital, Smith Centre.

**SMITH, Adam,** a Scottish philosopher, born at Kirkcaldy, Fifeshire, June 5, 1723, died in Edinburgh, July 8, 1790. He studied at the university of Glasgow for three years, and for seven years at Oxford. In 1748 he fixed his residence in Edinburgh, where under the patronage of Lord Kames he delivered lectures on rhetoric and belles-lettres. He was elected in 1751 professor of logic in the university of Glasgow, and was transferred in 1752 to the chair of moral philosophy in the same university, which he filled nearly 12 years. His course was divided into four parts. The first treated natural theology; in the second, devoted to ethics, he developed the doctrines contained in his "Theory of Moral Sentiments;" in the third, the subject of which was justice, he traced the gradual progress of jurisprudence and government; and in the fourth, the subject of which was expediency, he examined those political regulations which relate to commerce, finances, and ecclesiastical and military establishments, and which are calculated to increase the power and prosperity of a state. The last division included the substance of his work on the "Wealth of Nations." He published in 1759 his "Theory of Moral Sentiments," in which he maintains the doctrine that all moral emotions and distinctions spring from sympathy. (See Moral Philosophy.) From this time he devoted a larger portion of his lectures to jurisprudence and political economy. Near the close of 1763 he resigned his professorship to accompany the young duke of Buccleugh on his travels. They visited Paris, resided 18 months at Toulouse, passed two months at Geneva, and returning to Paris at the end of 1765, remained there nearly a year. He returned with his pupil to London in October, 1766, and soon after fixed his residence for ten years with his mother at Kirkcaldy, engaged in severe study, and occasionally visiting Edinburgh and London. For many years he enjoyed an intimate friendship with Hume. In 1776 appeared his "Inquiry into the Nature and Causes of the Wealth of Nations," which was the first complete and systematic statement of the principles of political economy. It received several additions in the third edition (1784), and was translated into the principal European languages. A new edition by J. E. T. Rogers was published in London and New York in 1870 (2 vols. 8vo). (See Political Economy, vol. xiii., p. 668.) Smith resided for two years after its publication chiefly in London, and in 1778 was appointed one of the commissioners of customs for Scotland, removing to Edinburgh. In 1787 he was elected lord rector of the university of Glasgow. A large proportion of his savings was allotted to secret charity.

**SMITH, Albert,** an English author, born at Chertsey, May 24, 1816, died at Fulham, near London, May 23, 1860. He was educated for the surgical profession in London and Paris, and joined his father in practice at Chertsey, but soon became a writer for the periodical press. Settling in London in 1841, he became a contributor to "Bentley's Miscellany," and within a few years produced "The Wassail Bowl," "The Adventures of Mr. Ledbury," "The Scattergood Family," "The Marchioness of Brinvilliers," "Christopher Tadpole," and "The Pottleton Legacy." He was also engaged for some time upon "Punch," his contributions to which included "The Physiology of Evening Parties," "The Medical Student," and other light varieties; and in 1847–'9 he produced a number of amusing trifles entitled "The Natural History of the Gent," "The Natural History of the Ballet Girl," "Stuck-up People," and "The Flirt." He also wrote Christmas adaptations from the tales of Dickens, burlesques, and other stage pieces, and was the dramatic critic of the "Illustrated London News." A journey to Constantinople in 1849 furnished him with materials for his "Month at Constantinople" (1850), and also for the public entertainment called the "Overland Mail," first brought out in May, 1850. In August, 1851, he made the ascent of Mont Blanc, and his "entertainment" founded thereon proved his most successful venture, being constantly repeated till 1858. He then visited China, and after his return gave a Chinese entertainment, which in the spring of 1860 was replaced by the more popular story of Mont Blanc. This he repeated until within two days of his death. His entertainments

were published under the titles "Story of Mont Blanc" (1853), and "To China and Back" (1859); and since his death his brother, Arthur Smith, has published from his sketches "Wild Oats and Dead Leaves" (1860), and "Paris and London" (1867).

**SMITH, Alexander,** a Scottish poet, born in Kilmarnock, Dec. 31, 1830, died at Wardie, near Edinburgh, Jan. 5, 1867. He was the son of a pattern designer, and himself became a pattern designèr for a lace factory in Glasgow. In 1852 he published serially in the "Critic" his poem "A Life Drama," issued with other poems in book form in 1853. In 1854 he was appointed secretary of the university of Edinburgh (a post which he retained till his death), and about the same time delivered a series of lectures. His later poetical works are: "Sonnets of the War," in conjunction with Sydney Dobell (1855); "City Poems" (1857); and "Edwin of Deira" (1861). He also wrote in prose "Dreamthorp" (1863); "A Summer in Skye" (2 vols., 1865); "Alfred Hagart's Household" (2 vols., 1866); and "Miss Oona McQuarrie" (1866). A posthumous volume, "Last Leaves," was edited by P. P. Alexander, with a memoir (1868).

**SMITH, Eli,** an American missionary, born at Northford, Conn., Sept. 15, 1801, died in Beyrout, Syria, Jan. 11, 1857. He graduated at Yale college in 1821, and at Andover theological seminary in 1826, and on May 23 of the latter year sailed as a missionary of the American board for Malta, where he took charge of the missionary printing establishment. In 1827 he went to Beyrout to study Arabic, and in 1828 returned to his work at Malta. In 1829 he made a tour with Dr. Anderson through Greece, and in 1830–'31 with Dr. Dwight of Constantinople through Armenia and Georgia to Persia, opening the way for the Nestorian mission at Urumiah. In 1832 he visited the United States, and published a work by himself and Dr. Dwight entitled "Missionary Researches in Armenia." He returned to Beyrout in 1833. In 1838 and again in 1852 he was the travelling companion and coadjutor of Dr. Edward Robinson in his explorations in Palestine. After the journey of 1838 he went to Leipsic to superintend the casting of a new font of Arabic type, in which he improved the form of the letters, making them more distinct and nearer the style of the written letters. He revisited the United States in 1839, and again, on account of illness, in 1845. From 1847 he was engaged upon a translation of the Bible into modern Arabic, which was completed by Dr. C. C. Van Dyke. He published a volume of sermons and addresses (1834).

**SMITH, Francis Hopkinson.** See p. 891.

**SMITH, George,** an English oriental scholar, born in 1840, died in Aleppo, Aug. 19, 1876. In 1866 he discovered among the Assyrian paper casts in the British museum an inscription of Shalmaneser II., giving an account of the war against Hazael. In 1867 he assisted in preparing a new volume of "Cuneiform Inscriptions of Western Asia" for the British museum. Thereafter the study of the cuneiform texts became his sole occupation. His principal earlier discoveries, published in the "Transactions of the Society of Biblical Archæology," are: a tablet noticing the eclipse of June 15, 763 B. C.; notices of the Israelitish kings Azariah, Pekah, and Hoshea; accounts of the conquest of Babylonia by the Elamites in 2280 B. C.; a curious religious calendar of the Assyrians; and a tablet containing the Chaldean account of the deluge, which he afterward discovered to be the eleventh in a series of twelve giving the history of an unknown hero, whom he believes to be the same as the Nimrod of the Bible. In 1871 he published, at the cost of Mr. Fox Talbot and Mr. J. W. Bosanquet, his great work on the history of Asshur-bani-pal, giving the cuneiform texts, transcriptions, and translations of the historical documents pertaining to this reign. In 1873 the proprietors of the "Daily Telegraph" sent him on an exploring expedition to Nineveh, and in 1874 he went there again. He obtained over 3,000 entire or fragmentary inscriptions, and many other objects of great importance. He published in 1875 an account of these explorations, and contributed a volume on the history of Assyria to the series of "Ancient History from the Monuments;" also "The Chaldean Account of Genesis" (German translation by H. Delitzsch, with notes by F. Delitzsch, 1876), a series of legends from the cuneiform inscriptions resembling the Biblical accounts. In March, 1876, he went again to the East.

**SMITH, Gerrit,** an American philanthropist, born in Utica, N. Y., March 6, 1797, died in New York, Dec. 28, 1874. He inherited from his father Peter Smith, a partner of John Jacob Astor in the fur trade, one of the largest estates in the country, consisting chiefly of land in almost every county of New York and in nearly all the states of the Union. He graduated at Hamilton college, Clinton, N. Y., in 1818, and for many years his chief occupation was the management of his property, his residence being at Peterboro, Madison co. He studied law, and was admitted to the bar when 56 years old (1853). In 1825 he joined the colonization society, and contributed largely for the removal of colored people to Africa. Ten years later he withdrew from it and joined the American anti-slavery society. He gave away large quantities of land in public and private charity, and in 1848 distributed 200,000 acres, in parcels averaging 50 acres. In 1852 Mr. Smith was elected a representative in congress; but he did not like public life, and resigned at the close of the first session. While in congress he voted with the party opposed to slavery, and made several speeches on that side. A few years later he contributed largely to the struggle for free institutions in Kansas, in which his friend John Brown became

prominent; and in 1859 he gave pecuniary aid to Brown in preparing for the attack on Harper's Ferry, though he probably had no precise knowledge of his plans. The failure of that attempt, and grief and anxiety for the loss of life which it occasioned, temporarily overthrew his reason, and for some months he was an inmate of the insane asylum at Utica. During the civil war he strongly advocated the cause of the Union and contributed largely for the raising of troops. After its close, he joined with Horace Greeley in 1867 in signing the bail bond by which Jefferson Davis was liberated. Mr. Smith was of a strongly religious nature, and he was in the habit of preaching in a church built by himself. His originally orthodox views underwent great changes, but he is said to have finally returned to them. He printed and distributed gratuitously many pamphlets, speeches, and addresses, and published in book form "Speeches in Congress" (1855); "Sermons and Speeches" (1861); "The Religion of Reason" (1864); "Speeches and Letters" (1865); "The Theologies" (2d ed., 1866); "Nature the Base of a Free Theology" (1867); and "Correspondence with Albert Barnes" (1868).

**SMITH, Goldwin,** an English author, born in Reading, Aug. 13, 1823. He was educated at Eton and Oxford, and was called to the bar at Lincoln's Inn, but never practised. In 1858 he became regius professor of modern history at Oxford. During the American civil war he was a warm friend of the federal government, and published "Does the Bible sanction Slavery?" (1863), "On the Morality of the Emancipation Proclamation" (1863), "Letter to a Whig Member of the Southern Independence Association" (1864), "England and America" (1865), and "The Civil War in America" (1866). In September, 1864, he visited the United States. In 1866 he resigned his chair at Oxford, with a view of taking up his residence in America. Coming to this country in 1868, he became professor of English history in Cornell university, and resided at Ithaca till 1871, when he exchanged his chair for that of a non-resident professor, and removed to Toronto. He has since been appointed a member of the senate of the university of Toronto, and from 1872 to 1874 was the editor of the "Canadian Monthly." In 1874 he revisited England. He contributed to the "Anthologia Oxoniana," the "Oxford Essays," and the "Encyclopædia Britannica." His other publications are: "Inaugural Lecture before the University of Oxford" (1859); "Lectures on Modern History," "Lectures on the Study of History," "Foundation of the American Colonies," "On some supposed Consequences of Historical Progress," and "Rational Religion" (1861); "Irish History and Irish Character," and "On Church Endowments" (1862); "Empire, a Series of Letters" (1863); "Plea for Abolition of Tests in Oxford" (1864); "Three English Statesmen," sketches of Pym, Cromwell, and Pitt (1867); "Reorganization of the University of Oxford" (1868); and "Relations between America and England" (1869).

**SMITH, Henry Boynton,** an American clergyman, born in Portland, Me., Nov. 21, 1815, died in New York, Feb. 7, 1876. He graduated at Bowdoin college in 1834, was some time a tutor there, and studied theology at Andover and Bangor, and subsequently at Halle and Berlin. He became pastor of the Congregational church in West Amesbury, Mass., in 1842, and professor of mental and moral philosophy in Amherst college in 1847. In 1850 he became professor of church history in the Union theological seminary, New York, and in 1855 of systematic theology, which chair he resigned in 1873. He was elected in 1863 moderator of the New School general assembly of the Presbyterian church, and at the opening of the next general assembly in Dayton, Ohio, in 1864, delivered a discourse which was published under the title "Christian Union and Ecclesiastical Reunion." He was subsequently a member of the general assembly's committee on reunion with the Old School general assembly, and presented a report on a doctrinal basis of union ("The Reunion of the Presbyterian Churches," 8vo, 1867). In 1867 he was a delegate to the evangelical alliance in Amsterdam, where he read a "Report on the State of Religion in the United States." He was a founder of the "American Theological Review," and its editor from 1859 to 1862, when it was consolidated with the "Presbyterian Review," which he edited till 1871. His principal works are: "The Relations of Faith and Philosophy" (8vo, 1849); "The Nature and Worth of the Science of Church History" (1851); "The Problem of the Philosophy of History" (1853); "The Idea of Christian Theology as a System" (1857); "An Argument for Christian Colleges" (1857); "History of the Church of Christ, in Chronological Tables" (fol., 1859); a new edition of the Edinburgh translation of Gieseler's "Church History" (5 vols. 8vo, 1859-'63), of which vols. iv. and v. were chiefly translated by Prof. Smith; a revised edition of the Edinburgh translation of Hagenbach's "History of Christian Doctrine" (2 vols. 8vo, 1861-'2); with James Strong, a new edition of the Edinburgh translation of Stier's "Words of the Lord Jesus" (in parts, 1864 *et seq.*); and with R. D. Hitchcock, "The Life, Character, and Writings of Edward Robinson" (1864).

**SMITH, James,** a signer of the Declaration of Independence, born in Ireland about 1719, died in York, Pa., July 11, 1806. He came to America with his father's family in 1729, studied law in Lancaster, Pa., and after his admission to practice removed to the neighborhood of Shippensburg, and engaged in surveying. After a few years he removed to York, which became his permanent home, and entered upon the legal profession. In 1774 he was chosen a deputy to attend the provincial

meeting, or rather "Committee for the Province of Pennsylvania," which convened at Philadelphia July 15. At this meeting he was one of those who were appointed to "prepare and bring in a draught of instructions to the representatives in assembly met." In 1776 he was chosen a member of the continental congress, in which he continued till 1778; and when congress held its sessions in York, the board of war occupied his law office.

**SMITH, James** and **Horace,** English authors, associated together in literary history. The former was born in London, Feb. 10, 1775, and died there, Dec. 24, 1839; and the latter was born in London, Dec. 31, 1779, and died at Tunbridge Wells, July 12, 1849. They were the sons of Robert Smith, a legal practitioner of London, and were early trained to an active business life, James in the professional business of his father, and Horace as a member of the stock exchange, in which business he acquired a fortune. The poetical imitations entitled "Horace in London," originally contributed to the "Monthly Mirror," and afterward republished in England and America, were written principally by James. In 1812 the rebuilding of Drury Lane theatre led to the offer of a prize for an opening address; the brothers, in six weeks, completed a series of parodies on the popular authors of the day, in the form of addresses for the prize, and thus arose the well known volume of "Rejected Addresses." The publisher Murray originally declined giving £20 for the copyright, but after it had run through 16 editions (1819) he purchased it for £131. James Smith during the remainder of his life wrote anonymously for amusement or relief from physical suffering, contributing *vers de société* and epigrams to the magazines or annuals, or assisting Charles Mathews the actor in the preparation of his "Country Cousins," his "Trip to France," and other "entertainments." A collection of his miscellaneous pieces in prose and verse was published after his death by his brother (2 vols., 1840). Horace, subsequent to 1820, when he retired from business, was for 25 years one of the most industrious authors of England. In 1826 appeared "Brambletye House," one of his earliest novels, and his most successful one. It was succeeded by "Tor Hill," "Reuben Apsley," "Jane Lomax," "The New Forest," and other novels, few of which are now known outside of the circulating libraries. In 1845 the author took a formal leave of the public in the preface to "Love and Mesmerism." A selection from the poetical works of Horace and James Smith, including the "Rejected Addresses," with a memoir by Epes Sargent, was published in New York in 1857. "The Tin Trumpet" (2 vols. 8vo), published anonymously in 1836, was republished in 1869 as the work of Horace Smith.

**SMITH,** Sir **James Edward,** an English botanist, born in Norwich, Dec. 2, 1759, died there, March 17, 1828. He studied medicine at Edinburgh, purchased the books, manuscripts, and herbarium of Linnæus, commenced the practice of his profession in London, received the degree of M.D. at Leyden, and in 1788 founded the Linnæan society of London, of which he was the first president. In 1796 he returned to Norwich, though he lectured on botany for two months each year at the royal institution. He wrote "English Botany" (36 vols., with 2,592 colored figures by Sowerby, London, 1792–1807); *Flora Britannica* (3 vols., 1800–'4); "Exotic Botany" (2 vols., 1804–'5); "Introduction to Systematical Botany" (1807); and "The English Flora" (3 vols., 1823–'5); and he edited Sibthorp's *Flora Græca* (1808).

**SMITH, John,** the founder of Virginia, born at Willoughby, Lincolnshire, England, in January, 1579, died in London, June 21, 1631. When young he took part in the wars in the Netherlands, and after four years' service returned home, but went abroad again to fight against the Turks. He distinguished himself by daring exploits in Hungary and Transylvania, and received from Sigismund Báthori a patent of nobility and a pension, but finally was taken prisoner, and sent as a slave to Constantinople. Here he gained the affection of his young mistress, who to secure his safety sent him to her brother, a pasha on the sea of Azov, with a letter in which she confessed her feelings. The proud prince, indignant at the attachment of his sister to a Christian, maltreated Smith, who at length, maddened by an insult, beat out his master's brains with a flail, put on the dead man's clothes, mounted his horse, and finally reached a Russian garrison on the Don. He was here kindly treated and helped on his journey to Transylvania, where he was furnished with money to repair his losses. Smith now returned to England, reaching it after a long journey and an attempt to take part in a war in Barbary, and was persuaded by Capt. Gosnold, who had already visited the coasts of America, to engage in the founding of a colony. The expedition, consisting of three vessels and 105 men, under the command of Newport, set sail Dec. 19, 1606. By the charter, the government of the colony was placed in the hands of a council app[illegible] and removable by the crown; their names [illegible] in a sealed box, not to be opened until their arrival at Virginia. On the voyage dissensions sprang up among the leaders, and much enmity was shown to Smith. At the Canaries he was charged with a conspiracy to make himself king of Virginia, and was kept prisoner for the rest of the voyage. After landing the box was opened, and although Smith was named one of the council, he was excluded. With Newport he headed a party of 20 men to discover the source of the James. About six weeks after, when Newport was returning to England, Smith's enemies urged him to return and be reprimanded by the council in England rather than suffer the disgrace of a public conviction in the colony; but he demanded a trial, which

resulted in his acquittal, and he was made a member of the council. Bad and scanty food brought on disease among the colonists and reduced their number. The president, Wingfield, embezzled the stores and was deposed. Ratcliffe was made his successor, but the real head was Smith, and to his efforts the salvation of the infant colony was owing. He set about the building of Jamestown, and after providing the settlers with lodgings made excursions into the neighboring country to obtain corn. On one of these expeditions he was taken prisoner by the Indians, and his life was saved, it is said, by the interference of Pocahontas. (See POCAHONTAS.) Sent back to Jamestown by Powhatan after an absence of seven weeks, he found the colony reduced to 40 men, and the most of these had determined to return to England. This, however, Smith prevented, and the arrival of Newport with 120 men raised the spirits of the colonists. In June and July, 1608, Smith explored the coasts of Chesapeake bay as far as the mouth of the Patapsco. On July 24 he started on another expedition, and explored the head of the Chesapeake, returning to Jamestown on Sept. 7. In these two voyages Capt. Smith sailed, by his own computation, about 3,000 m., and from his surveys constructed a map of the bay and the country bordering upon it. Being now president of the colony, he administered its affairs with energy; and his influence restored quiet to the colony, which had been filled with dissensions and disturbed by fears of the Indians. Smith's administration, however, had not been satisfactory to the company in England, whose too brilliant hopes had been disappointed, and whose irritation Smith's soldierly bluntness did not conciliate. A new charter was granted, and the powers previously reserved to the king were transferred to the company. Lord Delaware was made governor, and three commissioners, Newport, Sir Thomas Gates, and Sir George Somers, were empowered to manage the affairs of the colony till his arrival. They set sail with more than 500 emigrants, and a part of the fleet, in a shattered condition, and without the commissioners, reached Virginia in August, 1609. The new emigrants were mostly "dissolute gallants, packed off to escape worse destinies at home, broken tradesmen, gentlemen impoverished in spirit and in fortune, rakes and libertines, men more fitted to corrupt than found a commonwealth." Disorders quickly ensued, and Smith, at the request of the better part of the colony, resumed the government. The refractory were put in prison, and new settlements established. Returning from one of them, he was severely injured by the explosion of a bag of gunpowder, and in September, 1609, returned to England. In 1614 he explored with two ships the New England coast, and on his return presented to Prince Charles a map of the country between the Penobscot and Cape Cod. In 1615 he sailed again to New England, to found a colony. His vessel was captured by a French man-of-war, and he was carried to La Rochelle. He escaped, and on his return home wrote an account of his voyages to New England, which was published in 1616. The remainder of his life was passed in retirement. He published several works, the most important of which are "The Generall Historie of Virginia, New England, and the Summer Isles" (1626), and "The True Travels, Adventures, and Observations of Captain John Smith, in Europe, Asia, Affrica, and America, from 1593 to 1629" (1630). These two works were reprinted at Richmond in 1819. In 1631 he published also "Advertisements for the Unexperienced Planters of New England, or anywhere, or the Pathway to Experience to Erect a Plantation." This has been reprinted with a facsimile of Smith's map of New England (4to, Boston, 1865); also the "Description of New England" (4to, 1865), and "A True Relation of Virginia," reprinted from the London edition of 1608, with an introduction and notes by Charles Deane (4to, 1866).—See "Life of Capt. John Smith," by G. S. Hillard, in Sparks's "American Biography," vol. ii.

**SMITH, John Augustine,** an American physician, born in Westmoreland co., Va., Aug. 29, 1782, died in New York, Feb. 9, 1865. He went in 1809 to New York, where he edited the "Medical and Physiological Journal," and was a lecturer on anatomy in the college of physicians and surgeons. In 1814 he removed to Virginia, and was president of William and Mary college till 1826, when he resigned and returned to New York. He was president of the college of physicians and surgeons from 1831 to 1843, and editor of the "Medical and Physiological Journal." He published "Introductory Discourse at the New Medical College in Crosby Street" (1827); "Select Discourse on the Functions of the Nervous System" (1840); "The Mutations of the Earth" (1846); "Monograph upon the Moral Sense, two Discourses" (1847); "Prelections on Moral and Physical Science" (1853); and numerous essays and lectures on moral philosophy, physical science, &c.

**SMITH, John Lawrence,** an American chemist and mineralogist, born near Charleston, S. C., Dec. 16, 1818. He graduated at the university of Virginia and at the medical college of South Carolina, and for three years studied chemistry, physiology, physics, mineralogy, and geology in Europe. In 1844 he commenced the practice of medicine in Charleston, delivered lectures on toxicology, paid attention to agricultural chemistry, and ascertained the character and value of the marl beds extending 100 m. back of Charleston. In 1846 he was employed by the Turkish government to suggest improvements in the cotton culture in Asia Minor, and accepted the appointment of mining engineer. He remained four years, and in 1849 made a report on the "Thermal Waters of Asia Minor." His mining researches

in Asia Minor led to the subsequent discovery of emery and corundum in localities in the United States. After his return in 1851 he invented the inverted microscope, and was professor of chemistry in the university of Virginia, and subsequently in the medical department of the university of Louisville, Ky., and is now (1876) scientific superintendent of the Louisville gas works. In 1867 he was a commissioner to the Paris exposition, making a report on "The Progress and Condition of Several Departments of Industrial Chemistry," and in 1873 to the Vienna exhibition. In 1872 he was elected president of the American association for the advancement of science. His scientific reports are numerous, and his original researches, about 50 in number, have been collected in a volume, "Mineralogy and Chemistry: Original Researches" (8vo, Louisville, 1873). (See EMERALD, and EMERY.)

**SMITH, John Pye,** an English clergyman, born in Sheffield, May 25, 1774, died in Guildford, Surrey, Feb. 5, 1851. In his 22d year he entered the Independent academy at Rotherham, and in 1800 was chosen classical tutor in the Homerton theological academy. He subsequently became pastor of a church at Homerton, and in 1813 he was appointed divinity tutor. From 1843 to 1850 he was again classical tutor; but on the consolidation of Homerton, Highbury, and Coward academies into New college, he resigned. He was a fellow of the royal and of the geological society. His principal works are: "The Scripture Testimony to the Messiah" (3 vols., 1818–'21; 5th ed., 2 vols., 1868); "Four Discourses on the Sacrifice and Priesthood of Jesus Christ" (3d ed., 1827); "On the Personality and Divinity of the Holy Spirit" (1831); "The Mosaic Account of the Creation and the Deluge illustrated by the Discoveries of Modern Science" (1837); and "Scripture and Geology" (1839; 4th ed., greatly enlarged, 1848; 5th ed., 1854).—See "Memoirs of the Life and Writings of John Pye Smith," by J. Medway (1853).

**SMITH, Joseph,** founder of the Mormon church, or church of Latter Day Saints, born at Sharon, Vt., Dec. 23, 1805, killed at Carthage, Ill., June 27, 1844. His parents, of Scotch descent, early removed to Palmyra, N. Y. The family was disreputable, and Joseph's education was very defective. With the aid of Sidney Rigdon he brought forth the "Book of Mormon," which he pretended to have discovered under angelic guidance, written on plates and hidden in the earth; and on this he founded and organized his church in Manchester, N. Y., April 6, 1830. In 1831 he went with his disciples to Kirtland, O., and erected a costly but very singular temple. Here Smith and Rigdon engaged in fraudulent banking, were tarred and feathered for this and other offences in 1832, and after the failure of their bank in January, 1838, fled to Missouri. There, in a town named Far West, Smith's disciples gathered; but their irregularities occasioned an outbreak against them, and their speedy removal to Hancock county, Ill., where they built a city called Nauvoo, and constructed another costly temple. Here Smith, who combined in his own person the chief military, municipal, and ecclesiastical offices, introduced polygamy under a pretended revelation; but several outraged husbands revolted and established an opposition press, which Smith with a mob demolished. For this warrants were issued against Smith, his brother Hyrum, and others. The Smiths refused obedience to the authorities, the state militia were summoned, and war was threatened; but they were finally induced to surrender, and were imprisoned. Fearing their release, a mob gathered, overcame the prison guard, and shot the prisoners dead, Joseph defending himself with a revolver till his ammunition failed. (See MORMONS.)

**SMITH, Joseph Mather,** an American physician, born at New Rochelle, N. Y., March 14, 1789, died in New York, April 22, 1866. He graduated in medicine in 1815 at the college of physicians and surgeons, New York. In 1826 he was appointed professor of the theory and practice of medicine in the college of physicians and surgeons, and in 1829 attending physician to the New York hospital. In 1855 his chair was exchanged for that of materia medica and clinical medicine. His most important publications are: "Elements of the Etiology and Philosophy of Epidemics" (New York, 1824); "Report on Practical Medicine" ("Transactions of the American Medical Association," 1848, vol. i.); "Report on Public Hygiene" (ibid., 1850, vol. iii.); "Medical Topography and Epidemics of the State of New York" (ibid., 1860, vol. xiii.); and "Therapeutics of Albuminuria" ("Bulletin of the New York Academy of Medicine," 1863, vol. ii.).

**SMITH, Robert Payne,** an English orientalist, born in Gloucestershire in November, 1818. He graduated at Pembroke college, Oxford, in 1841, took orders, was curate of Trinity church and master of the academy in Edinburgh, and subsequently was head master of the proprietary school in Kensington. In 1857 he was appointed sub-librarian of the Bodleian library, with special charge of the oriental manuscripts. In 1865 he was made canon of Christ church, Oxford, and regius professor of divinity in the university. Since 1871 he has been dean of Canterbury. He has published annotated copies and English versions of Syriac manuscripts, including "Cyril of Alexandria's Commentary on St. Luke's Gospel" (4to, Oxford, 1858; English version, 2 vols. 8vo, 1859) and "Ecclesiastical History of John of Ephesus" (8vo, 1860). He has also published a Latin "Catalogue of the Syriac MSS. in the Bodleian Library" (4to, 1864), "Authenticity and Messianic Interpretation of the Prophecies of Isaiah" (8vo, 1862), and "Prophecy a Preparation for Christ" (Bampton lectures for 1869). In 1873 he prepared a paragraphic Bible for the society for promoting Christian

knowledge. In 1874 he was understood to be preparing a commentary on Jeremiah, for the "Speaker's Commentary," and was engaged upon the *Thesaurus Syriacus*, of which up to 1872 two parts had been published.

**SMITH, Samuel Stanhope**, an American clergyman, born at Pequea, Pa., March 16, 1750, died in Princeton, N. J., Aug. 21, 1819. He graduated at Princeton college in 1767, and from 1770 to 1773 was tutor there. He was then for some time a missionary in western Virginia, and was principal of the seminary which became the Hampden Sidney college. In 1779 he was appointed professor of moral philosophy in the college of New Jersey, of which he was president from 1794 to 1812. In 1786 he was associated with several other clergymen of the Presbyterian church in preparing the form of presbyterial government which continues to the present time. He published "Causes of the Variety in the Figure and Complexion of the Human Species" (8vo, 1787); "Sermons" (1799); "Lectures on the Evidences of the Christian Religion" (12mo, 1809); and "A Comprehensive View of the leading and most important Principles of Natural and Revealed Religion" (8vo, 1816). His "Sermons," with a memoir of his life and writings, were published in 1821 (2 vols. 8vo).

**SMITH. I. Seba**, an American author, born in Buckfield, Me., Sept. 14, 1792, died in Patchogue, L. I., July 29, 1868. He graduated at Bowdoin college in 1818, and settled in Portland, where he edited the "Eastern Argus" (1820–'24) and the "Courier" (1830–'37). In 1842 he removed to New York. He published "Life and Letters of Major Jack Downing" (Boston, 1833), a celebrated series of humorous political letters; "Powhatan," a metrical romance (1841); "Dewdrops of the Nineteenth Century," miscellanies (1846); "New Elements of Geometry" (1850); "Way Down East, or Portraitures of Yankee Life" (1854); and "My Thirty Years out of the Senate, by Major Jack Downing" (1859–'60). **II. Elizabeth Oakes** (Prince), an American authoress, wife of the preceding, born in North Yarmouth (now Cumberland), Me. She married Mr. Smith at the age of 16, and about the same time became an anonymous contributor of poems to the periodical press. After her removal with her husband to New York in 1842 she frequently appeared before the public as a lecturer. In 1843 appeared the first considerable collection of her poetical pieces under the title of "The Sinless Child and other Poems," and her metrical contributions to the magazines have since been numerous. She is the author of "The Roman Tribute" and "Jacob Leisler," tragedies; "The Western Captive" and "Bertha and Lily," novels; "The Salamander, a Legend for Christmas;" and children's books and miscellaneous publications. In 1851 she published "Woman and her Needs," a work devoted to the rights of woman, which Mrs. Smith has at various times advocated by her pen and as a lecturer. Among her later publications are: "Hints on Dress and Beauty" (1852); "Shadow Land" (1852); "The Newsboy" (1855); "Bald Eagle, or the last of the Ramapaughs" (1867); "Two Wives" (1871); and "Kitty Howard's Journal" (1871). She now (1876) resides at Hollywood, Carteret co., N. C.

**SMITH, Sydney**, an English author, born at Woodford, Essex, June 3, 1771, died in London, Feb. 22, 1845. He was educated at New college, Oxford, where in 1790 he obtained a fellowship of £100 a year. He took orders, and in 1794 became curate in the parish of Netheravon, in Salisbury plain; but three years later he went to Edinburgh as a private tutor. In 1802 he was associated with Murray, Jeffrey, Brougham, Horner, and others in establishing the "Edinburgh Review," to the first number of which, as editor, he contributed seven articles. Soon afterward he went to London, where his sermons attracted large and fashionable congregations, and in 1804–'6 he delivered courses of lectures on moral philosophy before the royal institution. A posthumous volume, entitled "Elementary Sketches of Moral Philosophy" (1850), contains the substance of these. Upon the return of the whigs to power in 1806, he was presented to the living of Foston-le-Clay in Yorkshire, worth about £500 a year. In 1807–'8 appeared anonymously his "Letters on the Subject of the Catholics, by Peter Plymley," which, owing to an admirable mixture of sound sense, irony, and pleasantry, had an immense circulation; and his efforts in the cause of Catholic emancipation were never relaxed until that measure was accomplished. In 1809 he published two volumes of sermons, and in the summer of that year removed with his family to Heslington, near York, where he resided for a few years, in the hope of being able to exchange Foston-le-Clay for some more desirable parish. Failing in this, he turned his thoughts toward Foston, the forlorn condition of which he characteristically described by saying it was "actually twelve miles from a lemon," constructed a parsonage, and in the spring of 1814 moved with his family into his new quarters. In 1828 Lord Lyndhurst appointed him canon of Bristol and rector of Combe-Florey, near Taunton, and three years later he received a prebendal stall in St. Paul's. The remainder of his life was devoted to the discharge of his official duties, and to literary labors; but he wrote nothing for the "Edinburgh Review" subsequent to 1827. Having come into the possession of a considerable estate by the death of his brother Courtenay in 1843, he invested largely in the public stock of Pennsylvania; and the neglect of that state to pay the interest on her bonds called out his "Petition to Congress" and "Letters on American Debts," writings overflowing with humorous invective. His humor never left him, and under the last regimen of his physician he expressed his longing for "even the wing

of a roasted butterfly." A collection of his writings, comprising his review articles, "Peter Plymley's Letters," and various pamphlets and miscellanies, was published in 1839–'40 (4 vols. 8vo; afterward in several other forms). He left also in manuscript an account of English misrule in Ireland, which his widow was advised by Macaulay not to publish. In 1855 appeared a memoir of him by his daughter Saba, the wife of Sir Henry Holland; and a volume of his writings and sayings, entitled "The Wit and Wisdom of Sydney Smith," was collected with a memoir by E. A. Duyckinck (New York, 1856).

**SMITH, Thomas Southwood,** an English physician, born at Martock, Somersetshire, Dec. 21, 1788, died in Florence, Italy, Dec. 10, 1861. He studied medicine at the university of Edinburgh, and settled in the country, but in 1820 removed to London, and was one of the founders of the "Westminster Review." His work on "The Use of the Dead to the Living," reprinted from the earlier numbers of the "Review," was instrumental in the passage by parliament of the anatomy act, which put an end to the business of "resurrection." In 1824 he was appointed physician to the London fever hospital, and somewhat earlier to the eastern dispensary. In 1832 he was one of the commissioners to inquire into the condition of factory children, and his report led to the passage of the factory act. In 1838 he presented to the poor-law commissioners the first of a series of reports on the "Physical Causes of Sickness and Mortality which are capable of Removal by Sanitary Regulations." This led to the appointment of a sanitary committee by the house of commons in 1840, and of the health of towns commission in 1842. Dr. Smith was appointed in 1840 a commissioner to inquire into the condition of children and young persons in the mines and factories not reached by the factory act, and his reports induced the exclusion of young children and women from mining labor. In 1847, as one of the metropolitan sanitary commissioners, he made a report on the means requisite for the improvement of the health of the metropolis, of which the result was the public health act of 1848 and the establishment of a general board of health. On its abolition he received a pension of £300. His principal works are: "Illustrations of the Divine Government" (Glasgow, 1814; 5th ed., London, 1866); "Treatise on Fever" (1830), long a standard with the profession; and "The Philosophy of Health" (2 vols. 12mo, 1835–'7; 12th ed., 1868).

**SMITH, William,** called the father of English geology, born at Churchill, Oxfordshire, March 23, 1769, died in Northampton, Aug. 28, 1839. In his youth he was a land surveyor and civil engineer, and was led to geological studies by his professional observations. He began in 1794 a "Map of the Strata of England and Wales," and in 1799 published in tabular form "The Order of the Strata and their Organic Remains in the vicinity of Bath, examined and proved prior to 1799." In 1801 a small geological map of England was produced, and in 1815 the "Geological Map of England and Wales, with Part of Scotland," with a treatise. Between 1819 and 1824 he published 21 geological maps of English counties, colored to represent the strata, and some works on organic remains. In 1824–'8 he lectured on geology. In 1831 he received from the geological society the Wollaston medal for his discoveries in geology.

**SMITH, William,** an English scholar, born in London in 1814. He was educated at University college, London, and studied law, but became professor of the Greek, Latin, and German languages at the Independent collegiate schools of Highbury and Homerton. In 1850 he was appointed professor of Greek and Latin in New college, London, and in 1853 classical examiner in the university of London. In 1867 he became editor of the "Quarterly Review." He has edited a "Dictionary of Greek and Roman Antiquities" (8vo, 1842); "Dictionary of Greek and Roman Biography and Mythology" (3 vols. 8vo, 1843–'9); "Dictionary of Greek and Roman Geography" (2 vols., 1854–'7); and "Dictionary of the Bible" (3 vols., 1860–'63). All these dictionaries have been abridged by him for the use of schools. The first and the abridged edition of the second and third combined have been edited by Charles Anthon (New York, 1843 and 1850). The "Dictionary of the Bible" has been abridged by the Rev. S. W. Barnum (New York, 1868), and edited and enlarged by Prof. H. B. Hackett (4 vols., New York, 1868–'70). He has also published a "History of Greece," and an abridgment of the same, an edition of Gibbon's "Decline and Fall of the Roman Empire," and a "Student's Gibbon," a "Student's Hume," and "Student's Hallam's Middle Ages," each in one volume; a Latin-English dictionary (1855), based on Forcellini and Freund; with J. D. Hall, "A copious and critical English-Latin Dictionary" (1870); with George Grove, a "Historical Atlas of Ancient Geography, Biblical and Classical" (1873); and "Modern Geography for Schools" (1873). In 1874 he was preparing "A Dictionary of Christian Antiquities" and "A Dictionary of Christian Biography and Doctrines." He has also published Latin and Greek courses for schools, and other educational works, of which numerous editions have been issued.

**SMITH, William Andrew,** an American clergyman, born in Fredericksburg, Va., Nov. 29, 1802, died in Richmond, March 1, 1870. In 1825 he was admitted to the Virginia conference of the Methodist Episcopal church. In 1833 he became agent of Randolph Macon college, after which he served as pastor of the principal Methodist churches of Richmond, Petersburg, Norfolk, and Lynchburg. He was a member of every general conference from

1832 to 1844, and also of the Louisville convention at which was organized the Methodist Episcopal church, South, and of every general conference of this body until his death. From 1846 to 1866 he was president of Randolph Macon college, and during this period not only filled the chair of moral science and presided over the college, but lectured extensively in Virginia and North Carolina. In the autumn of 1866 he was transferred to the St. Louis conference, and in 1869 was chosen president of Central university, Missouri. He was for a time editor of the Richmond "Christian Advocate," and published "Lectures on the Philosophy of Slavery" (Richmond, 1860), a defence of the institution as it existed in the southern states.

**SMITH,** Sir **William Sidney,** an English admiral, born at Midgham, Sussex, in 1764, died in Paris, May 26, 1840. He entered the navy at the age of 12, and before he was 20 was post captain, serving to the close of the American war. He subsequently participated in the war between Sweden and Russia as a captain in the Swedish service. Afterward, in command of a small English flotilla, he harassed French commerce in the channel, but in April, 1796, was captured by a superior force and confined in the prison of the Temple in Paris. The French government refused to exchange him, but he escaped by French aid after an imprisonment of two years. In 1798 he was put in command of a squadron to operate against the French on the coast of Egypt, and conducted the memorable defence of St. Jean d'Acre against Gen. Bonaparte. He signed a treaty with Gen. Kléber for the evacuation of Egypt by the French, which was disavowed by the British government; and he continued to participate in the war until compelled by wounds to return to England in 1801. He afterward returned to service, and at the close of the war received a pension of £1,000. In 1821 he was made an admiral. He was an early advocate of the abolition of the slave trade. Memoirs of his "Life and Times" were written by Sir John Barrow (2 vols., London, 1847).

**SMITHSON, James,** an English physicist, founder of the Smithsonian institution, born about 1765, died in Genoa, June 27, 1829. He was a natural son of Hugh, third duke of Northumberland, and Mrs. Elizabeth Macie, heiress of the Hungerfords of Audley, and niece of Charles, duke of Somerset. In 1786 he took the honorary degree of A. M. at Oxford, under the name of James Lewis Macie, but between 1791 and 1803 adopted the name of Smithson, the family name of his father. At the university he distinguished himself as a chemist, and was one of the first to adopt the method of minute analysis. He became the friend and associate of Wollaston, Banks, and Davy, and in 1787 was elected a fellow of the royal society and contributed eight papers to its "Transactions." His papers subsequent to 1818 were published in the "Annals of Philosophy" and other scientific periodicals. At his death he left about 200 manuscripts, probably intended to form portions of a philosophical dictionary. He bequeathed to his nephew £120,000, the whole of his property, which in case of the death of the latter without heirs was to go to the government of the United States to found at Washington, under the name of the Smithsonian institution, an establishment for the increase and diffusion of knowledge. (See Smithsonian Institution.)

**SMITHSONIAN INSTITUTION,** a scientific establishment in Washington, D. C., organized by act of congress in August, 1846, to carry into effect the provisions of the will of James Smithson. The condition on which the bequest was to take effect in favor of the United States having occurred in 1835, by the death of a nephew of the testator without issue, the Hon. Richard Rush was sent to London to prosecute the claim. On Sept. 1, 1838, he deposited in the United States mint the proceeds in English sovereigns, which amounted to $515,169. Suggestions were invited by the president as to the mode of disposing of the fund, which was in the mean time lent to Arkansas and other states to aid in internal improvements. The first section of the act of 1846, passed after several years' discussion of conflicting plans, creates an "establishment" for the increase and diffusion of knowledge among men, to consist of the president and vice president of the United States, the several members of the cabinet, the chief justice of the supreme court, the commissioner of the patent office, and the mayor of Washington, during their respective terms of office, with such other persons as these may elect honorary members of the institution. The second declares the original fund to be lent in perpetuity to the treasury of the United States at 6 per cent., payable semi-annually; appropriates the interest from Sept. 1, 1838, when the money was received, to July 1, 1846, amounting to $242,129, or so much thereof as might be necessary, for the erection of buildings and other current incidental expenses; and provides that all expenditures and appropriations shall in future be made exclusively from the accruing interest and not from the principal of the fund. By the third section a board of managers is constituted, under the name of "Regents of the Smithsonian Institution," to be composed of the vice president of the United States, the chief justice, the mayor of Washington, three members of the senate and three of the house of representatives, to be selected by the president and speaker thereof, with six other persons not members of congress, of whom two shall be resident in the city of Washington and the other four inhabitants of the United States, but no two of the same state. This board is required to elect one of its members as presiding officer, to be styled the chancellor of the institution, and also a suitable person to act as secretary both of the institu-

tion and the board. To this body is assigned the duty of a general superintendence, and of making an annual report to congress on the operations, expenditures, and condition of the institution. Sections 4, 5, and 6 assign a location and give power for "the erection of a suitable building of sufficient size, with apartments for the reception and arrangement upon a liberal scale of objects of natural history, including a geological and mineralogical cabinet; also a chemical laboratory, a library, a gallery of art, and the necessary lecture rooms;" and provision is made that all objects of art, natural history, &c., belonging to the United States, with such as may be collected from whatever source by the institution itself, shall be deposited in the building. Section 7 devolves on the secretary the charge of the building and property, and the duties of librarian and keeper of the museum, with the power of employing assistants, subject to the approval and removable at the discretion of the regents. Section 8 defines the visitorial relations of the members of the establishment toward the board of regents, and also limits the expenditure for the library. Section 9 authorizes the managers to dispose of such portion of the interest of the fund as the act has not otherwise appropriated, in such manner as they shall deem best suited for the promotion of the purpose of the testator. On this clause the present organization of the institution principally depends. In accordance with the requirements of this act of congress, a spacious building was erected, making provision for a library, museum, gallery of art, and lectures. The entire cost of the building, improvement of the grounds, &c., has been upward of $500,000. A library was begun, consisting chiefly of transactions and proceedings of learned societies obtained by exchange, and of other works by purchase necessary for general use, which has become unequalled in this country as a resource for scientific reference.

Smithsonian Institution.

The museum, enriched by the fruits of governmental expeditions and the contributions of individual explorers under the direction of the institution, has attained a magnitude and completeness seldom surpassed in collections for the illustration of natural science. A gallery of art was commenced, consisting principally of Indian portraits, engravings, and such articles as were presented to the institution by foreign governments; and lectures, chiefly on scientific subjects, were delivered up to 1865, when they were abandoned in consequence of a fire which destroyed the lecture room and afforded an opportunity of making important changes in the operations of the institution. The library was incorporated with that of congress, making the latter at once the largest in the United States, to which the institution annually contributes a copy of the transactions and proceedings of each of the principal societies of the world, and in return receives the use of all the books in the collection. Mr. W. W. Corcoran of Washington having founded a free public gallery of art, the institution has deposited in it its art collection. This is in accordance with the general plan of coöperating with the different establishments in the city of Washington, the institution having transferred to the department of agriculture its botanical collections, and to the army medical museum all specimens relating to medicine and anatomy, while it receives in return from these departments everything which relates to natural history and ethnology. The expense of the care of the grounds around the building, which at first devolved upon the institution, has been subsequently defrayed by government, and congress has been induced to make an annual appropriation for the support of the museum of $20,000. By these changes the burdens which congress placed upon the institution have been removed, and an opportunity is afforded for the expenditure of the income of the Smithson legacy, in strict conformity with the terms of the will, for the "increase and diffusion of knowledge among men."—In December, 1846, the board of regents selected Prof. Joseph Henry, then of the college of New Jersey at Princeton, as their secretary, which office he still holds (1876). His assistants are Prof. Spencer F. Baird, formerly of Dickinson college, Carlisle, Pa., in the natural history department (appointed in 1850), and William J. Rhees as chief clerk (appointed in 1853). The board of regents from its composition has necessarily changed to some extent almost every year, and of its original members none now remain. Soon after his appointment Prof. Henry submitted to the board a "programme

of organization" of the proposed operations under the 9th section, which was adopted, and still constitutes the basis of management. He suggested that men of talent and erudition should be afforded the means of conducting researches, and stimulated to exertion through facilities of publication and occasional compensation; and for its diffusion, the publication of such works as, while adding materially to the sum of human knowledge, would not find a remunerative sale in the ordinary channels of trade. He insisted that it ought to be a rule of the institution to do nothing which can be equally well done by any organization or instrumentality already in action. The results are as follows: 1. *Researches.* The claims of different classes of scientific research to the countenance and aid of the institution have always been pressing and difficult of adjudication; yet a preference has been given to those of widest influence and benefit to the race. Ethnology was believed to be one of these, and a valuable and expensive memoir on the archæology of the Indian tribes was the first to receive assistance. In connection with this, aid was extended to the compilation of a Dakota grammar and dictionary, and a grammar of the Yoruba language. The circulation of these has led to other researches in ethnology and kindred branches of science, some of which are receiving or will receive assistance. Astronomy has also engaged the earnest and continued efforts of the institution for its promotion theoretically and practically, and pecuniary assistance has been furnished to expeditions undertaken with a view to astronomical and other observations. It has not only furnished instruments for physical observation to expeditions, but in most cases has defrayed the expense of the reduction and publication of the results. In meteorology it had for many years 500 regular observers scattered over every part of the continent, and accumulated data through this and other measures steadily and systematically pursued for developing the laws which govern the phenomena of the weather. In accordance with the plan of coöperation adopted, this system has been transferred to the United States signal service. The natural history, geography, climatology, geology, mineralogy, botany, and archæology of this continent have through its aid received a greater impulse, and more material has been collected for increasing and diffusing the knowledge of them than through all other instrumentalities during the national existence. 2. *Publications.* These are of three classes. 1st. "The Smithsonian Contributions to Knowledge," comprised up to 1875 in 20 large quarto volumes, and in many cases expensively illustrated. No memoir is admitted into this series which rests on unverified hypothesis, or which does not offer some positive addition to the sum of existing knowledge; and the pretensions of each in this respect are decided by submission to the judgment of two or more arbiters of unquestionable competence and impartiality. The volumes thus far issued form a series for the publication of which no learned society in this country possessed the means, and which have only been equalled by foreign societies when aided by their governments. They have been distributed gratuitously among all the important libraries and learned associations of the world, and have afforded the means of obtaining by exchange those invaluable sets of the "Transactions" of foreign learned societies, not otherwise to be found in this country. 2d. The "Smithsonian Miscellaneous Collections," an occasional series comprising meteorological and physical tables, treatises on subjects of practical or scientific interest, and manuals for the collection and preservation of objects of natural history, as well as methods for various physical observations. This series includes 12 octavo volumes. 3d. The "Annual Reports" to congress, which, besides a popular analysis of the memoirs to be contained in the several forthcoming volumes of the "Contributions," are accompanied by a synopsis of lectures and original or translated articles, which introduce the student to information and topics of discussion much above the range of those usually presented even to the educated public. These are printed at the expense of congress, and are circulated through the members of both houses, as well as by the institution itself. 3. *Exchanges.* The institution now acts as the principal, and is gradually becoming the exclusive means of communication between the literary and scientific associations of the old and the new world. 4. *Scientific Correspondence.* The correspondence of the Smithsonian institution with all quarters of the globe is vast and constantly increasing. Almost every day brings narratives of real or supposed discoveries which are referred to the institution, inquiries on scientific topics of all kinds, or unusual phenomena, &c. These letters are all answered.—In 1865 a residuary legacy of Smithson was received, amounting to $26,210 63; and in 1874 a bequest of $1,000 from James Hamilton of Carlisle, Pa. With these, and savings of income and increased value of investments, the total permanent Smithson fund in the United States treasury, drawing interest at 6 per cent. in gold, now amounts to $651,000. There are besides depreciated investments valued in January, 1875, at $35,000, which with a cash balance on hand of $15,909 99 made the total resources at that time $701,909 99.

**SMOKE TREE.** See SUMACH.

**SMOLENSK. I.** A W. government of Russia, bordering on Tver, Moscow, Kaluga, Orel, Tchernigov, Mohilev, Vitebsk, and Pskov; area, 21,637 sq. m.; pop. in 1870, 1,140,015. The surface is an elevated undulating plain, broken occasionally by low hills. The chief rivers are the Dnieper and Desna. It is interspersed with numerous small lakes and morasses; and there

are immense forests of excellent timber, which abound with game. The soil is generally productive. Great numbers of cattle and of the celebrated Lithuanian horses are raised. Much attention is given to raising bees, and honey and wax form important articles of export. Iron, copper, and salt are found. Linen and woollen goods are manufactured, and fine carpets are exported. **II.** A city, capital of the government, on both sides of the Dnieper, 230 m. W. S. W. of Moscow; pop. in 1867, 22,977. It is considered the key to Moscow, and is strongly walled and fortified. It is the seat of a bishop, and has a remarkable cathedral and more than 20 other Greek churches. Its manufactures consist chiefly of linen and woollen cloths, leather, hats, and soap. It was important in the 9th century, and was long independent under its own princes. The Tartars, Lithuanians, and Russians afterward held it successively; and in the 16th and 17th centuries it was the scene of conflicts between the Poles and Russians, often changing masters, but finally taken by the latter in 1654. On Aug. 17, 1812, was fought the battle of Smolensk, between the French and the Russians. In the night the Russians abandoned the town, and on the morning of Aug. 18 it was occupied by the French, who next marched upon Moscow, leaving most of Smolensk in ashes. The town was subsequently rebuilt and greatly embellished.

**SMOLLETT, Tobias George,** a British author, born in Dalquhurn house, parish of Cardross, Dumbartonshire, in 1721, died at Monte Nero, near Leghorn, Oct. 21, 1771. He was educated at the grammar school of Dumbarton and at the university of Glasgow, and was apprenticed to a medical practitioner. When his apprenticeship expired, in his 19th year, he set out for London, carrying with him a tragedy entitled "The Regicide," which he vainly attempted to produce on the stage. Thwarted in his purpose, he accepted in 1741 the post of surgeon's mate on an 80-gun ship, and sailed on the disastrous expedition against Cartagena, which he has described in "Roderick Random," and with more detail in the "Compendium of Voyages." He left the navy at Jamaica, and while there became acquainted with Anne Lascelles, whom he married in 1747. Returning to England in 1746, after the battle of Culloden, he produced anonymously "The Tears of Scotland," an ode lamenting the atrocities of the royal army. He also published "Advice, a Satire" (1746), and "Reproof, a Satire" (1747), and wrote "Alceste, an Opera," for the Covent Garden theatre, which was withdrawn in consequence of a quarrel with the manager. In 1748 appeared the first of his novels, "The Adventures of Roderick Random." He made a short visit to Paris in 1750, and in 1751 published "The Adventures of Peregrine Pickle," which is disfigured by an episode detailing the intrigues of Lady Vane, for inserting which he is said to have received a liberal reward from her. He now resumed the medical profession, settled at Bath, and published in 1752 "An Essay on the External Use of Water." Obtaining no practice, he removed to Chelsea, and devoted himself again to literary pursuits. In 1753 appeared his "Adventures of Ferdinand Count Fathom." In 1755 he published by subscription his translation of "Don Quixote," more animated and elegant but less accurate than that of Jarvis, on which it was founded. Afterward he undertook the management of the "Critical Review." His irritable temper and capricious tastes involved him in numerous vexations and quarrels; a contemptuous critique on the "Rosciad" provoked against him the spleen of Churchill; and in 1759 an attack on Admiral Knowles, one of the commanders at Cartagena, caused him. to be arraigned for libel and sentenced to a fine of £100 and three months' imprisonment. He had meantime produced a "Compendium of Authentic and Entertaining Voyages" (7 vols., 1757), a comedy entitled "The Reprisals," which Garrick brought out on the stage, and a "Complete History of England" (4 vols., 1757–'8), written in 14 months, which became very popular. While in prison he wrote "The Adventures of Sir Launcelot Greaves," a sort of travesty of "Don Quixote," which appeared in the "British Magazine" in 1760–'61. He afterward contributed the accounts of France, Italy, and Germany to the "Modern Universal History," and continued his "Complete History of England," bringing the narrative down from 1748 to 1764. The whole work was in 16 vols. 8vo, of which only the last 5 vols., forming a continuation to Hume, are now read. On the accession of George III. he undertook to defend the administration of Lord Bute in a weekly paper entitled "The Briton." He was effectively and abusively answered by Wilkes in his "North Briton," and his services being unpaid, and his side most unpopular, he withdrew from the contest. His health was shattered by this discomfiture, by his labors on a translation of the works of Voltaire and on a compilation entitled "The Present State of All Nations," and by the death of his only child; and in 1763 he went abroad for two years. In 1766 he published "Travels through France and Italy," which was ridiculed by Sterne in his "Sentimental Journey." On returning from Italy he visited Scotland, resided at Bath during the following year, and there wrote "The Adventures of an Atom," a political satire, in which he assailed Lord Bute and the earl of Chatham. His broken health obliged him again to seek a milder climate, and he went to Italy in 1770, beginning on his way to write "The Expedition of Humphrey Clinker," which appeared in 1771, just before his death.—His life has been written by Thomas Roscoe, Dr. Moore, and others. One of the best editions of his works appeared in 1873 (8 vols. 8vo, London).

**SMYRNA** (Turk. *Ismir*), a town of Asiatic Turkey, capital of the vilayet of Aidin, near the head of the gulf of Smyrna, on the W. coast of Asia Minor, 210 m. S. W. of Constantinople; pop. (according to the Austrian consul general Scherzer's estimate in 1873) about 155,000, including 75,000 Greeks, 45,000 Turks, 15,000 Jews, 10,000 Roman Catholics, 6,000 Armenians, and 4,000 Europeans and Americans. Another estimate places the population at 180,000. Owing to the large preponderance of the Christians, it is called by the Turks the Giaour city. It stands upon a plain between the ancient Mt. Pagus and the sea, part of it on the slope of the hill. The streets are generally narrow and dirty. An interesting locality is the so-called caravan bridge, with adjoining grounds for the accommodation of camels during the night. Along the shore and in its vicinity reside the Christians, excepting the Armenians, whose quarter is partly on the lower slopes of the hill, the upper slopes being occupied by the Turks; and in the region between the Armenians and Turks live the Jews, who are chiefly of Spanish descent and mostly poor. On the summit of the hill is a castle. A quay is in course of construction. Smyrna contains a governor's palace, churches for various denominations, a convent, and several schools, that of the Prussian deaconesses being the best. A large Roman Catholic cathedral is in course of construction. An archæological school was projected in 1874 for promoting excavations at the site of ancient Ephesus, adjoining a station on the Smyrna and Aidin railway. Another line to Ala-Shehr (the ancient Philadelphia) was extended from Kassaba in 1875. A Turkish governor general, and Greek, Armenian, and Roman Catholic archbishops reside in the city; and there are

Smyrna.

American and other missionaries. In the adjoining villages of Burnabad and Budja are fine villas. Smyrna is an important station for steamers and a great commercial emporium; the harbor is magnificent, and at all times crowded with shipping. The entrances in 1873 were 630 steamers and 785 sailing vessels, tonnage 659,247; clearances, 627 and 693, tonnage 648,579. The imports, chiefly cotton and other manufactured goods, amounted to $23,332,780, and the exports, including cotton, figs, raisins, opium, sponges, and valonia, to $20,794,332. The shipments of cotton, now so important, were insignificant previous te the American civil war. In 1873-'4 the imports from the United States, chiefly petroleum, were valued at $300,000, and the exports to the United States, including opium, figs, liquorice root, wool, and rags, at $2,234,344.—Smyrna was probably colonized by Æolians from Cyme, but early fell into the hands of the Colophonians, and in the 7th century B. C. formed the 13th city of the Ionian league. According to Strabo, it was destroyed by Sadyattes of Lydia about 627, and remained in ruins for several centuries. It was rebuilt and enlarged by Antigonus and Lysimachus, successors of Alexander the Great, and became one of the first cities of that era. One of the seven churches mentioned in the book of Revelation was at Smyrna, and Polycarp was its first bishop. The town was destroyed by an earthquake in A. D. 178, and rebuilt by Marcus Aurelius. It afterward had many changes of fortune; and being occupied by a Seljuk chieftain about the end of the 11th century, it was nearly destroyed by the Byzantine fleet. It was again rebuilt, and subsequently the Genoese held it for a long period. In the latter part of the 14th century it was taken by the Turks, in whose

possession it ultimately remained, after being captured in 1402 by Tamerlane. Among its many calamities in modern times were the conflagration of 1841 and the earthquake of 1846. In July, 1853, Martin Koszta was delivered here from the hands of the Austrians by Capt. Ingraham.—See Scherzer's *La province de Smyrne* (1875).

**SMYTH**, a S. W. county of Virginia, bounded S. E. by the Iron mountain range and drained by the head streams of Holston river; area, about 500 sq. m.; pop. in 1870, 8,898, of whom 1,244 were colored. The surface is an elevated valley between the Iron mountain range and Walker's mountain; the soil is very fertile. Limestone, gypsum, and salt are found. It is traversed by the Atlantic, Mississippi, and Ohio railroad. The chief productions in 1870 were 44,681 bushels of wheat, 96,829 of Indian corn, 66,323 of oats, 3,327 tons of hay, 1,575 lbs. of tobacco, 10,514 of wool, 64,910 of butter, 26,820 of cheese, 3,113 of flax, and 9,897 of honey. There were 1,595 horses, 1,846 milch cows, 3,193 other cattle, 4,553 sheep, and 4,059 swine. Capital, Marion.

**SMYTH, Thomas**, an American clergyman, born in Belfast, Ireland, June 14, 1808, died in Charleston, S. C., Aug. 20, 1873. He was educated in Belfast and London, and in 1830 entered the theological seminary at Princeton, N. J. From 1832 till his death he was pastor of the second Presbyterian church in Charleston, S. C. Among the numerous works of Dr. Smyth are: "Lectures on the Prelatical Doctrine of Apostolic Succession" (Boston, 1841); "The Ecclesiastical Catechism" (1841); "Ecclesiastical Republicanism" (1843); "Presbytery and not Prelacy the Scriptural and Primitive Polity" (1843); "Calvin Defended" (Philadelphia, 1844); "The Rite of Confirmation" (1845); "The Name, Nature, and Functions of Ruling Elders" (1845); "The History, Character, and Results of the Westminster Assembly of Divines" (New York, 1847); "The Unity of the Human Races proved to be the Doctrine of Scripture, Reason, and Science" (1850); "Nature and Claims of Young Men's Christian Associations" (Philadelphia, 1857); "Faith the Principle of Missions" (1857); "The Well in the Valley" (1857); and "Obedience the Life of Missions" (1860).

**SMYTH. I. William Henry**, a British naval officer, born in Westminster, Jan. 21, 1788, died near Aylesbury, Sept. 9, 1865. He entered the navy in 1805, and rendered important aid in the defence of Cadiz in 1810. He became lieutenant in 1813, and soon afterward was appointed to a command in the flotilla under Sir Robert Hall detailed for the defence of Sicily. By order of the lords of the admiralty he made an elaborate survey of Sicily and the adjacent islands, which occupied him for several years, and resulted in the publication by the admiralty of an atlas of Sicily. As an accompaniment to this, he published a "Memoir descriptive of the Resources, Inhabitants, and Hydrography of Sicily and its Islands, interspersed with Antiquarian and other Notices" (4to, 1824). He afterward completed the survey of the shores of the Adriatic, and was employed in 1823 and 1824 in a survey of the coasts of Sardinia, and published a "Sketch of the present State of the Island of Sardinia" (8vo, 1828). He attained the rank of post captain in February, 1824, and settled soon after at Bedford, where he built a small observatory, and in 1844 published a "Cycle of Celestial Objects, for the use of Naval, Military, and Private Astronomers" (2 vols. 8vo). In 1853 he attained the rank of rear admiral, and in 1857 he was appointed hydrographer to the admiralty. His most valuable work is entitled "The Mediterranean, a Memoir, Physical, Historical, and Nautical" (8vo, 1854), in which he gives in systematic and condensed form the results of his numerous surveys and observations on the physical geography of that sea. He also wrote "Sidereal Chromatics" (1864), and "The Sailor's Word Book" (1867). **II. Charles Piazzi**, son of the preceding, has held the post of astronomer royal for Scotland. In 1856 he transported a large collection of meteorological, magnetical, and astronomical instruments to the peak of Teneriffe, where he selected two stations, one 8,840, and the other 10,700 ft. above the sea, and obtained important results detailed in his "Teneriffe, an Astronomer's Experiment" (London, 1858). He has since written "Three Cities in Russia" (1862); "Our Inheritance in the Great Pyramid" (1864; new ed., 1874); "Life and Work at the Great Pyramid" (1867); "On the Antiquity of Intellectual Man, from a Practical and Astronomical Point of View" (1868); and "Equal Surface Projection for Maps of the World" (1871). He maintains that the pyramids are memorials of a system of weights and measures intended to be perpetual.

**SNAIL**, the common name of the *helicidæ*, a large family of gasteropod mollusks, terrestrial and air-breathing. The number known is now so large that the treatment of the subfamilies and genera would require a volume. Restricting the name *helicidæ* to such as have a well developed external spiral shell, the snails may be characterized as animals breathing air by means of branchial vessels spread like a network over the internal walls of a cavity in the anterior part of the body, covered by the shell, and communicating with the atmosphere by a small valvular opening on the right side; they have four retractile tentacles, the upper two the largest and having eyes at the apex; there is a dentated horny jaw on the upper lip, which is opposed by the tongue; the gullet is wide, with large white salivary glands on its sides, and the liver is well developed; the whole body is very glutinous; the locomotion is slow, by means of the ventral foot; they are hermaphrodite, with reciprocal impregnation. The shells are always external, vary much in form, and contain the entire animal;

they have no operculum, the opening during hibernation being closed by a secretion from the mantle, which hardens into what is called the epiphragm; the shell is generally turned from left to right, the free edge to the right, but they are often reversed; the newly hatched young resemble their parents, and have a shell of one whorl and a half. They are sensitive to cold, and like moist places; the sense of touch is acute, especially in the tentacles, and they appear to have a sense of smell; they are nocturnal, and feed principally on plants, though sometimes devouring each other. The reproductive season is toward the end of spring; the eggs, to the number of 30 to 100, are deposited in moist places, in natural or artificial holes; the young come out in 20 to 30 days. Snails are distributed very widely, from the northern limit of trees to Tierra del Fuego, from the hot and moist plains to a height of 11,000 ft. on mountains; some are cosmopolite, ranging wherever their food is found, and others are restricted within narrow limits. About 1,500 species have been described, some of which from their voracity are very injurious to vegetation, and some useful to man as food; they are very tenacious of life, and able to resist long droughts. A specimen of the desert snail of Egypt (*helix desertorum*), which remained dormant in the British museum four years, afterward lived in the possession of one of the curators more than two years.—The genus *helix* (Lam.) is the type of the family. The Roman or vineyard snail (*H. pomatia*, Linn.) is a large species, reddish brown with paler bands; these snails were used as food by the ancient Romans, who reared them in parks, and fattened them on cooked meat and flour, obtaining them from the islands of the Mediterranean; they are still eaten in many countries of Europe, especially by Roman Catholics during Lent, being considered as fish; great numbers are eaten in France; they are also recommended as an ingredient in soups for consumptive persons. The reproductive internal organs, in the apex of the shell, consist of many parallel cæca, each of which has an external layer producing eggs, and an internal sac producing semen; the apparatus is very complex. The *H. aspersa* (Linn.), or common garden snail, originally from Europe, but now naturalized in most parts of the globe, is also used as food, when boiled in milk, for consumptives. These species when abundant are very destructive, laying waste whole gardens in a single night, always attacking the tenderest and most succulent plants; besides their natural enemies, mammals and birds, great numbers are killed by fires, inundations, sudden changes of temperature, felling of forests, cultivation of the land, and by hogs and poultry following the plough; the remedies for their depredations are the same as for the slugs. The largest of the American snails is the *H. albolabris* (Say), of a yellowish horn color, with white, broadly reflected lip; the shell has five or six whorls, with minute revolving lines and the umbilicus closed; in October they cease feeding, and select a place under some log or stone, where they fix themselves for the winter,

American Snail (Helix albolabris).

mouth upward. For details on the American species, see Dr. A. Binney's "Terrestrial Air-breathing Mollusks of the United States" (3 vols., Boston, 1851, and vol. iv., a continuation by G. W. Binney, Boston, 1859).

**SNAKE.** See SERPENT.

**SNAKE BIRD.** See DARTER.

**SNAKE RIVER** (also called Lewis fork or river, Saptin river, and Shoshone river), a tributary of the Columbia, rising in the Rocky mountains in N. W. Wyoming, near the sources of the Yellowstone and Madison rivers, at an elevation of about 8,000 ft. above the sea, about lat. 44° N., lon. 110° 30′ W. It flows N. W. to the junction of Lewis fork, the outlet of Shoshone and Lewis lakes; then S., expanding in its course into Jackson lake, and again N. W. to the junction of Henry's fork (a total course of nearly 200 m.) in Idaho, about lat. 43° 15′, lon. 112°. Henry's fork rises in Henry lake (6,443 ft. above the sea, about lat. 44° 30′, lon. 111° 30′) in E. Idaho, on the border of Montana, near the head waters of Jefferson river, and has a S. course. From the junction the Snake describes a curve of more than 350 m. through S. Idaho, flowing S. W. and then N. W., and strikes the Oregon border in about lat. 44° 40′; it then flows N. about 200 m., separating Idaho from Oregon and Washington territory, when in about lat. 46° 30′ it turns W. into Washington, and after a further course of about 150 m. falls into the Columbia about 20 m. above the Oregon boundary, about lat. 46° 15′, lon. 119°. Its total length is upward of 900 m. Steamers ascend to Lewiston on the Idaho border; navigation is then impeded for more than 100 m. by shallows and rapids, above which the river is again navigable for 150 or 200 m. In its course through S. Idaho, the Snake flows through a vast cañon, varying in depth from 100 to 1,000 ft.; many of its tributaries sink, and, passing under the strata of lava, fall from the sides of the cañon into the main stream; and here occur the American, Shoshone, and Salmon falls, for an account of which see IDAHO, vol. ix., p. 167. Its chief tributaries on the right bank are the Malade from the north; the Boisé, Payette, Weiser, Salmon, and Clearwater (which enters at the point where the Snake leaves the Idaho boundary) from the east; and the Palouse (in

Washington) from the north. On the left bank it receives among others the Blackfoot, Port Neuf, Bannack, Raft, Goose, Salmon, and Bruneau, in Idaho; the Owyhee, Malheur, Burnt, and Powder, in Oregon; and the Grande Ronde, just within Washington territory.

**SNAKEROOT,** a common name, usually with a prefix, for several plants which are botanically very distinct, applied to them because they were supposed, especially by the Indians, to be efficacious against the poisonous bites of serpents. 1. Seneca snakeroot (officinal as senega) is *polygala senega.* The genus *polygala* (Greek *πολύς*, much, and *γάλα*, milk, as some species were formerly supposed to increase the secretion of milk) has about 200 species, widely distributed, about 25 of which belong to this country, and a few showy exotics are grown as greenhouse plants. The flowers have the general appearance of those of the *leguminosæ*, but their structure is quite different and is difficult to describe; two of the five sepals are colored and petal-like, while the three proper petals are united, the middle one keeled-shaped and often bearing a crest; the six or eight stamens are united by their filaments in two sets, the anthers one-celled and opening by a hole at the top; pod small and two-seeded. *Polygala polygama* and *P. pauciflora*, both pretty native species, produce, besides ordinary flowers, numerous fertile flowers on short underground runners. *P. senega*, the thick, hard, and knotted rootstocks of which are the seneca snakeroot of the shops, is found from New England southward and westward; the stems are about a foot high; leaves lanceolate, and the white flowers in close terminal spikes. The dried root has a peculiar odor and an acrid taste when chewed; it contains a principle called senegine, probably the same that has been called polygalic acid, and closely allied to saponine. The drug was first introduced into Europe as the Seneca rattlesnake root about 1734, and in 1749 Linnæus wrote a dissertation upon the drug. It is a stimulant expectorant, and in large doses emetic and diaphoretic; it is chiefly used in the compound sirup of squills, or hive sirup.

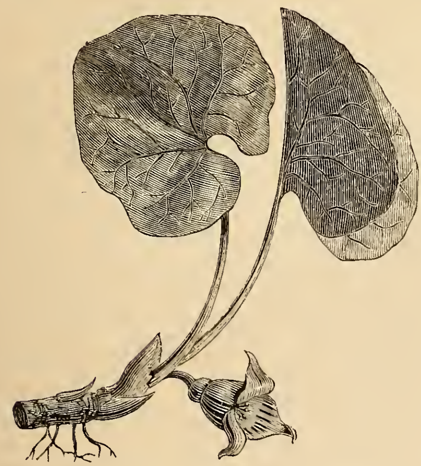
Seneca Snakeroot (Polygala Senega). Part of Root of natural size.

2. Virginia snakeroot, as found in the shops, is the root of *aristolochia serpentaria* and its varieties. The genus *aristolochia* is apetalous, and comprises low herbs and climbing vines; the tubular calyx is often curiously bent and inflated, and in some of the hothouse exotic species presents some of the strangest forms to be found among flowers.

Virginia Snakeroot (Aristolochia serpentaria).

The best known species is *A. sipho*, which, under the name of Dutchman's pipe (from the shape of the flowers), is often cultivated as a vine for verandas. The medicinal species has a weak stem about a foot high, usually heart-shaped leaves, and a few inconspicuous flowers close to the root, the calyx tube being curved like the letter S. It is most abundant in the middle states and southward, but like most medicinal plants has become rare in the older states. The dried root, when bruised, has a marked odor and taste, which have been compared to camphor, valerian, and turpentine combined; it contains an essential oil and a resin. Virginia snakeroot had a high reputation with the Indians as a cure for snake bites, and was early introduced into England as a remedy for the bite of reptiles and rabid dogs, and was officinal in the London Pharmacopœia of 1650. It is now used only as a stimulant tonic and diaphoretic, and has been employed in the treatment of intermittent fevers. 3. Canada snakeroot, also called wild and Indian ginger, is *asarum Canadense.* The genus *asarum*, with the preceding one, belongs to the family of *aristolochiaceæ*, and consists of low stemless herbs, from the creeping rootstocks of which rise usually one or two heart-shaped leaves on long petioles, and a short-peduncled flower, which appears in early spring; the regular calyx has three equal lobes, brownish purple, enclosing 12 stamens and the large pistils. *A. Canadense* has broadly heart-kidney-shaped deciduous leaves, in pairs, with the flower between them. The dried rootstock is in contorted pieces about the size of a quill, with an odor and a taste somewhat between

those of ginger and cardamoms; it contains an essential oil; it is an aromatic stimulant, and is sometimes used to modify the action of other medicines; in domestic practice a tincture is used in colic, and in some parts of the country it is made to serve the purpose of ginger in cookery; it is one of the things chewed to conceal a bad breath. Two evergreen species are found from Virginia southward: *A. Virginicum*, with small round-heart-shaped, and *A. arifolium*, with large halberd-shaped leaves; both possess similar aromatic rootstocks, and the leaves of all three, when dried, powdered, and used as snuff, are said to have similar properties with the foreign *A. Europæum*, or asurabacca, in producing sneezing and a copious flow of mucus from the nose.—Black snakeroot is *sanicula Canadensis* and *S. Marilandica.* Button snakeroot is *eryngium yuccæfolium;* the same name is also given to some



Canada Snakeroot (Asarum Canadense).

species of *liatris.* White snakeroot is *eupatorium ageratoides.* Snakehead is *chelone glabra.*

**SNAKES,** a family of American Indians. See Shoshones.

**SNAPPING TURTLE** (*chelydra serpentina*, Schweig.; genus *chelonura*, Fleming), an American species of fresh-water chelonians, characterized by a large head, with both jaws strongly hooked and two barbels under the chin, short and pointed snout, the nostrils near together, and the eyes large, prominent, and far forward; the sternum is small, cruciform, immovable, and covered with twelve plates and three supplemental ones; the carapace oblong, depressed, more or less tricarinated, deeply notched behind with three points on each side of the central notch; the neck long and thick, with a warty skin; tail very long, surmounted by a scaly or tuberculated crest; the anterior limbs with five nails, the posterior with four; the skin of the limbs above and below scaly. The head may be in great part retracted within the shell, whence it can be very suddenly extended by the long and extensile neck, but the limbs and feet are mostly exposed. The shell is dusky above,

Snapping Turtle (Chelydra serpentina).

and the lower parts yellowish; it attains a length of more than 4 ft. and a weight of 50 lbs.; it prefers sluggish and deep water in ponds or rivers, keeping principally at the bottom; it is very voracious, and feeds on fish, reptiles, and such aquatic birds as come within its reach, especially young ducks and goslings and wounded birds; it has been known to attack man, and is not unfrequently caught with hooks; its flesh is much esteemed for soups, though in the old animals it has a musky odor. It goes far from water to deposit its eggs; though an excellent swimmer, it is awkward on land, walking slowly, with the head, neck, and tail extended, raised on the legs like an alligator, whence it is called by the negroes alligator cooter; it is very savage if attacked, raising itself with such quickness on its legs as to elevate the whole body from the ground and enable it to make considerable hops, snapping with great ferocity and quickness at any object coming within reach of its long neck; its bite is severe and tenacious. It is distributed from Maine to Georgia, and westward to the Mississippi, being replaced further west by the *C. Temminckii* (Troost; genus *gypochelys*, Ag.), characterized by a larger triangular head, rougher shell, and neck and limbs covered with spiny warts. In the northern states it lays its eggs, 20 to 40, between June 10 and 25, generally in the forenoon, and in captivity a month later; it excavates a hole at first directly down and then laterally, so that the widest part, where the nest is, is on one side; sometimes several holes are dug, before one is found to suit; the females lose their shyness at this time, and smooth the earth over with care after the eggs are deposited.—In some parts of the country, the soft-shelled turtles (*trionycidæ*) are called snapping turtles. The eggs in these species are nearly globular, about an inch in diameter, white, and with hard shells.

**SNEEZING,** a modification of the ordinary respiratory movements, accompanied by a violent expiratory effort, sending forth a blast of air from the lungs intended to expel some irritating substance from the nasal air passages. It differs from coughing in the communication between the larynx and mouth being partly or wholly cut off by the drawing together of the

sides of the soft palate over the back of the tongue, so that the blast of air, by a convulsive movement, passes through the nose with more or less noise instead of through the mouth. It may be excited by acrid vapors, irritating liquids or solids, diseased secretions, or the simple entrance of air when the Schneiderian membrane is peculiarly irritable.

**SNELL, Willebrord,** a Dutch mathematician, born in Leyden in 1591, died there, Oct. 31, 1626. He studied law, but devoted himself principally to mathematics. When 17 years old he published an essay in which he endeavored to restore a lost treatise of Apollonius. He travelled in Germany, and won the friendship and esteem of Kepler. In 1613 he succeeded his father as professor in the university of Leyden. He was the first to make a trigonometrical measurement of an arc of a meridian, and thence to calculate the size of the earth. His result was erroneous, on account of the imperfection of the instruments then in use; but he himself discovered the errors. He also discovered the law of the refraction of light (see LIGHT, vol. x., p. 438), and improved the methods of approximating to the ratio of the radius to the circumference of the circle. His most important work is *Eratosthenes Batavus, sive de Terræ Ambitus vera Quantitate* (Leyden, 1617).

**SNELLING, Josiah,** an American soldier, born in Boston in 1782, died in Washington, D. C., Aug. 20, 1828. He was appointed a lieutenant in the 4th infantry in 1808, became captain in 1809, distinguished himself in the battle of Tippecanoe in 1811, and was made brevet major for services at the battle of Brownstown, Aug. 9, 1812. In 1814 he was made inspector general with the rank of colonel, and was prominent in the affair of Lyon's creek. In 1819 he was made colonel of the 5th infantry. He was a witness against Hull at his trial, and wrote "Remarks on General William Hull's Memoirs of the Campaign of the Northwestern Army, 1812" (8vo, Detroit, 1825).

**SNETHEN, Nicholas,** an American clergyman, born at Fresh Pond (now Glen Cove), Long Island, N. Y., Nov. 15, 1769, died in Princeton, Ind., May 30, 1845. In 1794 he entered the itinerant ministry of the Methodist Episcopal church, travelled and preached for four years in Connecticut, Vermont, and Maine, labored at Charleston, S. C., for a year or more, and thence was ordered to Baltimore, where he attended the general conference in May, 1800, and took a prominent part in favor of limiting the episcopal prerogative, a delegated general conference (his plan for which was finally adopted in 1808), and a preachers' anti-slavery tract society, and against the future admission of any slaveholder into the church. He afterward travelled with Bishop Asbury as his private secretary. In 1804-'6 he was stationed in New York, whence he removed to his farm on Longanore, Frederick co., Md. By his marriage he became the holder of slaves, whom he emancipated as soon as the law would permit (1820). From 1809 to 1814 he was again an itinerant, and was stationed successively in Baltimore, Georgetown, Alexandria, and on the circuit of his farm residence. While in Georgetown he was elected chaplain to congress. In 1829 he removed to Indiana. He was the first to introduce camp meetings into Maryland and New York. In 1821 he began to write in favor of lay representation. The refusal of this right by the general conference in 1828, and the expulsion from the church of many of its advocates, led to the formation of the Methodist Protestant church, in which Mr. Snethen bore a prominent part, and in connection with which he continued to travel and preach after his removal to the west till a short time before his death. He published "Lectures on Preaching the Gospel" (1822), "Essays on Lay Representation" (1835), and "Lectures on Biblical Subjects" (1836). A volume of his sermons, edited by Worthington G. Snethen, was published in 1846.

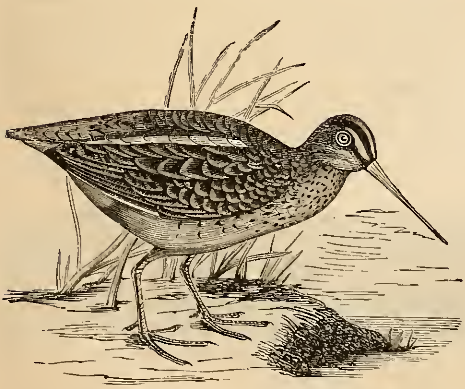
**SNEYDERS.** See SNYDERS.

**SNIPE,** a group of wading birds, of the subfamily *scolopacinæ*. It is characterized by a long, straight, slender bill, obtuse and flexible, covered with a soft, sensitive skin, abundantly supplied with nerves toward the end; the upper mandible the longest, somewhat bent down at the end, and grooved on the sides, in which the nostrils are placed; the tongue long, slender, and pointed at the end, the œsophagus narrow, and the stomach very muscular; eyes far back in the head; wings moderate and pointed; tail short and rounded; legs short, feathered lower down than in most waders; hind toe small, elevated, but reaching the ground, the anterior long and slender, and free except in the genus *macroramphus*. Snipes are migratory and small, going north to breed; they frequent marshy places and the margins of rivers and ponds, where they probe the soft mud perpendicularly with the bill in search of worms, insects, and larvæ; the nest is a slight hollow on the ground, lined with grass and sedge, and the eggs, usually four, are placed with the pointed end inward; the young are able to leave the nest as soon as hatched; the flesh is considered a great delicacy. The subfamily includes the genera *macroramphus* (Leach), *gallinago* (Leach), *rhynchæa* (Cuv.), *scolopax* (Linn.), and *philohela* (Gray), of which the last two will be noticed under WOODCOCK.—In *macroramphus* the wings are long and pointed, with the first and second quills equal; the tarsi are longer than the middle toe, which is united to the base of the outer by a short web. The species are found in Europe and North America, occurring in large flocks near the sea, feeding on small mollusks, worms, and insects; they fly rapidly and irregularly with a quivering whistle. The gray or red-breasted snipe (*M. griseus*, Leach) is about 10 in. long and 18 in. in alar extent, the bill 2¼ in., and weighs 3½ oz.; the prevailing colors above

are dark ashy, pale reddish, and black, with rump and upper tail coverts white; under parts pale ferruginous, with spots and bands of brownish black; the quills brownish black,

Wilson's Snipe (Gallinago Wilsonii).

the shaft of the first primary white; the young are dull white below, marked with ashy; the plumage is more gray in winter, and more red in summer. It occurs over temperate North America, in large flocks, occasionally going inland in autumn on the return from the north, where it goes to breed; the flight is rapid and strong, accompanied by a single mellow "weet;" the call note is a whistle; the flesh is not so good as that of the common American snipe.—In *gallinago* the tarsus is shorter than the middle toe, and there is no web. The American or Wilson's snipe (G. *Wilsonii*, Bonap.) is about 10½ in. long, with an alar extent of 17 in., the bill 2½ in., and weighs 3 oz.; above the feathers are brownish black, spotted and edged with yellowish brown or ashy white; a black line from base of bill over top of head;



Common European Snipe (Gallinago media).

throat and neck before reddish ashy, under parts white, quills and tail like back, the latter widely tipped with bright rufous, with a narrow subterminal black band. It occurs over temperate North America, going in summer as far as Nova Scotia, where it breeds in June in the elevated moss-covered marshes; the eggs are yellowish olive, spotted with brown; they return to the south in October, and are very fond of the rice fields; they rarely visit the seashore, and never the interior of woods; the cry resembles the syllables "wau-aik." They are fond of leeches and other food not generally coveted by man, though most epicures, ignorant of this, are in the habit of cooking and eating them, contents of intestines included. The great or double snipe of Europe (*G. major*, Steph.) is 11 or 12 in. long, varied with black and bright reddish above, the red arranged longitudinally, and whitish red below; the shaft of the first quill is whitish; it inhabits N. Europe. The common snipe of Europe (*G. media*, Steph.) is 10 or 11 in. long, with two blackish longitudinal bands on the head, the neck spotted with brown and fawn color, the mantle blackish with two longitudinal fawn-colored bands, the wings brown waved with gray, quill shafts brown, and lower parts white waved with blackish on the flanks; it flies very high, with a shrill cry; from its wavering flight it is generally difficult to shoot; its flesh is delicious.—In *rhynchæa* the bill is shorter and more curved, the first three quills equal and longest, the tertials as long as the quills, and the tail very short; the species are adorned with bright yellow ocellated spots on the quills and tail; they occur at the Cape of Good Hope, in the East Indies, and Australia. The Cape snipe (*R. Capensis*, Cuv.) is 10 in. long, variegated with black and cinereous; around the eye, a little way down the neck, pectoral band, and abdomen, white.

**SNOHOMISH,** a N. W. county of Washington territory, bordering W. on Puget sound and E. on the Cascade mountains, and drained by several streams; area, 1,500 sq. m.; pop. in 1870, 599. Extensive forests skirt the streams, and lumber is the chief source of wealth. Coal is found in various places. Along the sound are extensive cranberry marshes, and in the interior large tracts adapted to agriculture. The chief productions in 1870 were 1,290 bushels of oats, 1,415 of barley, 11,680 of potatoes, and 857 tons of hay. The value of live stock was $25,305. Capital, Snohomish City.

**SNORRI STURLASON,** or **Snorre Sturluson,** an Icelandic historian, born on the shores of Hvammsfiord, a bay on the W. coast of Iceland, in 1178, murdered at Reykholt, Sept. 22, 1241. He was of distinguished family, was carefully educated, and became proficient in Greek and Latin. Though originally poor, he became by marriage the wealthiest man in Iceland; and his legal attainments, bravery, and eloquence obtained for him the highest positions in the field and in the *althing* or legislature. His residence was a fortified stronghold, and he appeared in the national assembly with a retinue of hundreds of armed followers. Traces of his sumptuous abode at Reyk-

holt still exhibit stone structures of finished elegance for hot baths, supplied from boiling springs through an aqueduct of hewn stone 500 ft. in length. On being elected to the chief magistracy, he gave proof of great judicial learning. In 1213 he produced an ode to a Norwegian warrior, which was requited by liberal presents. This poem was followed by others, one of them composed in honor of the king of Norway, Haco V. On a visit to Norway he was made an honorary marshal of the court, and upon re-embarking for Iceland was loaded with rich presents. Faction and disorder prevailed throughout Iceland, and the king of Norway seized the moment to advance his designs for the subjugation of the island. Snorri became involved in domestic feuds, and in 1237 appeared in Norway as a fugitive. The king created him a jarl, but soon became hostile to him, and Snorri returned to Iceland. Emissaries were employed to seize him and send him in irons to Norway, but he was murdered at Reykholt by his son-in-law, Gissur. His most important work is the *Heimskringla*, or "Chronicle of the Norwegian Kings." It is probable that in this work he made large use of the writings of Ari Frode, fragments of whose Scandinavian histories, composed a century earlier, still remain. The Younger Edda also bears the name of Snorri Sturlason alone, but it was gradually formed by the successive additions of several writers. The first copy of it was found by Arngrim Jonsson in 1628. The original Icelandic text of the *Heimskringla* was first printed by Peringskiold in 1697, though a Danish translation was current 100 years before. The last edition is by Schöning and others, in Icelandic, Danish, and Latin (6 vols., Copenhagen, 1777–1826). There is an English translation, "The Heimskringla, or Chronicle of the Kings of Norway," by Samuel Laing (3 vols., London, 1844).

**SNOW**, the flocculent white masses of crystals in which the aqueous vapor of the atmosphere at low temperatures is precipitated from the clouds. The other forms in which atmospheric vapor appears are treated of under DEW, FROST, HAIL, and RAIN. The primary condition necessary to the formation of snow is the saturation of the air at a freezing temperature with vapor; the exact limits of temperature are not known, but probably vary with the density of the air and the vapor; the surplus vapor is precipitated from its invisible state in minute crystals, the primary form of which is that of a rhomboid having angles of 60° and 120°. (See CRYSTALLOGRAPHY.) By far the larger part of

FIG. 1. FIG. 2. FIG. 3. FIG. 4. FIG. 5.

snow falls during the night, and in many localities the maximum fall is between 1 and 7 A. M., which suggests that the cooling necessary to the production of snow is mainly due to radiation; a secondary maximum between 8 and 10 A. M. is explicable as due to the influence of the dynamic cooling of rising currents. The complexity of the forms of snow

FIG. 6. FIG. 7.

flakes increases with the quantity of moisture in the air, and probably with the variety of alternations of temperature to which they are exposed. Their size increases with the temperature and humidity; thus they are much larger from 9 to 11 A. M. than before sunrise. Little however is satisfactorily known on these points. More than 1,000 forms of snow crystals have been observed and figured

FIG. 8. FIG. 9. FIG. 10. FIG. 11.

by Scoresby, Glaisher, Green, Stephen Lowe, and others. A very beautiful contribution to this subject was published anonymously in New York in 1863, under the title of "Cloud Crystals," in which over 150 new forms are added to those described by previ-

ous authors, and several interesting observations are given upon the conditions of their formation. The accompanying figures, representing specimens of the simple and the more complicated forms of crystals, are from Buchan's "Meteorology." Scoresby, who first studied these forms, classified them into: 1, thin plates (figs. 1 to 7); 2, spherical nuclei studded with needles (fig. 8); 3, three- or six-sided prisms or needles (fig. 9); 4, six-sided pyramids (fig. 10); 5, prisms terminated by planes (fig. 11). The conditions regulating the occurrence of each figure are probably quite definite, inasmuch as it is rare that more than three or four kinds of flakes occur at the same time. The high cirrus clouds are probably generally formed of spiculæ, or possibly small flakes of snow, which when the clouds are not too thick give rise to the phenomena of halos (see Halo), and the geometrical explanation of these latter seems generally to require that the snow flakes present in these clouds should be principally of the simplest forms. The amount of snowfall in different parts of the earth is known with less accuracy than is that of rainfall, owing partly to the drifting of the snow, but especially to the fact that a too great diversity has existed in the methods adopted by the observers to ascertain either the quantity or the depth of the snow. It is generally assumed that $\frac{1}{10}$ or $\frac{1}{12}$ of the depth of snow measured immediately after falling will give the corresponding depth of melted snow. Quetelet, as the mean of many observations, says $\frac{1}{9}$, but for very dry or very wet snow these fractions are very uncertain. The total depth of snowfall is greatest, other conditions being the same, where the strong winds of winter are laden with moisture; thus it averages annually 4 to 7 ft. in the interior of Maine, Vermont, New York, and Upper Canada, but only 2 ft. for the states in the same latitude further west. One of the heaviest snowfalls recorded in America was that which continued from Feb. 19 to 24, 1717, when the snow remained 5 or 6 ft. deep over all the settled parts of New England. The geographical distribution of snow at sea level is such that in general in the eastern parts of North America and Asia it is rarely seen S. of lat. 30°, and in western Asia S. of lat. 36°. On the W. side of North America it is rarely seen at the sea level on the immediate coast, but is quite common in the interior.—Falls of snow may occur in any month in extreme polar latitudes; in New England and Canada snow falls mostly from November to March inclusive, but in the latitude of Washington, D. C., it falls mostly during January and February. The average number of days on which snow falls is, for St. Petersburg, 170; Paris, 12; Washington, D. C., 20; Gibraltar, 0; San Francisco, 0; Charleston, S. C., 1. But on ascending above the sea level we soon come to altitudes such that snow may fall and remain on the ground at any season; the altitude at which accumulations remain throughout the year is called the limit of perpetual snow. The conditions governing this lower limit were first studied carefully by Humboldt in his climatology of Asia, and more recently has been investigated by Grad (1873); according to these, the limit in question has a general apparent connection with the isotherms of 32° F., but departs therefrom to an important degree when the prevailing winds are dry or moist. Thus the limit is lower in the southern than in the northern hemisphere; lower on the S. than on the N. side of the Himalaya mountains; lower within the tropics than under the latitudes 20° to 35°. From these latitudes it diminishes, according to Grad, to about 3,000 ft. in lat. 60° S. and 65° N.; but only in the high polar regions is the limit below 1,000 ft., it being higher in Greenland or Spitzbergen, where it is only the glaciers that descend to sea level. (See Glacier.)—Owing to the innumerable reflecting facets of the minute crystals and the quantity of air caught between the crystals, a layer of snow is a remarkably perfect non-conductor of heat; for this reason the covering of snow on the ground forms an almost perfect protection to the plants beneath against the freezing that would otherwise follow the radiation of their heat into the atmosphere. In Ebermayer's "Influence of Forests" (1873) a case is quoted (by no means an extreme one) in which the temperature of the air was −6·8° F., and that of the surface of the earth beneath the snow +33·8° F., while below the surface the earth was still warmer. On the other hand, the individual crystals of snow have probably the same large radiating power as ice in larger solid blocks, which according to Leslie is 85, that of lampblack being 100. The consequence of this is, that during the night very hard frozen crusts are formed on the surface of the snow which has been somewhat thawed during the day; the same property, together with that of regelation, explains the peculiar structure of the surface snows of glaciers, and assists in the formation of areas of colder air over snow fields than over bare land. Equally important is the great absorptive power of snow for solar heat, since by reason of it the surface of a layer of snow is melted rapidly, and a large amount of moisture is thrown into the air, giving rise to extensive fog and haze, and having a decided influence on the development of storms.—Snow flakes in falling bring with them nearly all the fine dust floating in the air, leaving the atmosphere extremely pure; thus in northern Europe Nordenskiold has found freshly fallen snow impregnated with a black dust of carbon and iron such as could only have come from meteors; at other times the dust is such as could only have come from eruptions of volcanoes, especially those in Iceland.—Snow is occasionally tinged black, yellow, red, or green, as was known to Pliny. These colors are due to the presence of microscopic organisms, as was

suspected by De Saussure (1760), which were described by Dr. Wollaston as minute spherical globules having a transparent covering and divided into seven or eight cells filled with a red oily-like liquid insoluble in water. Girod-Chantraus (1797 and 1802) described these as plants under the name *volvox lacustris*. Bauer (1820) demonstrated that they are a fungous growth, which he named *uredo nivalis*. Robert Brown concluded them to be algæ allied to the *tremella cruenta*. Agardh confirmed the views as to their vegetable nature, and gave them the title *protococcus permesina*. Bravais and Martins, as members of the northern commission, verified the identity of red (*hæmatococcus nivalis*) and green (*protococcus viridis*) globules as being one and the same plants in different stages of growth, the green being probably the riper. The most recent authority on this difficult subject is Rostafinski (1875), who retains the generic name *hæmatococcus*, and has further confirmed the identity of these microscopic algæ. Ehrenberg (1847) found, besides vegetable spores, animalcules properly so called, among which the most abundant in red snow is that to which he gave the name *philodina roseola*.—The glare of the sunlight reflected from snow-covered ground gives rise, unless the eyes are protected by glasses or goggles, to a very severe inflammation of the optic nerve. (See Amaurosis, and Blind.)

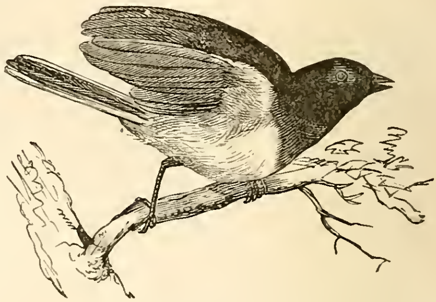
**SNOWBALL.** See Guelder Rose.

**SNOWBERRY,** the common name for a native shrub, given on account of its large, very pure white berries, which ripen in autumn and remain after the leaves have fallen. The genus *symphoricarpus* (Gr. συμφορεῖν, to bear together, and καρπός, fruit, from the clustered berries), to which it belongs, is exclusively North Amer-

Snowberry (Symphoricarpus racemosus).

ican, extending from British America to Mexico, and contains about six species; it belongs to the honeysuckle family, and differs from the honeysuckle (*Lonicera*) itself in having a regular corolla and a fewer-seeded berry. All are small branching shrubs, with ovate entire (or sometimes wavy-toothed), opposite leaves, and small, bell-shaped, four- to five-lobed, white or rose-tinted flowers in short spikes or clusters. The snowberry (*S. racemosus*) is found from Vermont westward to Oregon, and as far south as Pennsylvania; it is one of the most common garden shrubs, and is cultivated for its white berries. The wolfberry (*S. occidentalis*), growing from Michigan westward, has also white berries. The Indian currant or coralberry (*S. vulgaris*), found from western New York to Texas, and sometimes cultivated, has small dark red berries in dense clusters.

**SNOW BIRD,** a well known member of the finch family, and genus *junco* (Wagler). With the general characters of the finch family, the middle toe is shorter than the short tarsus, the outer the longest; the wings are rather short, and the tail slightly notched; the second quill is the longest. The common snow bird (*J. hyemalis*, Sclater) is about 6¼ in. long, and 9 in.



Snow Bird (Junco hyemalis).

in alar extent; the upper parts are nearly uniform dark plumbeous, darkest anteriorly, without any red in the interscapular region; lower parts white; the external two tail feathers white, the third white margined with black. It is found from the eastern United States to the Missouri and the Black hills of the west, and from Louisiana to the fur countries. It appears in New England from the south early in April, while the ground is covered with snow, going north to breed, and returning south late in autumn. They are found in small families, which usually keep by themselves, often visiting farm yards and hopping after domestic poultry, and in cold weather retiring into holes in hay stacks. They are fond of grass seed and berries; the flesh is delicate and juicy, and is often sold in the New Orleans market; the spring notes are agreeable. The nest is on the ground, the entrance generally concealed; the eggs are four, three fourths by five eighths of an inch, yellowish white with numerous small reddish brown dots. A nearly allied species in the Rocky mountains is the *J. caniceps* (Baird), having a reddish spot in the interscapular region but not on the wings. On the

Pacific coast is the *J. Oregonus* (Sclat.), head and neck sooty black, a chestnut patch on the back and wings, and the belly pure white.

**SNOW BUNTING.** See Bunting.

**SNOWDROP,** an early spring flower, the name being derived, according to Prior, from the

Snowdrop (Galanthus nivalis).

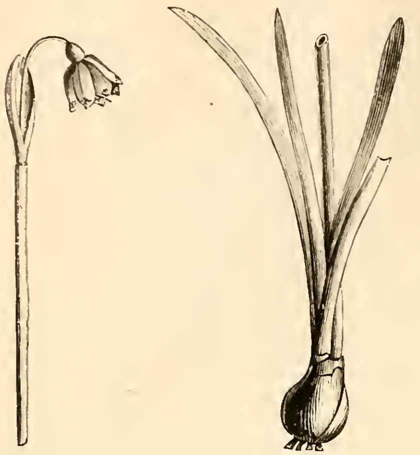
German *Schneetropfen*, which does not refer to a drop of snow, but, so far as the drop is concerned, to the pendents or ear drops worn by ladies in the 16th and 17th centuries. The genus, *galanthus* (Gr. γάλα, milk, and ἄνθος, flower), belongs to the amaryllis family, and consists of three or four European species. The small bulbs throw up two or three narrow leaves and a flattened scape which bears (usually) a single fragrant flower on a slender nodding pedicel; the perianth has six separate divisions, the three inner tipped with green and shorter than the three pure-white outer ones. The common snowdrop is *G. nivalis*, which, though very common in England, is supposed to be naturalized there; its leaves are very narrow, and its flower stalk 3 to 6 in. high; there is a double variety; the plant blooms early, often appearing in February. The Crimean snowdrop (*G. plicatus*) has the same general appearance as the common, but is larger in all its parts. The bulbs, which are small, should be planted in clumps, and bloom more satisfactorily if left undisturbed for several years. (For cultivation, see Hyacinth.)

**SNOWDROP TREE,** a name given to shrubs or small trees of the genus *Halesia*, on account of the pure white pendulous flowers, which have also suggested the equally common name of silver-bell tree. *Halesia* belongs to the storax family, and is a genus of two or at most three species, which have large, veiny, pointed, deciduous, alternate leaves without stipules; the flowers, in clusters or short racemes, open just as the leaves appear, from axillary buds of the previous year; the small calyx is four-toothed, its tube cohering with the ovary; petals four, united at the base or to the middle, forming a bell-shaped corolla; stamens 8 to 16, more or less united at the base; ovary two- to four-celled, becoming a large, dry, bony, two- to four-winged fruit with one to four cells, each of which contains a cylindrical seed. The best known species is the four-winged snowdrop tree (*H. tetraptera*), so called from the four wings to the fruit; it is found from Virginia southward; it sometimes reaches the height of 50 ft., but is more generally much smaller; the bark is dark-colored, marked by light fissures, which give it a characteristic netted appearance; the ovate-oblong leaves have glandular petioles, are 2 to 4 in. long, and finely serrate; the flowers have four-lobed corollas, nearly an inch long, with 12 to 16 stamens distinctly united below the middle. This tree is quite hardy in the northern states. The two-winged species (*H. diptera*) is more southern, and is found from the Carolinas southward; the larger leaves are coarsely serrate; the flowers are larger than in the preceding, and consist of four nearly distinct petals, and the 8 to 12 stamens are nearly distinct; the fruit, which is about an inch long, has only two wings; the tree does not grow so large as the other. This species is quite rare and difficult to find in the nurseries, forms of the preceding being confounded with it. Michaux described a third species, *H. parviflora*, which seems to be nearly unknown, if indeed it be not a form of one of the others. The trees are raised from seeds, which, unless sown as soon as ripe, lie in the ground a year before they germinate.

Snowdrop Tree (Halesia tetraptera).

**SNOWFLAKE,** a name said to have been invented by Curtis for *leucoīum vernum*, to distinguish it from snowdrop, to which it is nearly related and which it closely resembles. *Leucoïum* (the ancient Greek name) is a small genus of the amaryllis family, of three species, all of which are European; it differs from *galanthus* (see Snowdrop) in having one to seven flowers upon the scape, and the divisions of the flower are of equal length. In our catalogues *L. vernum* is the plant offered as snowflake, but the English designate this as spring snowflake, as summer and autumnal species are also sold more commonly than with us. The spring snowflake comes very early, and is much like

a large snowdrop, its scape, about 12 in. high, bearing a single, large, very fragrant, pure white flower, each division of which is tipped



Spring Snowflake (Leucoïum vernum), Flower and Bulb.

with green. The summer snowflake (*L. æstivum*) has a scape about 2 ft. high, with three to seven flowers about an inch long, blooming in late spring or early summer. The autumnal snowflake (*L. autumnale*, also called *Acis*) has narrow leaves and a scape 6 in. high, bearing two to three small flowers, which are pure white or suffused with rose, and appearing before the leaves in September. This is only a greenhouse plant here; the others are treated like other spring bulbs. (See Hyacinth.)

**SNUFF.** See Tobacco.

**SNYDER,** a central county of Pennsylvania, bounded E. by the Susquehanna river; area, about 260 sq. m.; pop. in 1870, 15,606. The surface is hilly and the soil fertile. Iron ore and coal are found in great abundance. It is traversed by the Pennsylvania railroad, and the Pennsylvania canal passes along the E. border. The chief productions in 1870 were 247,381 bushels of wheat, 12,752 of rye, 255,831 of Indian corn, 283,841 of oats, 73,889 of potatoes, 4,762 of clover seed, 18,939 tons of hay, 9,366 lbs. of wool, and 241,246 of butter. There were 3,964 horses, 3,900 milch cows, 4,489 other cattle, 3,367 sheep, and 9,050 swine; 3 manufactories of carriages and wagons, 11 of tanned and 10 of curried leather, 21 flour mills, and 8 saw mills. Capital, Middleburg.

**SNYDERS, Sneyders, or Snyers, Francis,** a Flemish painter, born in Antwerp in 1579, died there in 1657. He is celebrated for his pictures of animals and hunting scenes, excelling in those which represent violent action. He produced many pictures jointly with Rubens, Jordaens, and others, they executing the human figures and Snyders the animals.

**SOAP** (Gr. σάπων, Lat. *sapo*), a compound formed by the union of alkalies with oils and fats. The invention of soap is ascribed by Pliny to the Gauls, and he gives the Germans credit for manufacturing both hard and soft soaps. From them the Romans learned the art, but soap was for a long time principally used by them as a wash for the hair. A complete soap-boiling establishment, and soap in a good state of preservation, have been discovered at Pompeii. Some natural productions possess the qualities of soap, as the berries of the soap tree (*sapindus saponaria*) of South America and the West Indies, and the bark of the *quillaja saponaria*, which has been carried from Peru to Liverpool for washing woollens. The juice of soapwort or bouncing Bet (*saponaria officinalis*) forms a lather with water, and is used in England for scouring dresses. In California the roots of the *phalangium pomaridianum*, which grows there abundantly, and has the odor of brown soap, is much used for washing clothes. Alkaline waters, when used upon greasy fabrics, form soaps similar to those produced in the regular manufacture. Different kinds of oils may be used in soap making, having different proportions of the proximate principles of fatty bodies, stearine, palmitine, and oleine (see Oils and Fats), and also upon the kind of alkali, soda making a harder soap than potash. The hardest soaps are made with stearine and soda, the softest with oleine and potash. The natural combination of glycerine with the fatty acids is broken up by the action of the alkali, and the glycerine exists in a free state in the soap, or it may be extracted as a separate product. The principal fats and oils used for making soap are tallow, and palm, cocoanut, rape, poppy, linseed, hempseed, and olive oils; the last is used in the manufacture of the celebrated Castile, Marseilles, and other marbled and plain soaps of southern Europe. The best oils for marbled soaps come from Naples, and the Spanish oils are also highly esteemed. The oils from the East are not so rich in stearine, and are more or less colored green, which is objectionable. The mottling or marbling of soaps is produced by sprinkling the surface of the newly made body successively with lyes of less and less concentration, by which the soap is again rendered sufficiently pasty or semi-fluid to allow of the aggregation in different masses of the particles of coloring matter.—The ordinary method of saponification, as the conversion of fats into soaps is called, is by boiling them with solutions of caustic potash or soda. Most fats require long continued boiling with excess of alkali, but others, as lard, beef marrow, and oil of sweet almonds, may be saponified by agitation with caustic alkali at ordinary temperatures; and under increased pressure the alkaline carbonates will readily produce saponification of fats. Rosin, which is capable of forming a soap with either potash or soda, is frequently added to soaps. Every kind of soap contains a variable quantity of water, partly

in chemical combination. Soap is perfectly soluble in alcohol and hot water, but both solutions solidify to a jelly at a certain stage of concentration. Opodeldoc is soap mixed with alcohol in this state, to which camphor is added. Cold water does not dissolve the alkaline oleates, palmitates, and stearates which constitute ordinary soap, without decomposition, the alkali being dissolved and the oily acid precipitated; and when hot solutions are cooled the same action takes place. Soap is quite insoluble in a solution of common salt containing more than one part in 400 of water, so that on the addition of salt to the contents of a soap pan, a curd consisting of a solid soap will rise to the surface, while the alkaline salts and glycerine remain dissolved in the water. Some soaps, as those made from cocoanut oil, are not so easily separated from their solutions by common salt. Other chlorides, as those of potassium and ammonium (sal ammoniac), have a similar action to that of common salt. Soaps are scented and colored by mixing coloring matter and volatile oils or odorous matters with them. They are sometimes medicated with antiseptic and other substances, such as creosote, carbolic acid, chlorate of potash, and sulphur, and are used as detergents and in skin diseases. Arsenic is sometimes added to soap and used by taxidermists in preserving their preparations. Those medicinal preparations called liniments are soaps whenever they are made by the mixture of an alkali or an alkaline earth with an oil. Silicate of sodium (soluble glass) may be mixed with soap and used with advantage as a domestic cleansing agent. Soaps mixed with fine sand or pumice stone do not possess the same detergent properties, but are useful for scouring. The manufacture of soap is more largely carried on in Great Britain than in any other country, although great quantities of toilet soaps are made in France, especially for the American market. The annual product of Great Britain is often considerably over 200,000,000 lbs. The manufacture is also carried on to a considerable extent in the United States, and some fine toilet and other soaps are made.—The history of soap may be found in Beckmann's "History of Inventions;" its technology in Parnell's "Chemistry applied to the Arts," Knapp's "Chemical Technology," Wagner's "Chemical Technology," Muspratt's "Chemistry," Morfit's "Applied Chemistry in the Manufacture of Soaps and Candles," and in "A General Treatise on the Manufacture of Soap," by H. Dussauce (8vo, Philadelphia, 1869). The French manufacture is described in one of the *Manuels Roret* entitled *Nouveau manuel théorique et pratique du savonier, ou l'Art de faire toutes sortes de savons* (Paris, 1852).

**SOAPSTONE.** See Talc.

**SOBIESKI.** See John III. Sobieski.

**SOCIALISM,** the doctrine that society ought to be reorganized on more harmonious and equitable principles. Communism and coöperation are its principal divisions or varieties. Communism and socialism are sometimes used as synonymous; but generally the former term specially refers to the plans of social reform based on or embracing the doctrine of a complete community of goods. Coöperation is understood to be that branch of socialism which is engaged exclusively with theories of labor and methods of distributing profits, and which advocates a combination of many to gain advantages not to be reached by individuals. Viewed as a whole, socialistic doctrines have dealt with everything that enters into the life of the individual, the family, the church, or the state, whether industrially, morally, or spiritually. The origin of all is to be sought in the desire to ameliorate the condition of the less favored classes, and in the attempt to overcome by association the deprivations to which individuals, especially those without rank, culture, and capital, are exposed. After many experimental attempts in recent times to effect a radical modification of society in all its parts, the simplified socialism of the present day mostly aims only to protect the laborer in his rights, or to shield him against the oppression of capitalists.—The history of socialism runs parallel with that of property. Wherever the power of individual proprietors became oppressive, communistic doctrines usually arose. Such was the origin of the schemes of the ancient Greeks. Phaleas of Chalcedon expected gradually to remove the disparities of property by making a law that the rich should give but not receive dower in marriage; and in order that none should be intellectually superior to others, he desired that all should receive the same education. Plato's ideal republic was to consist of three classes: the educated, who are the law makers and rulers; the common people, including agriculturists and other laborers; and the soldiers. The state was to assign to every one his rank and sphere of activity; the soil was to be the property of all, and its fruits were to be equally shared by all. The women also were to be common property, as well as the slaves. Communistic doctrines more or less evolved from peculiar religious views, and advocating the founding of isolated communes, existed among the ancient Hindoos and Egyptians. Among the earliest attempts at socialistic life was that of the Jewish sect known as the Essenes, who had established themselves on the western shores of the Dead sea about the 2d century B. C. Though there are few trustworthy accounts of their teachings and practices, it may be accepted as certain that they held their property in common, and discountenanced marriage, without really prohibiting it. (See Essenes.) The Carpocratians, an early Christian sect, which continued to exist until the middle of the 6th century, also practised community of goods and of women. Many features of the monas-

ticism of the middle ages are more or less communistic. Societies of women were formed for the relief of the sick and poor in the 11th century, possessing at first nothing of the later conventual type. They had clusters of houses and gardens, whose inmates supported themselves by their own labor, grouped round a hospital and similar institutions. In time the dormitories, refectories, and work rooms were also occupied in common. Such was the origin of the beguinages of the Netherlands. Later, various ascetic communistic societies arose, as the "Brethren and Clerks of the Common Life," founded by Gerard Groot about 1378 in the Netherlands, whose members, chiefly priests, supported themselves by manual labor and by teaching and preaching. Along with these existed communities whose members indulged in the wildest license, and were finally extirpated by the authorities; such were the Adamites, who walked about naked and had a community of wives. At the reformation a communistic tendency was wide-spread in Germany, and it led to a revolt of the serfs against their lords, a movement of social reform avowedly based upon the doctrines of the New Testament. (See PEASANTS' WAR.) Some of the Anabaptists, the movements begun by Storch and Münzer (see MÜNZER), the familists, the levellers, and numerous other fanatical sects of this period, all show more or less of the same spirit of hostility to the rich, of a desire for a better distribution of property, and a struggle to realize an ideal social state. In the same period appeared the first works which, depicting a more or less fanciful or ideal community, may be considered the precursors of the more recent scientific socialistic schemes. The first edition of Sir Thomas More's "Utopia," an account of an imaginary commonwealth, where there are only good and happy citizens and the government is perfectly paternal, was printed in Latin at Louvain in 1516, and it was soon translated into English, French, Dutch, and Italian. Another Utopia was depicted by Campanella in his *Civitas Solis* (1623). A vast hierarchy of officials assign and direct the duties of the people; four hours a day are devoted to labor, the women performing the lighter tasks; the rest of the day the people are trained in philosophy and the sciences. Similar schemes were sketched by Hall in his *Mundus Alter*, Fénelon, Morelly, Defoe in his "Essay on Projects," and Bacon in the "New Atlantis." In 1656 Harrington published his "Oceana," of which Hume said that it was the most valuable model of a commonwealth hitherto offered. The first complete plan of an industrial community intended for immediate adoption was John Beller's scheme of a "College of Industry" (1696). The shareholders were to divide among themselves the profits of the college, but the laborers were to be guaranteed all things necessary in case of sickness, for the education of their children, for the maintenance of their widows, and the like. In France there have been at various times small communities in which work was divided according to the capacity of the members, who received equal shares of the profits, and elected a master of the community, vested with full power of command, and constituting their legal representative. In the United States there are about 70 communistic societies, all based on a religious belief of some form. The Shakers were established in the northern states about 1780, and in the west about 30 years later; the Rappists were established in 1805, the Zoarites in 1817, the Eben-Ezer or Amana communists in 1844, the Bethel community in 1844, the Oneida Perfectionists in 1848, the Icarians in 1849, and the Aurora commune in 1852. Though the Icarians reject Christianity, yet they raise to the position of a creed their doctrine of brotherly love, or their communistic idea. In the Bethel and Aurora communes unselfishness takes the place of a religious system. Community of women is practised only by the Perfectionists (see NOYES, JOHN HUMPHREY); the Shakers and Rappists are celibates; and at Icaria, Amana, Aurora, Bethel, and Zoar the family relation is held in honor. Only the Perfectionists are of strictly American origin; the principles of the Shakers, though first established here, originated in England; the Icarians are French, and the others are German. The Shakers are the most numerous.—After the reign of terror in France, Babeuf and his friends formed a conspiracy to overthrow the state. They taught that all men had equal rights in all property and in the enjoyment of it; every exclusive appropriation of the soil or of a branch of industry was a crime; all persons should receive the same kind and degree of education; the functions of the government should be to superintend the division of labor, the collecting of the produce in public stores, and the distribution of it to communities and individuals. The marriage relations and religious subjects were not specially discussed by them. Babeuf perished on the scaffold, and his doctrine seemed to have perished with him; but in 1834 Buonarotti revived it, and by means of pamphlets and the *Moniteur Républicain*, the *Homme Libre*, and other journals, it was again propagated. After some vain attempts at instituting social equality by insurrectionary means, the Babeuvists were content to continue as secret organizations, many of them developing the original doctrine, and the *travailleurs égalitaires* going to the extent of abrogating marriage as being a species of personal property, of wishing all towns destroyed as the natural hotbeds of tyranny, &c. In opposition to the *travailleurs égalitaires* Cabet (1788–1856) wrote his *Voyage en Icarie*, advocating a comparatively innocent communism, a small model of which he established in this country.—Saint-Simon (1760–1825) gathered about him men of science, and travelled in or-

der to enlarge his views; gave balls, dinners, and festivals, to extend his knowledge of mankind; and finally, when his wealth had been scattered, found himself abandoned to the most painful privations. He was thus fitted, as he thought, by a trial of all the conditions of humanity, to become their exponent and their reformer. He contrived what he denominated a new Christianity, or a scheme for the reconstruction of the religion, politics, industry, and social relations of mankind. To each man according to his capacity, to each capacity according to its works; such was the grand formula of the St. Simonian gospel. But the author did not live to witness its propagation. It was reserved for Rodrigues, Enfantin, Bazard, Buchez, and others to disseminate it over France. By their lectures and a journal established by them called *Le Producteur*, it soon gained many disciples, and at one time seemed on the point of absorbing the best youthful mind of the nation. Many men, who have since attained distinction as statesmen and men of letters, took part in the famous expositions of the rue Taranne, Paris, where the new school had its academy. But Saint-Simon had left his doctrine in the vague state of an aspiration or a sentiment rather than a system. His followers began to differ when they began to define. Sects arose in the bosom of the new faith. A common family was established in the rue Monsigny, but the order of functions had not been arranged in a satisfactory way. An open quarrel between two of the chiefs, Enfantin and Bazard, led to other dissensions. The finances of the general association failed, and the police interfered with its meetings, which had become, in consequence of the vivacity of the discussions and the appearance of women on the tribune, more attractive than the theatre. Enfantin collected his friends again at a patrimonial estate which he held at Ménilmontant, where a multitude of laborers were organized into groups of industrials, artists, priests, &c.; but the experiment could not be made to pay, Enfantin was seized and imprisoned, and the new family gradually dispersed. In spite of its want of practical success, the school of Saint-Simon exercised and continues to exercise a powerful influence over the French mind.—Charles Fourier (1772–1837) saw very clearly what his predecessors had not seen, that society was a growth, and not a construction; he saw that as it had followed fundamental laws of development in the past, so it must follow the same laws in the future; these laws, he also discerned, must be in analogy with the other laws of the living universe; and he concluded that the science of society must be the flower and consummation of all other sciences. But not satisfied with these grand generalizations, and the practical applications to which they inevitably lead, he assumed the character of a universal social philosopher and legislator, and lost himself in magnificent *a priori* speculations as to the formation and propagation of worlds, and the future destinies of all humanity. His vigorous thought procured him many disciples in France, England, and the United States; many efforts have been made to reduce his more practical maxims to practice, but no signal or decisive result has anywhere been achieved. (See Fourier.)—While Fourier and his disciples intended to carry out their socialistic reforms by their own exertions and without receiving any material aid from the government, Louis Blanc wanted the government to undertake the regeneration of society by the "organization of labor," holding that the evils of large capital and destructive competition could and ought to be cured by means of the state, the largest capitalist of all, from which every laborer that needs it has a right to demand employment (*droit au travail*). The government should purchase or gradually absorb the large industrial institutions of the country, and eventually render it more profitable to every laborer to join the large governmental workshops than to follow his calling on his own account. The wages of all laborers should be equal. As soon as the state had succeeded in becoming the only and general controller of production in the country, and the workmen had had sufficient opportunity to appreciate the abilities of individuals among them, the governmental administration should be superseded by the self-government of the laborers, on democratic principles. Louis Blanc opposed to the maxim of Saint-Simon, "To each according to his ability," his own, "From each according to his ability, to each according to his need." The revolution of 1848 put him in a position to experiment with his scheme. The provisional government erected public workshops, and paid wages to hundreds of thousands of laborers; but these were productive only of confusion, and contributed toward the socialistic insurrection of June, which ended in a crushing defeat.—Proudhon (1809–'65) desired to carry out his reforms without the aid of the state, and argued in opposition to Louis Blanc that the state not only should not, but could not inaugurate new social systems. In fact, Proudhon was opposed to systematic socialism of any sort. Though himself a Utopian, he combated the Utopias of everybody else. The infallibility which he claimed for his own doctrines he rendered still more odious in the eyes of his opponents by his peculiar manner of expressing his ideas. In one of his earlier principal publications, *Qu'est ce que la propriété?* (1841), he seemed to attack all property as being a kind of theft, while his intention was only to demonstrate the illegality of incomes received without labor. Similarly, his expression that he wanted to reduce the state to "anarchy" utterly obscured his real meaning, which was that the artificial centralization of the French government should give way to a government controlled by the masses. Like most socialists, Proudhon considered the

application of justice in the distribution of the wages of the labor and the profits of the capital employed in production to be the most important problem of political economy. The means proposed by him for making wages and profits proportional to each other were, that each citizen should unite in his own person the four necessary factors of production: laborer, capitalist, merchant, and employer. To bring this about, he held that employment should be guaranteed to the laborer, and that there should be a reorganization of the credit system, which he himself attempted by establishing the *banque du peuple* in 1849. This bank was an association of 20,000 laborers, who pledged themselves to take the paper issued by it in lieu of cash. Proudhon believed that a conventional sign of this sort, costing but little labor to produce, could take the place of gold and silver coins, the production of which requires a large amount of labor. The bank advanced to any member, on articles produced by him, four fifths of their value in its own notes, and demanded no interest for the loan. On security being given, it would advance upon work not yet done. Proudhon expected that this gratuitous credit, enabling men to consume at any time the wages of their labor, would be the means of inciting the members of the association to as great industry as the hope of accumulating interest-bearing capital, since their means of present enjoyment would depend upon their energy. The government soon closed the bank for violation of the laws of trade, and Proudhon's followers maintain that his scheme has never had a fair trial.—Robert Owen (1771–1858), in England, was arousing the public mind to the necessity of a new order of society at the same time that Saint-Simon and his disciples were preaching in France. They proceeded, however, on wholly different grounds. Owen's fundamental axiom was that man was made entirely by his external circumstances, so that, to form his character, and to produce his entire happiness, nothing was requisite but a change in his external relations. Possessed of great wealth, he established a manufacturing colony at New Lanark, in which his principles were applied to the laboring classes. Justice in the payment of labor, vast domestic economies, and a thorough system of infant and adult education gave it for a time great and increasing prosperity. Statesmen and churchmen alike admitted the success of the attempt, and the system, or parts of the system, were in a fair way of being introduced into other manufacturing districts. But Owen was encouraged by the promise of his plans to step forth as a philosopher. He taught in pamphlets, speeches, letters, and books, his doctrine of the omnipotence of circumstances and of human irresponsibility, attacking at the same time all religions and all governments, and thus provoking the earnest hostility of the clergy as well as of politicians. Other establishments were subsequently erected at New Harmony, Indiana, and Orbiston, Scotland, but they failed. His popularity declined rapidly, except among a portion of the laboring classes, and he accomplished nothing beyond his earlier success. He had travelled over the world to indoctrinate it with his principles, but the world remained to the end of his life stubbornly incredulous. Nevertheless he has a just claim to be considered the originator of modern coöperation.—In 1869 England alone numbered 1,308 coöperative societies, under general regulations prescribed by act of parliament; 749 of these sent in their returns to government at the end of 1870, from which their condition appears to have been as follows: number of members, 249,113; share capital, £2,034,261; loan capital, £197,128; average stock in trade during the year, £912,127; value of buildings, fixtures, and land, £962,276; dividend to members, £467,164; to non-members, £16,523; allowed for educational purposes, £3,775. The most successful experiment of the English coöperators is that of the Rochdale "Equitable Pioneers' Society," established mainly on the principles of Owen. Its primary object was the founding of a store for the sale of the necessaries of life, which was opened in December, 1844. In 1847 the pioneers opened a drapery department, in 1850 a slaughter house, in 1852 shoemaking and tailoring establishments; and after a history of continuous success, in the last quarter of the year 1870 they numbered 5,560 members, and had a share capital of £81,232. Similar stores and associations now exist in various parts of Europe, America, and Australia. The varieties of coöperation so far developed are numerous, but they are all founded upon the original idea of associated as opposed to isolated efforts. The power which the joint-stock principle places in the hands of small capitalists, the coöperative system places in the hands of the smallest capitalists; it even enables the man without capital to accumulate it. Morier describes coöperation as "the child of socialism, rescued by the economists from the dangerous custody of its parents." In Germany this movement on the part of the laborers was urged forward by Schulze-Delitzsch in opposition to the socialism of Lassalle and Marx, which led to the formation of the "International Association." (See International Association.) Schulze-Delitzsch originated a new form of coöperation, which has been successful in Germany to an extraordinary degree. He devised a people's bank, or coöperative credit bank, from which the members can borrow small sums up to 1,000 thalers. The capital is derived from the entrance fees and subscriptions of the members. The shares are fixed at 40 thalers, and may be paid by instalments. A 40-thaler shareholder may borrow 60 thalers without security; money is borrowed by the society at a low rate of interest; members on leaving receive the amount paid up on their shares, and are relieved from all liabilities after two years.

In 1870 the number of loan or credit banks in Germany was estimated at 2,000, and numerous associations of a similar nature are now established in Russia, Denmark, Italy, France, and England. There is in Germany a political party of socialists called *Socialdemokraten*, another development of the same movement which produced the international association, mainly composed of workingmen and their friends. This party aims to establish complete liberty, equality, and fraternity, by uniting all the working classes in associations, and securing to all the same rights and opportunities to work; there are to be no favored classes or individuals, and the whole world is to form one great solidarity. The so-called *Kathedersocialisten* are not socialists in the ordinary sense of the word, but a school of political economy opposing the free traders.—See, besides the works named in the biographies of the principal socialists, Stein, *Der Socialismus und Communismus des heutigen Frankreich* (Leipsic, 1844), and *Geschichte der socialen Bewegung in Frankreich* (3 vols., Leipsic, 1849–'51); Bluntschli, *Die Communisten in der Schweiz* (Zürich, 1843); Schäffle, *Kapitalismus und Socialismus* (Tübingen, 1870; English translation by Kaufmann, London, 1875); Noyes, "History of American Socialisms" (Philadelphia, 1870); Dühring, *Kritische Geschichte der National-Oekonomie und des Socialismus* (Berlin, 1871); Le Play, *L'Organisation du travail* (Paris, 1871), and *La réforme sociale en France* (Paris, 1872); Nordhoff, "The Communistic Societies of the United States" (New York, 1875); and Holyoake, "History of Coöperation" (London, 1875).

**SOCIETIES, Literary and Scientific.** The origin of this distinctive title for private intellectual associations is as ancient as that of academies. (See ACADEMY.) Societies existed in antiquity and in the middle ages, and in Germany and the Netherlands they acquired importance in the 15th century by promoting classical culture. The associations or corporations of the Meistersingers flourished till the 16th century. The 17th century witnessed the formation of bodies in Germany for the improvement of the language, after the model of the Florentine La Crusca and the French academy, and the rise and progress of scientific societies, especially of the "Royal Society of London," incorporated in 1663 for the investigation and advancement of physical science. Many important societies were formed in Great Britain in the 18th century, including the "Society of Antiquaries" (London, 1717), the "Royal Society of Dublin" (1731), "Royal Society of Edinburgh" (1783), "Medical" (London, 1773), and "Linnæan" (1788); and in 1800 sprang up in London the "Royal Institution of Great Britain," celebrated for chemical and other lectures. (See LONDON, vol. x., pp. 604–'5.) The subsequent increase of learned bodies was still more rapid. The United Kingdom now has societies for almost all branches of science, letters, learning, and art; and with a view of establishing greater unity, the royal society of London, and the astronomical, geological, Linnæan, and chemical societies, are to meet, after the completion of the palace of learning in the new Burlington house, in the same building, which is also to contain their extensive libraries, collections, and reading rooms. Most remarkable for stimulating many of the important discoveries of the century are the "Geological Society" (1807) and the "Royal Geographical Society" (1830). Those engaged in antiquarian and archæological researches also display great vigor; and special bodies, as for instance those relating to explorations in Palestine, have achieved signal results. Among other peculiarly valuable institutions are the "Royal Astronomical Society" (1820), which is one of the most important of the kind; the "Statistical Society" (1834), which throws much light upon the national resources; and the "Royal Asiatic Society of Great Britain and Ireland" (1823), with branches in Bombay, Madras, Hong Kong, and elsewhere. The "Royal Asiatic Society of Bengal," at Calcutta, dates from 1784. There are learned societies in other parts of the East, in Canada, Australia, and in almost every important part of the British empire; and all the leading societies publish the results of their labors. The most important English perambulatory body is the "British Association for the Advancement of Science," founded in 1831. (See ADVANCEMENT OF SCIENCE.) The "National Association for the Promotion of Social Science" held its first public meeting at Birmingham, Oct. 12, 1857, under the presidency of Lord Brougham. It embraced originally the five departments of jurisprudence, education, punishment and reformation, public health, and social economy; and a sixth department relating to trade and international law was added in 1860. The annual meetings are held at a different place each year, and are chiefly occupied in reading disquisitions and in discussions.—The continent of Europe emulates England in encouraging explorations, and this is especially the case with the geographical societies of Berlin, St. Petersburg, and Vienna, and the "Institute" at Gotha. In France and Italy the number of societies is diminished by the omnipotence of the academies. The former country, however, has several of importance, especially the *société géographique* of Paris, which publishes a celebrated monthly *Bulletin*, and the *société asiatique*, which has called into existence oriental societies in Germany and England. In the latter part of last century Germany had a poets' union (*Göttinger Dichterbund* or *Hainbund*) among its societies, with Klopstock at its head. In the present century it has initiated scientific congresses and other associations in the interest of political and social science, and the country abounds with societies devoted to every branch of knowledge, art, and industry. Among the oldest is the *Wissen-*

*schaftlicher Verein* at Göttingen (1750), and the best known are devoted to natural history and geology, especially in Berlin. Switzerland, Austria, Hungary, Russia, Holland, Belgium, and the Scandinavian countries have various learned bodies apart from the academies. They abound also in the United States, especially in regard to investigations of local and national history, nearly every state having a historical society with a library. The "New York Historical Society" (founded in 1804) and the "New York Geographical Society" (1852) are described under New York, vol. xii., p. 404. The most important society in the United States is the "American Association for the Advancement of Science," founded in 1847. (See Advancement of Science.) A "Social Science Association," organized in Boston in 1865, had in 1874 about 300 members.

**SOCIETY ISLANDS**, a group in the S. Pacific ocean, extending between lat. 16° and 18° S., and lon. 148° and 155° W.; area, 666 sq. m.; pop. about 18,000. The group is formed of two clusters of islands, one of which lies about 70 m. N. W. of the other. They were formerly, and by some geographers still are, distinguished by the separate designations of the Society islands (proper) and the Tahiti or Georgian islands. The latter are under the French protectorate; area, 453 sq. m.; pop. 13,800, of whom about 970 are emigrants, 400 soldiers, and 600 foreign residents. The former are independent; area, 213 sq. m.; pop. about 4,000. Mariners usually speak of one cluster as the windward and the other as the leeward, applying the term Society islands to both combined. The Society islands, thus defined, exclusive of several islets, are Tahiti or Otaheite, Eimeo, Maiaoiti, Maitia, Tetuaroa, Huahine, Raiatea, Otaha or Tahaa, Borabora, Marua or Maupiti, and Tubai, the first five belonging to the Tahiti group, and the remainder to the Society islands proper. The islands are mountainous in the interior, the highest peak, on the island of Tahiti, reaching an elevation of 7,339 ft., and have a border from 1 to 5 m. wide of rich level ground extending from the base of the high lands to the sea. In general appearance they are alike, and lava, basalts, and pumice stone, which are found in several places, indicate that their origin was volcanic. They are surrounded by belts of coral rock, of various width, situated from a few yards to 5 m. from the shore, with openings which permit the passage of canoes, while some of them admit ships to smooth water and good anchorage. There are small lakes and lagoons in some of the islands, and all are watered by numerous streams, upon the banks of which, or along the shores, the inhabitants reside.—There is considerable variety of soil, the sides of the mountains being frequently covered with a thin layer of light earth; the summits of many of the hills have a thick stratum of red ochre or yellow marl, while the soil of the level tracts along the shores is a rich alluvial deposit, mixed with vegetable mould, and is exceedingly fertile. The climate is healthful and very mild, the range of the thermometer throughout the year being inconsiderable. Besides the breadfruit, these islands produce almost every tropical vegetable and fruit, including some peculiar to the group. A few fruits and vegetables have been introduced from the temperate regions. The guava shrub, brought from Norfolk island, is now common, and bears a profusion of fruit, upon which pigs and cattle feed with avidity. Garden produce is little cultivated, and agriculture is very backward. A botanic garden, established by the French, offers seeds to colonists and natives; but there is little demand for them, and prizes offered to stimulate production were withdrawn in 1865 as useless. The spontaneous production of fruits seems sufficient for the natives. An Anglo-Portuguese agricultural company, established in 1861 for the cultivation of cotton and coffee by Chinese coolies, has effected but little. The introduction of limes and oranges has been very successful. Pigs, dogs, and rats were the only quadrupeds found upon the islands at the time of their discovery; but all our domestic animals have been introduced, and with the exception of the sheep and rabbit have thriven remarkably well. Horned cattle are abundant. There are numbers of aquatic fowl; the albatross, tropic birds, and petrel are found on all the islands; herons and wild ducks frequent the lakes and lagoons; and there are several kinds of birds of prey, woodpeckers, and small paroquets. Domestic fowl are abundant, and were upon the group at the time it was discovered.—The natives belong evidently to the Malay race, and are generally above the middle stature. Their countenances are open and prepossessing, though their features are bold and sometimes prominent. Their complexion is olive or reddish brown, but there are great varieties of shades. The appearance of the men is vigorous and graceful, and their behavior affable and courteous. Tattooing is not now practised. The native costume has been altogether abandoned for dresses resembling those worn by civilized nations. The native manufactures have been entirely superseded by imported goods. The chief intercourse is carried on with Valparaiso, Sydney, and San Francisco, and the domestic exports of the group consist principally of cocoanut oil, arrowroot, sugar, and pearl shells. The annual exports amount to about $1,000,000, and the imports to about $650,000. The principal port, Papiete in Tahiti (pop. about 800), is the residence of several foreign merchants. It is a free port except for arms and spirits, has a dock for repairing vessels, government buildings, and a hospital; and two newspapers, one in the native language and one in French, are published.—The Spaniards lay claim to the discovery of Tahiti in 1606, by Quiros, who called the island Sagittaria. Capt. Wallis, in a British ship sent to make discoveries in the South sea,

reached Tahiti in 1767, and named it King George's island. Bougainville touched at it in 1768, naming it Nouvelle Cythère. Capt. Cook reached it in 1769, discovered most of the islands in the N. W. cluster, gave to the whole group the name of Society islands, in honor of the royal society of London, and restored the native name to Tahiti. The Spaniards attempted to colonize Tahiti in 1772–'4; and about that date Cooke visited the group a second time, and again on his last voyage in 1777, when he found a house and cross which the Spaniards had erected carefully preserved by the natives. After this 11 years passed without any communication between the Society islands and the rest of the world, when the Bounty arrived to transport plants of the breadfruit tree to the British West India islands. The interest excited by these voyages resulted in the formation of the London missionary society, which fitted out a ship to carry missionaries into the islands of the Pacific. This vessel arrived at Tahiti early in 1797. For a long time the labors of the missionaries were fruitless, till Pomare II. embraced Christianity about 1815. Pomare died in 1821, and during the minority of his son the missionaries acquired great influence; but the son having died before he attained manhood, he was succeeded by Queen Aimata or Pomare, the latter being the surname of the reigning family. From the conversion of Pomare II. the power of the missionaries continued increasing, till it became paramount in Tahiti. The success of the French Catholic missions on the islands to the east induced two priests to go to Tahiti. The English missionaries opposed this, and the priests were forcibly deported. The French government then sent a frigate to demand liberty for all French subjects, and $2,000 as the expenses of the voyage to France of the expelled missionaries. In 1843 a strong force landed on Tahiti and hoisted the French flag, taking possession in the name of Louis Philippe. (See Du Petit-Thouars.) The queen made her escape to a neighboring island, and several skirmishes took place between the natives and the invaders. There was also a protracted diplomatic dispute with England, which ended in the payment of an indemnity by the French government for the expulsion of the British consul Pritchard and the seizure of some of his property. In 1846 the French power was completely established in Tahiti. Pomare was recalled, and a treaty was entered into, by which she was restored to authority, and the whole of her dominions placed under the protection of France. Capt. Cook, from the crowds which collected on the coast, supposed the population of Tahiti to be 80,000; but the first missionaries estimated it, along with that of the neighboring island of Eimeo, at 10,000. A census by the French in 1864 made the population of Tahiti, Marua, Tetuaroa, and Maiaoiti, 13,847. The reduction from former years is due to infanticide, venereal disease, smallpox, and rum. Attempts have been made to increase the population by immigration. A few hundred Chinese coolies have been introduced, and the French deported convicts from New Caledonia, but were obliged to withdraw them in 1864, on account of their demoralizing influence upon the natives. By the labors of the missionaries the moral and social condition of the latter has been much improved, and education is extending. In 1865 school districts were established, with two schools, one Protestant and one Roman Catholic, in each district.

**SOCINUS** (Ital. Sozzini). **I. Lælius**, an Italian theologian, born in Siena in 1525, died in Zürich, March 16, 1562. His studies led him to doubt some of the fundamental doctrines of the church, including that of the Trinity. After various travels he resided in Switzerland, Germany, and Poland, finally settling in Zürich. In Wittenberg he gained the friendship of Melanchthon, and in Geneva of Calvin; but the favor of the reformers was withdrawn when his peculiar doctrines were discovered. His life was written in Latin by Illgen (8vo, Leipsic, 1814), who also published in 1826 two parts of another work in quarto, entitled *Symbolæ ad Vitam et Doctrinam Lælii Socini illustrandam.* **II. Faustus**, nephew of the preceding, born in Siena in December, 1539, died near Cracow, March 3, 1604. By his skeptical spirit he had early made himself obnoxious to the authorities of the church, and at the age of 20 was compelled to seek safety abroad. After the death of his uncle, whose property and manuscripts he inherited, he returned to Italy. After spending 12 years as an attendant upon the luxurious court of Florence, he resolved to be a religious reformer, and in 1574 took up his residence at Basel, where he busied himself in elaborating into a system the scattered hints and views in the writings of Lælius. In 1577 he appeared in open debate, maintaining that the Trinity was a pagan doctrine, and that Christ was a created and inferior being. This made him unpopular with the Swiss church, but gave him fame abroad. He was called to Transylvania to oppose Davidis, who had taken the extreme ground that all adoration of Christ was idolatrous. His efforts being unsuccessful, he passed into Poland, where the Anti-Trinitarian party had gained a strong foothold. But his moderate opinions made him unpopular here, and he was coldly received. After four years of residence in Cracow, his marriage with the daughter of a nobleman in the neighborhood gave him new influence. He found a comfortable home, and made proselytes from the noble and wealthy classes. But his wife and her father died, illness prostrated him, his lands in Italy were confiscated, and a few years before his death he was assailed by a mob, dragged into the street, and exposed in the market place; his furniture was broken and his manuscripts were destroyed. His works, contained in the

first two volumes of the *Bibliotheca Fratrum Polonorum*, consist of theological tracts, expositions of Scripture, and polemical treatises, with a great number of letters. Many of his unpublished letters are in the library of Siena. —Though Socinus was the founder of a school in theology, his influence was rather negative than positive. He denied the Trinity, the deity of Christ, the personality of the devil, the native and total depravity of man, the vicarious atonement, and the eternity of punishment. His theory was that Christ was a man divinely commissioned, who had no existence before he was conceived by the Virgin Mary; that human sin was the imitation of Adam's sin, and that human salvation was the imitation and adoption of Christ's virtue; that the Bible was to be interpreted by human reason, and that its metaphors were not to be taken literally. The name Socinian, which is often given to those who hold Unitarian opinions as a term of reproach, was for a century the honorable designation of a powerful and numerous religious body in Poland, Hungary, and Transylvania. It was only the union of the secular and ecclesiastical force during the reigns of Sigismund III. and his successor that succeeded in breaking up and dispersing the Socinian party in Poland; and the Racovian catechism (so called from its place of publication, Raków in Poland), compiled mainly from the writings of Socinus, is still the text book of faith and worship in many Hungarian and Transylvanian churches. The opinions of Socinus are professed still by many churches in Holland, Switzerland, Great Britain, and the United States. His life was written by the Pole Przypcovius, and by the Rev. Joshua Toulmin (8vo, London, 1777).

**SOCIOLOGY**, the science which treats of the actions of men living together in society, and of the institutions thus created. Its scope embraces the whole history of man from the origin of language to the latest development of modern civilization. As a constructive science it is of very recent birth. In a looser sense, as consisting of general speculations upon social affairs, it is almost as old as society itself. Plato, doubtless founding on legendary ideas about the relation between the microcosm and the macrocosm, discovered the parallelism between the parts of a society and the faculties of the human mind; he also philosophically explained the rise of division of labor in a society. Aristotle classified politics, constructed a framework for speculations on government, and stated two of the three sources of the origin of society: instinctive gregariousness and experience of utility. The later Greek historians of Rome indulged in some arbitrary theories about the influence of climate. Hobbes, following the lead of Plato, tried to establish an erroneous parallelism between a society and the human body; but his conception of the state, the Leviathan, as an organism, a living whole made up of related parts, was a real sociological advance. Pascal developed this idea; he regarded the whole succession of human beings as a single individual man, whose youth is the world's antiquity, whose years are the world's generations, whose maturity is the world's prime; he thus formally enunciated the idea of progress, so vital to sociology. Vico held that it might be shown that peoples the most widely separated in place and time had followed nearly the same course in the development of their languages and political condition. About the middle of the 18th century, the French economic sect of the physiocrats maintained that there are natural laws of society which give it a direction of its own, irrespective of legislative interference. Turgot even earlier had discovered that all epochs of history are fastened together by a sequence of causes and effects, and had concluded that there is an ordered movement of advance in societies. Herder, in his *Ideen zur Philosophie der Geschichte der Menschheit* (1784), considers humanity as an individual tending through many vicissitudes to perfection, which it reaches in another world. Of the many socialist schemes which sprang up after the French revolution, that of Saint-Simon alone has any scientific value; and all that was true in his somewhat unscientific speculations has been incorporated by Saint-Simon's secretary and disciple Auguste Comte in his positive philosophy. Comte first subjected the whole course of history to a careful analysis, so as to throw new light on the development of society. He first fully apprehended the relations of biology or the science of man to sociology; first clearly stated the diminishing influence of physical surroundings on societies; first gave its entire weight to the increasing influence of social circumstances, both on the society in which we live and on that which has gone before us. Comte was consequently the first to lay down the lines, although they are rude and imperfect, on which a scheme of society as it will be may be constructed. His sociology, however, bears the marks of the incomplete erudition and backward science of the time. When, in the hands of the Thierrys, Guizot, Villemain, and many others, history had taken a new departure, Comte profited by the movement. But the studies of these distinguished writers were too closely confined to the political and intellectual aspects of society, and Comte followed them in their exclusiveness. Coming in the wake of the great modern scientific movement, Herbert Spencer has attempted to change the face of sociology. Taking up the analogy between society and man, erroneously treated by Plato and Hobbes, Pascal and Turgot, Spencer has converted it into a series of generalizations exhibiting a correspondence between individual organisms and societies, and of these he has made the basis of his new science. He describes each community as a social organism, which has structures and func-

tions. The structures are forms of government, civil, ecclesiastical, military, industrial, and ceremonial; the functions are sentiments, ideas, industrial processes, the fine arts; and both closely resemble the structures and functions of an individual organism. In his "First Principles" he goes further, and seeks to derive social and organic together with inorganic laws from certain ultimate principles. Thus the origin of division of labor in a community, and differences in industrial occupations, are clearly due to diversities of external circumstances. This is an induction; as a matter of fact all simple societies, various groups of which are exposed to unlike outward conditions, tend to become complex societies. Spencer's *a priori* explanation is that, all influence being force, river banks, sea shores, all climatic and local conditions, are forces. If they do not influence the feelings and thus modify the habits of organic beings near them, they are wasted; but this is inconceivable, for force persists. The instability of homogeneous or low forms of social life is therefore deducible from the persistence of force. Passing from general to special aspects of sociology, his plan embraces next the history of the domestic relations. Political organizations as historically based on the family will then be elucidated, and the functions of government discriminated. The necessary development of industry from slavery through serfdom to coöperation will be shown. Intellectual, æsthetic, and moral progress will be regarded as psychological processes determined by social conditions. And finally all phases of society will be shown to be connected with and reacting on one another. But one division of this immense work has been executed (1876).

**SOCORRO,** a S. W. county of New Mexico, bordering on Arizona, intersected in the east by the Rio Grande, and containing the sources of the Gila river; area, about 11,500 sq. m.; pop. in 1870, 6,603. There are fertile valleys along the streams, but the greater part of the county is mountainous and unproductive. Gold, iron, and other minerals are found. The chief productions in 1870 were 26,889 bushels of wheat, 26,860 of Indian corn, 24,006 lbs. of wool, and 2,150 gallons of wine. There were 271 horses, 1,313 milch cows, 1,628 working oxen, 1,514 other cattle, 23,500 sheep, 547 swine, and 4 flour mills. Capital, Socorro.

**SOCOTRA,** an island in the Indian ocean, belonging to the sultan of Oman, about 130 m. E. N. E. of Cape Guardafui, the eastern extremity of Africa; length about 75 m., breadth about 25 m.; area, 1,309 sq. m.; pop. about 3,000. Tamarida, the capital, is in lat. 12° 39′ N., lon. 54° 1′ E. The surface is generally about 800 ft. above the sea, and the shores are bold. Toward the north there is a ridge of mountains with several peaks rising to the height of 5,000 ft. There are some small streams, and where there is sufficient moisture vegetation is remarkably luxuriant. Date trees and cotton are cultivated; but Socotra is particularly famous for aloes and the gum of the dragon's blood tree, both of which are said to be the finest in the world. Camels, horned cattle, sheep, asses, and goats are reared. There is some trade with Muscat.—Christianity appears to have been planted on this island during the apostolic age, and it remained Christian until the end of the 15th century, sharing the fate of the Nestorian church, which the Socotrans had joined. The Portuguese several times attempted to occupy the island and to revive Christianity. In 1834 the English explored Socotra and appeared disposed to occupy it; but they abandoned the design when they occupied Aden. There are two peculiar tribes on the island, one said to be descendants of Jews, and the other of the Portuguese.

**SOCRATES,** a Greek philosopher, born in the immediate neighborhood of Athens between 471 and 469 B. C., died in that city in 399. He was the son of Sophroniscus, a sculptor, and of Phænarete, a midwife, and was trained in his father's art. Tradition ascribed to his chisel three draped figures of the Graces which in the time of Pausanias were shown at the entrance to the acropolis. As a philosopher he called himself self-taught, and referred his knowledge sometimes to books, but more frequently to intercourse with distinguished men. Though traditionally represented as an old, bald-headed man, it is probable that his extraordinary peculiarities were early manifested, and it is certain that he was famous both among wits and the populace in 423, when the "Clouds" of Aristophanes was first exhibited. Plato, Xenophon, and Aristophanes offer different phases and estimates of his philosophy, but agree in the outline of his personal qualities and habits. With remarkable physical strength and endurance, he trained himself to coarse fare, scanty clothing, bare feet, and indifference to heat or cold, aiming thus to reduce the number of his wants, as a distant approach to the perfection of the gods. He had a flat nose, thick lips, prominent eyes, bald pate, squat figure, and ungainly gait, and wandered about the streets of Athens, standing motionless for hours in meditation, and charming all classes and ages by his conversation; so that Alcibiades (in Plato's *Symposium*) likened him to an uncouthly sculptured Silenus containing within the images of the gods, and declared that "as he talks, the hearts of all who hear leap up and their tears are poured out." Though a sage and a martyr, he was wholly removed from asceticism, exemplified the finest Athenian social culture, was a witty as well as serious disputant, and on festive occasions would drink more wine than any other guest without being overcome. Few events of his life are recorded. Of his wife Xanthippe, all that has passed into history is that she bore him three sons, that she had a violent temper, and that he said he married and endured her for self-discipline. He was an enthusiastic lover of

the city, within which alone he found instruction, and beyond the walls of which he never went, except once to a public festival, and again to serve as hoplite at Potidæa (about 431), on the outbreak of the Peloponnesian struggle, at Delium (424), and at Amphipolis (422). At Potidæa he went barefoot over ice and snow, surpassed all other soldiers first in the cheerful endurance of hunger and then in the apparent enjoyment of plenty, and saved the life of Alcibiades, to whom, instead of himself, his own request caused the prize of valor to be awarded. His composure and bravery were alike distinguished at Delium and Amphipolis. He sought influence neither as a soldier nor statesman, and once only discharged a political office. In 406 he was one of the five prytanes of the senate, when the illegal sentence of death was proposed against the victors at the Arginusæ; and he, being epistates for that day, refused to put the question to vote, despite the menaces of the people and the assembly. With four other citizens he was summoned by the thirty tyrants to go to Salamis and bring back Leon to punishment; and he alone refused. Engaged as a missionary in the service of truth and virtue, he was warned from participating in public affairs by what he called a *δαιμόνιον*, *i. e.*, an internal voice, which he professed to hear from childhood in the way of restraint, but never in the way of instigation, and which he was accustomed to speak of familiarly and to obey implicitly. This demon or genius of Socrates, which was not personified by himself, was regarded by Plutarch as an intermediate being between gods and men, by the fathers of the church as an evil spirit, by Le Clerc as one of the fallen angels, by Ficino and Dacier as a good angel, and by later writers as a personification of conscience, or practical instinct, or individual tact. Nor was this the only way in which he thought he received the special mandates of the gods. By divinations, dreams, and oracular intimations, he believed his peculiar mission to be imposed upon him; and when the Pythian priestess pronounced him to be the wisest of men, he was perplexed between the decision of an authority which he deemed worthy of all respect and his own estimate that he had no wisdom whatsoever on any subject. With this sanction, he struck out the original path of an indiscriminate public talker for the sake of instruction. His disinterestedness, poverty, temperance, easy affability, and unrivalled sagacity, as well as his plausible and captivating voice and manner, commended his conversation. He spent the whole day in public, in the walks, the gymnasia, the schools, the porticoes, the workshops, and the market place at the hour when it was most crowded, talking with every one without distinction of age, sex, rank, or condition, discussing with politicians, sophists, military men, artists, and ambitious youths, eager to get self-knowledge and to awaken the moral consciousness, striving to win now Alcibiades and now Theodota to virtue, never accepting money in return for wisdom, attracting listeners during his later years even from the remoter cities of Greece, but founding no school, teaching in no fixed place, and writing no books. His custom was by systematic cross examination to convict every distinguished man whom he met of ignorance. Thus, after hearing the oracular eulogy from Delphi, as reported by Plato in his "Apology," he set out to examine the men whom he deemed wiser than himself. The politicians, the poets, and the artificers were in turn affronted as he attempted to demonstrate their conceit of knowledge without its reality, their skill without wisdom. His irony, or assumption of the character of an ignorant learner, till he involved his opponent in contradictory answers, added zest to his discussions. But he differed from the sophists, though he was ridiculed as the chief of them, in that, whether serious or humorous, he was ever seeking a positive basis for truth, while they for the most part denied the possibility of truth, and could ply the sophistical art with entire indifference to it. In his conception, virtue was as intellectual as vice, and he let slip no opportunity to engage with the masters of sophistry, to follow them through their subtleties, to unravel their captious inquiries, and to wield the weapons of rhetorical adroitness in the interest of truth. He exhibited undisguised contempt for the rulers, proclaiming that government was a most difficult science, and that men, who would not trust themselves in a ship without an experienced pilot, not only trusted themselves in a state with untried rulers, but even sought to become rulers themselves. He thus naturally and necessarily made for himself enemies in every direction and among all classes. Attached to none of the political parties, ridiculed in turn as a buffoon and as a moral corrupter, at once satirized by Aristophanes and hated by the thirty, especially odious from his intimate connection with Critias and Alcibiades, only a decent pretext was wanted to bring upon him the vengeance of power, and this was found in a charge of impiety. An orator named Lycon and a poet named Meletus united with the demagogue Anytus in impeaching him for despising the tutelary national gods, for introducing other and new deities, and also for corrupting the youth. The details of the accusers were, that he worshipped a demon unknown to the mythology, that he contemned the existing political constitution by ridiculing the practice of choosing archons by lot, that he taught young men the habit of depreciating the entire mode of life of their fathers, and that he quoted and perverted passages from the poems of Homer and Hesiod to favor aristocratic doctrines. He approached his trial with no expectation of acquittal, though he had always obeyed the laws, and even in religious opinions was identified with the public mind of Athens.

He commented upon all the imputations, and denied some. He mentioned his blameless life, his divine commission, and the consequent antipathies which he aroused, refuted the charge of irreligion, maintained a calm, brave, and almost haughty bearing, and declared his solicitude rather for the good repute of the Athenians than for himself. He heard without surprise the sentence of condemnation, which was passed by a majority of only five or six in the Athenian dicastery of 567 members. It is probable that the prosecution was designed rather to humble than to destroy him. Xenophon affirms that the defiant and fearless tone of his defence was the direct cause of his condemnation; and it is certain that the capital sentence which followed it was the consequence of his *libera contumacia*, as Cicero expresses it. The penalty of death having been pronounced, he declared himself satisfied both with his own conduct and with the result, calculated that his bearing on the trial would be the most emphatic lesson which he could read to the youth of Athens, and predicted that his removal would be the signal for numerous successors in so worthy a work. An interval of 30 days was allowed for the annual Theoric mission of the sacred ship to Delos, which he passed in prison, with chains on his legs, in conversation with his friends. The Platonic dialogues of "Crito" and "Phædo," in addition to their historic value, may be regarded as imitations or developments of his last arguments on the duty of obedience to the laws and on the evidences of immortality. There is no authority but that of late and untrustworthy writers for the statement that the Athenians lamented his fate and punished his accusers.—The *Memorabilia* of Xenophon and the dialogues of Plato have been supposed to represent an exoteric and an esoteric Socrates, and there has been a long controversy as to which contains the most complete and true history. The former professes to record actual conversations held by him, and was designed as an apology; while the Socrates of the latter is the spokesman of theories which may or may not have been the opinions of the master as well as the disciple. But the two pictures thus presented are in the main accordant. Socrates marks the epoch in Greek philosophy when speculation turned from physics to ethics. He directed his attention to human relations and duties. Astronomy he pronounced a divine mystery; geometry he valued only for land-measuring; general physics he discarded altogether as having furnished and promising nothing but hypothetical, contrary, and useless results; human practice alone, with the knowledge pertaining to it, was esteemed the proper subject of human investigation. According to Cicero, "Socrates called philosophy down from the heavens to earth, and introduced it into the cities and houses of men, compelling men to inquire concerning life and morals and things good and evil."—The most complete discussions concerning Socrates are in general histories of Greece and of philosophy. See also Moses Mendelssohn's life of Socrates, prefixed to his own *Phædon;* Nares, "An Essay on the Demon or Divination of Socrates" (1782); Wiggers, *Sokrates als Mensch, Bürger und Philosoph* (1811); Schleiermacher, *Ueber den Werth des Sokrates als Philosophen* (1815–'18); Lelut, *Du démon de Socrate* (1836); K. F. Hermann, *De Socratis Accusatoribus* (1854); and Zeller, "Socrates and Socratic Schools" (1868). Ueberweg's "History of Philosophy" (1872), vol. i., pp. 80–88, contains a full list of works.

**SODA,** a name given to sodic monoxide, or common oxide of sodium, $Na_2O$, the base of the important series of sodium salts; also to the hydrated oxide, or caustic soda, $NaHO$, and in commerce to the normal carbonate, $Na_2CO_3+10H_2O$. Anhydrous sodic monoxide, or the soda of the chemist, $Na_2O$, is formed when the metal is burned in dry air or oxygen gas, by exposing the dioxide to a high heat, or by heating sodic hydrate with an equivalent quantity of metallic sodium, whereby $NaHO+Na$ is converted into $Na_2O+H$. When sodium is burned in oxygen gas till its weight is constant a dioxide, $Na_2O_2$, is formed. When exposed to the air it deliquesces, and, uniting with carbon dioxide, resolidifies as carbonate. When a heap of it is moistened it becomes heated and evolves oxygen gas. The monoxide attracts moisture as powerfully as the corresponding potassic oxide, forming sodic hydrate or caustic soda, from which the water cannot be expelled by heat alone. The properties of caustic soda resemble those of caustic potash, and it may be prepared from the carbonate by a similar method (see POTASH, vol. xiii., p. 756); but its action upon acids is rather less energetic. Its specific gravity is 2·13. It is manufactured on a large scale in the alkali works according to a process proposed by Mr. Gossage, by which advantage is taken of the presence of caustic soda in the black ash solution. The crude solution of black ash vats is evaporated to a specific gravity of 1·5 or 1·6, during which operation most of the carbonate, sulphate, and chloride crystallize out. The "red liquor," as it is technically called, which owes its color to a compound of sulphide of sodium and sulphide of iron, and which is also contaminated with ferrocyanide and sometimes with sulphocyanide of potassium, has air forced through it while hot, which causes the precipitation of the iron as sesquioxide and the conversion of the sulphur compounds into sulphates. The addition of sodic nitrate completes the oxidation, and this salt may be used for the whole process. After its addition the evaporation is carried further until the whole mass is heated nearly to redness. When the temperature rises to 311° large quantities of ammonia are evolved, and as it increases nitrogen escapes abundantly. The fused soda is poured into sheet-iron vessels, in which it so-

lidifies.—The normal carbonate, existing in certain lakes in Egypt and Hungary, and in the volcanic springs of Iceland and North America, often containing sesquicarbonate, was long known in commerce as *natron*. Large quantities of it and of other soda salts occur in the form of an efflorescence on the "alkali plains" of the western territories. It was formerly prepared artificially from kelp, or the ashes of seaweeds and fuci, and also from barilla, the semifused ash of the *salsola soda*, a plant which has been cultivated with great care by the Spaniards, especially in the vicinity of Alicante, the seed being sown in light low soils which are irrigated by sea water. Barilla yields much more soda than kelp, the latter being now principally used for obtaining iodine. But the quantity of soda obtained from barilla is small in comparison with that manufactured by the process of Leblanc, which consists in first converting chloride of sodium or common salt into sulphate of sodium or Glauber's salt, and then converting the sulphate into carbonate by heating it with carbonate of lime and coal. The conversion of common salt into sulphate or "salt cake" is called the "salt-cake process," and is effected in a salt-cake furnace. One of the best forms of furnace contains two iron vessels or retorts placed in separate heating apartments or furnaces, but connected with each other by a neck. Into the first vessel, called the decomposer, which is oval, are introduced 5 or 6 cwt. of common salt and a rather less weight of sulphuric acid of sp. gr. 1·78, and a gentle heat is applied. Hydrochloric acid is evolved and passes off by a flue to condensing towers containing fragments of coke or stone, through which water is allowed to trickle. There are two towers, the first one receiving the vapors at the bottom, passing what are not absorbed to the top of the other, from the bottom of which the residue, mostly air and some impurities, issues and passes into a large chimney. In the first vessel about half the salt is decomposed, when the pasty mass, consisting of acid sulphate of sodium and undecomposed salt, is thrust into the second vessel or roaster, which is heated to a higher degree, and the decomposition completed. The reaction in the first vessel is as follows: $2NaCl + H_2SO_4 = NaCl + NaH,SO_4 + HCl$. In the second vessel the acid sodic sulphate reacts upon the unchanged salt, the hydrogen taking the chlorine to form hydrochloric acid, leaving two molecules of sodium to unite with the sulphion, $SO_4$; thus, $NaCl + NaHSO_4 = HCl + Na_2SO_4$. The hydrochloric acid gas from both vessels passes through the same flue and condensing towers. The neutral sulphate or "salt cake" is then removed from the second chamber, reduced to powder, and mixed with powdered chalk and coal, in the proportion of two parts each of sulphate and chalk and one part of coal. This mixture is then thrown in quantities of from 2 to 3 cwt. into a reverberatory furnace, and melted while being stirred. The mass is then raked out into a mould from which it is turned when cold, forming ball soda, or black ash, which contains from 20 to 27 per cent. of pure soda or neutral carbonate, minus its water of crystallization, and mixed with calcium sulphate, quicklime, and unburned coal. The reaction is represented as follows: $Na_2SO_4 + CaCO_3 + 4C = Na_2CO_3 + CaS + 4CO$, the chemical changes consisting firstly in the deoxidation of the salt cake, and its conversion into disodic sulphide with evolution of carbonic oxide, and secondly in the formation of sodic carbonate and calcic sulphide by interchange of the constituents of the disodic sulphide and calcic carbonate. The sodium salts are extracted in a series of vats, by warm water which passes from one to the other. Calcium sulphide, which is formed in large quantities, was formerly a waste product, but is now partly utilized in the preparation of hyposulphite of soda, which has been employed to a considerable extent as an "antichlor" for removing the last traces of chlorine from bleached paper pulp. The black solution obtained by the lixiviation of the black ash is allowed to settle, when it is pumped into iron pans and evaporated by the waste heat from the furnaces. Much of the salt crystallizes during ebullition and is removed by perforated ladles. The mother liquor retains a portion of caustic soda, which may be converted into carbonate by mixing it with sawdust and roasting in a reverberatory furnace. At present, however, this conversion into carbonate is not much practised, but the caustic soda is extracted according to the plan of Mr. Gossage, already described. The crude carbonate is crystallized by redissolving it in hot water, allowing this to become clear by standing, and then running it into deep pans, having a capacity to yield about one ton of crystallized carbonate. The solution cools in five or six days, and large crystals are formed. The mother liquor yields an inferior ash.—Sodic carbonate, or commercial neutral carbonate of soda, has a nauseous alkaline taste, and crystallizes in large transparent rhomboidal prisms, containing 10 molecules of water, which melt in their water of crystallization, are soluble in any proportion of hot water, and are also very soluble in cold water. The salt easily parts with its water, and melts at a red heat. If it is crystallized at a temperature of $-4°$ F., 15 molecules of water of crystallization are taken up. Mitscherlich obtained sodic carbonate with six molecules of water of crystallization. Above 93·2° the salt crystallizes in forms derived from the square-based octahedron, containing five molecules of water; but between 158° and 176° it crystallizes in four-sided prisms containing only one molecule of water. The maximum solubility of soda in water is at 100·4°.—The principal uses of commercial carbonate of soda are in the preparation of the bicarbonate and of caustic soda; in the manufacture of hard

soap, for which purpose it is better adapted than potash on account of not being deliquescent like the latter alkali (see SOAP); and also very largely in the preparation of paper pulp from various materials. The paper maker uses it in connection with quicklime, which reduces it to caustic soda. (See PAPER.) It is also used in the laundry, and for domestic and cleansing purposes generally.

**SODA POWDERS.** See EFFERVESCENCE.

**SODA WATER.** See MINERAL WATERS.

**SÖDERMANLAND,** a S. E. læn or province of Sweden, bounded N. by Lake Mælar, E. by the læn of Stockholm, which embraces a portion of the old province of Södermanland, and S. E. by the Baltic; area, 2,603 sq. m.; pop. in 1874, 138,696. It is generally level and fertile, and abounds in inland lakes, including part of Lake Hjelmar. Agriculture is the principal occupation, and the fisheries and lumber trade are of some importance. Capital, Nyköping.

**SODIUM,** the most abundant of the alkali metals, its chloride composing the principal part of the saline matter of the ocean, and also existing in extensive beds in geological strata. Large quantities of nitrate and carbonate of sodium are found in beds, and in some rocks it is combined with silica. The metal was obtained by Sir Humphry Davy soon after his discovery of potassium, and by a similar method. Gay-Lussac and Thénard afterward prepared it by decomposing sodic hydrate with metallic iron at a white heat. It may be prepared readily by the process of Brunner, which consists in distilling a mixture of the carbonate with powdered charcoal. The process has been improved by Deville and others, and employed on a large scale in manufacturing. The carbonate of soda used in the process is prepared by calcining the crystallized neutral carbonate. It is thoroughly dried, pounded, and mixed with a slight excess of charcoal. Ground chalk is also added, to preserve a pasty condition and prevent the carbonate of soda from separating from the charcoal. The following proportions are recommended by Deville for manufacturing operations: dry carbonate of soda, 30 kilogrammes; charcoal, 13; chalk, 3. The materials should be thoroughly mixed, and it is well to calcine the mixture before putting it into the distilling apparatus, by which it is made more compact, so that a greater quantity can be introduced. It is put into cylindrical iron retorts covered with clay, which are heated in a reverberatory furnace. The retorts have movable ends, so that at the close of the operation the charge may be withdrawn and a fresh one introduced without removing the cylinders or putting out the fire. The receivers are of the form used in the preparation of potassium. (See POTASSIUM, vol. xiii., p. 758.) The same precautions are necessary as in the preparation of that metal. The chalk is employed to prevent the charcoal from separating the carbonate of soda when it fuses. The charcoal combines with oxygen when the heat is sufficient to weaken the affinities between the constituents of the salt, and the metallic sodium is left free, when it distils over and is condensed in the receiver, nearly pure if the operation is well conducted. It is perfectly purified by melting it under naphtha, when it may be run into moulds like those used for lead.—Sodium is a brilliant silver-white metal, resembling potassium in its physical and in most of its chemical properties. It is a good conductor of heat and electricity. Its specific gravity is 0·972, its atomic weight 23, and its symbol Na (*natrium*). It is soft at common temperatures, fuses at 207·7° F., and oxidizes rapidly in the air. At the freezing point of water it is very ductile, and at the zero of Fahrenheit it is quite hard. If a small quantity of the metal is melted in a sealed tube filled with coal gas, and cooled till crystallization begins, when the liquid portion is turned off shining octahedral crystals will remain. When dropped into cold water it decomposes it with violence, evolving hydrogen gas, but does not produce enough heat to inflame it unless the metal is held in one spot so that the heat shall not be dissipated. If the water is previously warmed, the gas will take fire, burning with a bright characteristic yellow flame. Sodium is widely diffused in the mineral, animal, and vegetable kingdoms, united with silicic and carbonic acid in many minerals, forms a large share of the saline portions of animal fluids, and enters largely into the composition of marine plants. It unites with oxygen to form two well known oxides: the monoxide, $Na_2O$, the soda of the chemists, and the dioxide, $Na_2O_2$. These two oxides are formed when sodium is burned in common air. When burned in oxygen gas till it no longer increases in weight, it is wholly converted into the dioxide. With water it forms a hydrate, NaHO, which corresponds in composition to the monoxide, a molecule of hydrogen replacing one of sodium. This hydrate is the caustic soda of commerce. (See SODA.)—*Salts.* The salts of sodium are among the most important of all compounds, not excepting those of potassium. The principal one is the chloride, or common salt. (See SALT.) The iodide, NaI, and the bromide, NaBr, are analogous to the corresponding potassium compounds. At temperatures above 86° the bromide crystallizes in anhydrous cubes, but at lower temperatures it unites with two molecules of water and forms hexagonal tables. The iodide, at temperatures above 104°, crystallizes in anhydrous cubes; but at ordinary temperatures large, transparent, striated, oblique rhombic prisms are formed, containing two molecules of water. The small proportion of sodic iodide which is contained in sea water furnishes the commercial supply of iodine, the kelp from which iodine is obtained being the ashes of marine plants which assimilate the iodide from the sea water. (See IODINE.) The sulphides of sodium correspond to those of potassium, and

may be prepared by similar processes. The fluoride, NaF, exists in combination with aluminic fluoride in the mineral cryolite 6(NaF), $Al_2F_6$, found in Greenland and the Ural, which is the chief source of metallic aluminum. (See ALUMINUM, and CRYOLITE.)—Sodic sulphate, the well known Glauber's salt, is described under that title. Sodium unites with sulphurous acid to form a neutral and an acid sulphite. The neutral salt, $Na_2SO_3+10H_2O$, is procured by passing sulphurous anhydride (see SULPHUR), the product of sulphur burned in air, over moistened crystals of sodic carbonate as long as the gas is absorbed, dissolving the mass in water and crystallizing. It is extensively employed for the preparation of the hyposulphite of soda, which is largely used under the name of "antichlor" to remove the last traces of chlorine from bleached paper pulp. (See PAPER, vol. xiii., p. 46.) The acid sulphite, $NaHSO_3$, is of little importance. The hyposulphite, $Na_2S_2O_3+5H_2O$, was formerly made to some extent from impure sodic sulphide, or sulphuret of sodium, by passing sulphurous anhydride through it until it ceased to be absorbed; but it is now largely prepared from neutral sulphite of soda by digesting this salt with sulphuric acid for several days, at a moderate heat. It may also be prepared by digesting a solution of the sulphite with flowers of sulphur. The sulphur is gradually dissolved, forming a clear solution which yields crystals on evaporation; these are oblique prisms belonging to the right prismatic system, freely soluble in water, but insoluble in alcohol. Hyposulphite of soda possesses the property of forming double salts with silver compounds, and in photography it is employed in dissolving away ordinary insoluble compounds of silver, such as chloride and iodide. A mixed solution of sulphite and hyposulphite of soda dissolves malachite and blue copper ore, and Stromeyer has employed it in the hydro-metallurgical extraction of copper. It is also used for preparing antimonial cinnebar and aniline green. Hyposulphite of soda fuses at comparatively low temperatures in its water of crystallization, and advantage is taken of this property in the sealing of glass tubes containing explosive compounds to be used under water in torpedoes. Mr. M. Carey Lea employs it as a new test for ruthenium. If a salt of this metal is made alkaline with ammonia and boiled with the hyposulphite, it first acquires a rose color, and then a magnificent carmine. Employed in medicine, it appears to have deoxidizing powers, in consequence, it has been suggested, of conversion of hyposulphurous into sulphuric acid. It diminishes urea and increases uric acid in the urine, and also increases the sulphates and causes the appearance of sugar and oxalic acid. It has been used, in accordance with the suggestions of Dr. Polli, in zymotic diseases, or those which are supposed to be caused by ferments in the blood, the development of which it has the power of arresting. It has also been used in cases of yeasty vomiting, on account of its destructive effect on the *sarcenia ventriculi* which infests the stomach in that disease, and as a local application in parasitic affections of the skin and mucous membranes. It may be given in doses of from 10 to 20 grains three times a day, dissolved in water. For external use a dram may be dissolved in an ounce of water.—The nitrate, called also cubic nitre, is described in the article NITRATES.—The neutral carbonate, commonly called soda in commerce, is treated under SODA. Bicarbonate of soda, acid sodic carbonate, or monosodic carbonate, may be formed by saturating a strong solution of the neutral carbonate or sal soda with carbonic acid. It is also manufactured on a large scale by passing a current of carbonic acid gas over crushed and moistened crystals of commercial carbonate, exposed two or three inches in depth in a chamber upon cloths stretched horizontally above one another. The carbonate passes into the sesquicarbonate, and then into the bicarbonate, which may be redissolved and crystallized on evaporation in rectangular four-sided prisms, soluble in 10 parts of water at 50°. If the solution is heated, four molecules of bicarbonate lose one of carbonic acid and are converted into the sesquicarbonate ($4NaHCO_3=2Na_2CO_3, H_2CO_3+H_2CO_3$), which by heating to redness, or by continued boiling, is converted into normal carbonate. Bicarbonate of soda is much used in medicine as an antacid and promoter of mucous secretions and perspiration, and as an ingredient in effervescing powders. (See EFFERVESCENCE.) It is also used in bread making, as was formerly the sesquicarbonate. There are several compounds of sodium with boracic acid, but only one is of any practical importance, the acid borate (biborate of soda, or common borax), which is described in the article BORAX.—Sodium forms with the three varieties of phosphoric acid orthophosphates, metaphosphates, and pyrophosphates. Among the orthophosphates are trisodic phosphate, or subphosphate of sodium, $Na_3PO_4+12H_2O$, prepared from rhombic phosphate by adding caustic soda to its solution; and the hydric disodic phosphate, or rhombic phosphate of sodium, $Na_2HPO_4+12H_2O$, commonly called phosphate of soda, and the salt from which most of the phosphates are obtained. The latter is prepared by adding sodic carbonate to acid calcic phosphate, one of the salts formed in obtaining phosphorus. (See PHOSPHORUS, vol. xiii., pp. 464 and 465.) Tricalcic phosphate is precipitated while the disodic phosphate is held in solution. When decanted and evaporated it forms large, transparent, efflorescent, rhombic prisms, soluble in four parts of cold water, but fusing at 90° F. in their water of crystallization. It has an alkaline reaction, and corrodes flint glass, causing white silicious scales to separate from the surface. When evaporated at temperatures above 90°

it combines with seven molecules of water of crystallization, and does not effloresce. On adding free phosphoric acid to a solution of rhombic phosphate, biphosphate of soda, $NaH_2+PO_4+H_2O$, is formed, which crystallizes in right rhombic prisms having a strongly acid reaction. There are several metaphosphates of sodium, and also double salts of the same constitution in which another metal is one of the basyles. There are several pyrophosphates, embracing also both single and double salts, for a description of which the reader is referred to the larger works on chemistry.—The silicates of sodium are glasses of various degrees of fusibility, and also of solubility in water. (See CONCRETE, GLASS, and GLASS, SOLUBLE.) There are several organic salts of sodium, the principal of which are acetates, citrates, oxalates, tartrates, and valerianates; but they do not possess sufficient general interest to require notice here.—*General Characteristics of Sodium Salts.* There are no good direct tests of sodium salts, because they are nearly all soluble, so that the presence of sodium is often inferred when the absence of every other metal is proved, and yet a saline substance remains which yields yellow, striated, prismatic crystals on addition of chloride of platinum and evaporating the solution, a double salt of sodium and platinum being formed. The detection of this double salt is more certain by microscopic examination with polarized light, which tinges the crystals with various characteristic colors. Before the blowpipe the salts of sodium impart an intense yellow to the outer flame. Spectroscopic examination reveals pure yellow light having the same position in the solar spectrum as the double line D. The chief distinguishing characteristics between sodium and potassium salts are, that the latter impart a violet color to flames, and are generally more insoluble, as shown in the slight solubility of sulphate of potassium and the great solubility of Glauber's salt. Many sodium salts moreover effloresce on exposure to the air, while potassium salts generally deliquesce, a fact markedly shown in the carbonates.

**SODOM,** in Biblical history, one of the five cities of the plain or valley of Siddim, destroyed on account of the wickedness of the inhabitants. (See DEAD SEA.)

**SOEST,** a town of Prussia, in the province of Westphalia, 13 m. N. by E. of Arnsberg; pop. in 1871, 12,404. It has a Catholic cathedral, and among the Protestant churches the restored Weisenkirche is remarkable for its pure Gothic architecture. There are many breweries and several manufactories. The principal trade is in grain. The plain surrounding the town contains 10 villages, and is very fertile. Soest was once a Hanseatic town of great importance, but has never recovered from the effects of the thirty years' war.

**SOFALA. I.** A country on the E. coast of Africa, within the territory of Mozambique, of which it forms the southern half. It extends from about lat. 18° to 24° S., and from the seaboard to the Motapa mountains, having an extreme length of about 400 m. and a breadth of nearly 200 m. Along the coast the land is low and swampy, but it rises toward the interior till it terminates in the Motapa range. The country is watered by several considerable rivers, of which the most important are the Sofala, the Sabia, and the Inhamban or Inhambane. The Portuguese established colonial settlements in Sofala early in the 16th century, and the country is still nominally a dependency of Portugal, although European rule is really limited to the few garrisoned stations near the coast. The chief towns are Sofala and Inhamban; the latter port is 8 m. from the mouth of the river of the same name, in lat. 23° 57′ S., lon. 36° 6′ E., and has a good harbor. The exports are mainly amber, beeswax, and ivory. The natives are negroes, and the slave trade is carried on, but to no considerable extent. Sofala was formerly celebrated for its export of gold dust, and some geographers have supposed it to be the Ophir of the ancients. The coast region is very unhealthful. **II.** A town in the above country, formerly the capital of a native kingdom, at the mouth of the river Sofala, in lat. 20° 3′ S., lon. 34° 39′ E. It has a fort and a church, and consists of a few mud and straw huts, though once a place of considerable trade. A bar at the mouth of the river interferes with the approach of large vessels.

**SOGDIANA,** an ancient country of Asia, S. E. of the sea of Aral (*Oxianus Lacus*). It was separated from Bactria on the southwest by the Oxus, and from Scythia on the north by the Jaxartes, thus embracing a part of modern Bokhara. The Persians conquered it in the time of Cyrus. Alexander invaded it in 329 B. C., and established some colonies. After his death it belonged to Syria, and subsequently fell to the Turkomans.

**SOHAR,** a seaport town of Oman, Arabia, capital of the province of Batina, on the sea of Oman, 125 m. N. W. of Muscat; pop. about 20,000. It is surrounded by a wall, defended by a few guns. The castle, a handsome building with three walls around it, occupies a low hill, from which an open space planted with trees extends to the sea. The market place is large and regular, and contains good shops. Many of the houses are of two and three stories and well built. The roadstead is well protected, and offers good anchorage, but large vessels have to lie some distance off shore. Outside the walls is an open sandy space, but beyond it are gardens with shade trees and running waters. The chief manufactures of the town are arms, stuffs of wool, cotton, and silk, carpets, and coverlets. Sohar once had a large trade, but it has been injured by the prosperity of Muscat, and many of its buildings are now in a semi-ruinous condition.

**SOHL.** See ZÓLYOM.

**SOHN, Karl Ferdinand,** a German painter, born in Berlin, Dec. 10, 1805, died in Cologne, Nov. 25, 1867. He studied at the academy of Berlin and under Schadow, whom he accompanied to Düsseldorf and to Italy. He was professor at the academy of Düsseldorf from 1838 to 1855, and became one of the leaders of the Düsseldorf school. He especially excelled in the rich coloring of female figures, and in idealized portraits of ladies. His works include "Rinaldo and Armida" (1827); "Hylas captured by Nymphs" (1829); "Diana in her Bath" (1833); "The Two Leonoras," after Goethe's Tasso (1834); "Romeo and Juliet" (1836); "The Sisters" (1843); "Vanitas" (1844); "The Lute Player" (1848); "The Four Seasons" (1851); and "Loreley" (1853).—His son PAUL EDUARD RICHARD (born in 1834) excels in genre and portrait painting. His nephew and son-in-law WILHELM (born in 1830) has executed good genre pictures, including "A Delicate Question" (1864), and "The Consultation with a Lawyer" (1866).

**SOIL.** See AGRICULTURAL CHEMISTRY.

**SOISSONS** (anc. *Noviodunum*, and afterward *Augusta Suessionum*), a fortified town of France, in the department of Aisne, on the left bank of the river Aisne, 56 m. N. E. of Paris; pop. in 1872, 10,404. It has a cathedral built in the 12th and 13th centuries, the ruined abbey of St. Jean des Vignes, a castle, and a college. In the environs is the abbey of St. Médard, founded by Clotaire I. in 557, now occupied as an institute for deaf mutes. There are manufactures of fine tapestry, linen, hosiery, cordage, earthenware, and leather.—Soissons was the chief place of the Suessiones in the time of Cæsar, and at the beginning of the 6th century the capital of Clovis, who had there defeated the Roman general Syagrius (486), and it gave name to the kingdom of his fourth son. It has sustained many sieges. On Oct. 16, 1870, it surrendered to the Germans, after three weeks' investment and four days' bombardment. The council which condemned Abélard's doctrines met here in 1122.

**SOKOTO.** See SACKATOO.

**SOLANDER, Daniel Charles,** a Swedish naturalist, born in Norrland, Feb. 28, 1736, died in London, May 16, 1782. He was educated at Upsal under Linnæus, studied medicine, made a tour in Russia, and went to England in 1760, after spending some time in the Canaries. He was employed in preparing a catalogue of the collections in the British museum, and in 1766 published a catalogue of the Brander collection of fossils. In 1768–'71 he accompanied Sir Joseph Banks on Capt. Cook's first voyage round the world. In 1771 he received the degree of D. C. L. from Oxford university. In 1773 he was appointed under librarian to the British museum. He greatly promoted the study of botany in England.

**SOLAN GOOSE.** See GANNET.

**SOLANO,** a N. W. county of California, bounded S. E. by the Sacramento river and S. by Suisun bay: area, 800 sq. m.; pop. in 1870, 16,871, of whom 920 were Chinese. The surface consists mostly of valleys, marsh lands, undulating prairies, and high rounded hills. It is one of the best agricultural counties in the state. There is very little timber. Marble is found, and limestone from which a superior hydraulic cement is obtained. It is traversed by the California Pacific railroad. The chief productions in 1870 were 1,949,418 bushels of wheat, 443,400 of barley, 54,780 gallons of wine, 306,817 lbs. of wool, 119,969 of butter, and 37,469 tons of hay. There were 6,852 horses, 1,046 mules and asses, 4,123 milch cows, 8,815 other cattle, 41,890 sheep, and 17,133 swine; 1 manufactory of cars, 1 of cement, 1 of machinery, 7 of saddlery and harness, 8 of wine, 1 flour mill, 3 tanneries, and 3 breweries. Capital, Fairfield.

**SOLANUM,** the name (of unknown derivation) of a genus of plants which is the type of a large and important order, the *solanaceæ*. Some of the conspicuous species of *solanum* being popularly known as nightshade, the order or family is often called the nightshade family. The solanums are annual or perennial herbs, and in warm climates they include shrubs, and even trees, with alternate leaves; the flowers, sometimes terminal or axillary, are often extra-axillary, appearing upon the stem at some point between the leaves, an unusual position due to a more or less complete union between the flower stalk and the main stem. The calyx and wheel-shaped corolla are mostly five-parted or five-lobed, the five stamens with very short filaments, the large anthers crowded around the style, and opening by a pore at the apex of each cell; the (mostly) two-celled ovary is surmounted by a simple style with an obtuse stigma, and in fruit becomes a two-celled berry containing numerous flattened, somewhat kidney-shaped seeds with a fleshy albumen. The genus *solanum* is extensive; in its latest revision (Dunal, 1852) some 850 well defined species are admitted, and about 100 not sufficiently known are enumerated; they are found in all temperate countries, but in tropical regions, especially those of South America, they are very abundant. The most important species is *solanum tuberosum* (see POTATO), the tubers of which are so generally used as food. The tomato (described under its proper title) was placed here by Linnæus, and though later botanists have given it a separate genus, *lycopersicum*, it can hardly be kept distinct from *solanum*. Under EGG PLANT is described another cultivated species, and under NIGHTSHADE is given a common weed, *S. nigrum*. Several species are cultivated for ornament in gardens and greenhouses, and a few wild species, not elsewhere mentioned, are of importance as weeds.—The beaked solanum (*S. rostratum*), very abundant on the plains west of the Mississippi, is a much-branched annual, 2 to 3 ft. high and abundantly armed with strong yellow spines;

it has yellow flowers, one of the anthers of which is much larger than the others, and, being prolonged into a long curved beak, has given the species its name; the small berry is included in the very spiny calyx. This has been introduced into gardens, and in some places has become a weed; the plant is interesting from the fact that it afforded the Colorado potato beetle its chief food before the introduction of the potato in the far west. (See POTATO BUG.)—One of the worst weeds of cultivation is *S. Carolinense*, known in some localities as horse nettle, and in others as apple of Sodom; it has a perennial root, with prickly stems a foot or more high; the oblong, sinuate leaves prickly on both sides; the bluish white flowers, in small lateral racemes, are succeeded by orange-yellow berries about a third of an inch in diameter. This is especially abundant and troublesome in the southern states, and is sparingly found as far north as Connecticut. It is very hard to extirpate, and in some parts of Delaware it has gained such complete possession of the soil as to lessen materially the value of farms, and in some cases to cause fields to be abandoned.—A climbing species, *S. dulcamara*, is popularly known as bitter-sweet; the rind of the stalks is said to taste at first bitter and afterward sweet, a peculiarity recognized in the Latin name, *dulcis-amara*, given to the plant in the 16th century. It is a native of Europe, is thoroughly naturalized in all the older states, and is not rare in cultivation. The stem is somewhat climbing, and grows to the height of 6 to 10 ft.; it is woody at the base, but the upper part is killed back every winter; the leaves are usually ovate-heart-shaped, but frequently the upper ones have a lobe on each side at the base

Bitter-sweet (Solanum dulcamara).

and become halberd-shaped; the flowers are in small cymes; the corolla is pale blue or purple, against which the large yellow anthers appear in strong contrast, and make them rather showy; they are succeeded by an oval berry about half an inch long, and bright red; the plant begins to bloom in June and continues till autumn, and flowers and fruit in every intermediate stage up to full ripeness may usually be found upon it. Though bitter-sweet has been in use as a medicine for some centuries, there is very little positive knowledge concerning it; it appears to contain a very small amount of solanine in a modified form; it has been used in gout and rheumatism, in various affections of the chest, and in skin diseases. The berries are very showy, and, being not unpleasant to the taste, are liable to be eaten by children; in regard to their effects there is the most opposite testimony; some authors assert that they are highly poisonous, while Garrod says that he has administered to a patient half a pound of the fresh berries daily with no ill effect.—Several species of *solanum* are ornamental plants in the greenhouse and garden; some of these, valued for their ornamental fruit, are described under JERUSALEM CHERRY. The jasmine-like solanum (*S. jasminoides*) is a tall, climbing house plant from Brazil, with dark green, smooth, ovate or heart-shaped leaves, and large clusters of white or slightly bluish and pleasantly fragrant flowers, produced in profusion; it is an admirable greenhouse climber, and is often planted out in summer; in the southern states the root remains alive through the winter. Some of the erect tropical species have a very robust habit of growth and ample foliage; in some the large leaves are handsomely cut; in others they are marked by pleasing contrasts of color, and the flowers are often showy. Among the best are *S. crinitum*, *S. macranthum*, *S. marginatum*, and *S. Warscewiczii*, which grow from 3 to 8 ft. high and are highly ornamental.

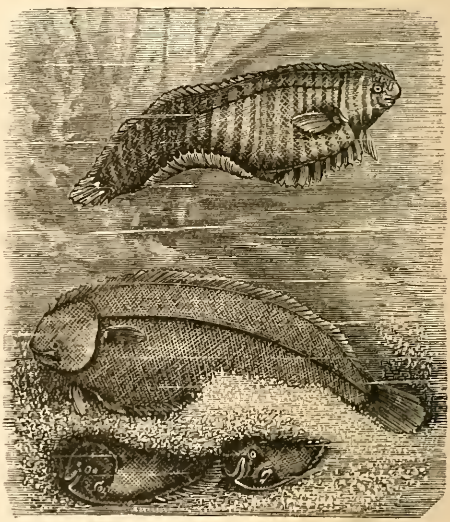
Ornamental-leaved Solanum (S. Warscewiczii).

**SOLAR SYSTEM.** See PLANET, and SUN.

**SOLAR TIME.** See DAY.

**SOLDER** (Lat. *solidus*, solid), a metal or alloy used for joining together different pieces of metal, whether of the same or of different kinds. Solders are divided into hard and soft. The soft solders may be used for joining all kinds of metals, but usually those having low melting points. The hard solders are better adapted for the less fusible metals, especially where strength is required. Practically the solder must be more fusible than either of the metals to be united, but the more nearly these points coincide the stronger will be the union. Gold in the form of leaf or fine shreds is used for soldering platinum vessels; it may be slightly alloyed with copper. Silver is considered the best solder for German silver. Copper in shreds is often used for iron when welding is not permissible, sometimes slightly alloyed with zinc. Soft solders have tin for a basis, generally alloyed with lead. Those containing much lead are sometimes ranked with hard solders. Pewter may be used for a solder, and by the addition of bismuth, antimony, or cadmium its fusing point may be lowered so that it can be used as a solder for pewter. The following are some of the more important solders. For gold: gold (18 carats) 66·6, silver 16·7, copper 16·7. A good gold solder for general purposes is 100 parts of gold, 40 of silver, and 30 of copper (Makins). For silver: silver 66·6, copper 30, brass 3·4; or silver 65, copper 24, zinc 11. It is better to add the metals separately than to use brass, which may have an uncertain composition. Pewterer's solder: coarse—tin 3, lead 4, bismuth 2; fine—tin 2, lead 1, bismuth 1. Plumber's solder: tin 1, lead 3; a finer kind has the same composition as fine pewterer's solder. Hard spelter solder, used for soldering copper, is made of copper 16, zinc 12. Soft spelter solder, for brass, is made of equal parts of copper and zinc. Fluxes are used to preserve the cleanness of the surfaces of the metals and free them from oxide while the operation of soldering is going on. The solder is applied in various ways. The surfaces, sometimes previously cleaned with a file or with muriatic acid or an acid solution of chloride of zinc, are brought together, and the solder in strips or grains laid on. Then a flux composed of borax or sal ammoniac, sometimes mixed with a little common rosin, is applied, and the parts are heated with a blowpipe or a stream of intensely heated air. But it is more common to use a soldering iron, an instrument consisting of a heavy square, pyramidal, or conical piece of copper, riveted in a fork of wrought iron, to which a wooden handle is attached. This "iron," being heated above the fusing point of the solder, is applied to it, and a few adhering drops of the melted alloy are carried to the parts to be joined, which are then held in position until the solder hardens. Aluminum cannot be soldered in the ordinary way, but must first be tinned. A good general solder for aluminum is composed of zinc 90, aluminum 6, copper 4.

**SOLE** (*solea*, Cuv.), a genus of soft-rayed flat fishes of the family *pleuronectidæ*. (See Flounder.) The genus has the jaws concealed under the scaly skin, the upper rounded and longest; the eyes are both on the right side, small, the lower behind the upper and almost at the angle of the mouth; the mouth is curved, and turned almost wholly to the left side, and the fine and villiform teeth are nearly all on this side; the snout is in advance of the mouth; the lateral line straight; branchial openings below the small pectorals; dorsal and anal very long, often confluent with the caudal; no air bladder, and no pancreatic cæca, and the intestine long and often doubled; the blind side is sometimes furnished with shred-like villi. The common sole (*S. vulgaris*, Cuv.) has the body more elongated than in most flat fishes, with a blunt and rounded muzzle; the length is from 10 to 20 in., and the color uniform dark brown above and white below, the pectorals tipped with black. It inhabits the sandy shores of Great Britain, keeping near the bottom, feeding on the spawn and fry of other fishes and on shell fish; it is found from the seas of Scandinavia to the Mediterranean. It is one of the best and most delicate fishes for the table, and is caught in immense numbers by trawl nets; the flesh is white and firm, and is in good condition all the year except in February and March, when they are spawning. Some are found reversed, or with the eyes and colored surface on the left side, and a few are dark and rough on both sides. In the genus *achirus* (Lac.) there are no pectorals; species



Common Sole (Solea vulgaris).

are found in the Indian seas, with the upper parts marbled with brown and lighter. The New York sole (*A. mollis*, Mitch.) is 6 to 8 in. long, dark brown, marked transversely with

irregular black bands, and has small scales; it is found from Nantucket to North Carolina.

**SOLEURE.** See SOLOTHURN.

**SOLFERINO,** a village of Lombardy, in the province and 20 m. S. E. of Brescia. It has a ruined castle, formerly the residence of a prince of Solferino; but it is chiefly remarkable for the great victory won here by the allied French and Sardinian forces over the Austrians on June 24, 1859. The battle lasted 16 hours, and four French corps under Marshals Baraguay d'Hilliers, MacMahon, Canrobert, and Niel, and led by the emperor Napoleon III., and four divisions of the Sardinian army, commanded by Victor Emanuel in person, were opposed to an immense Austrian force, under the command of the emperor Francis Joseph. The allies lost about 18,000 killed and wounded; the Austrians, 20,000, besides 6,000 prisoners and 30 cannon. The battle closed the war, and the peace of Villafranca followed. On June 24, 1870, the bones of the slain on this field were collected in three ossuaries, which were consecrated in the presence of representatives of France, Italy, and Austria.

**SOLGER, Karl Wilhelm Ferdinand,** a German author, born in Schwedt, Prussia, Nov. 28, 1780, died in Berlin, Oct. 20, 1819. After extensive studies and a varied career, he finally became in 1811 professor of philosophy at Berlin. His works include a translation of Sophocles (1808; 2d ed., 1824); *Erwin: vier Gespräche über das Schöne und die Kunst* (2 vols., 1815); *Philosophische Gespräche* (1817); posthumous writings and letters, edited by Tieck and Raumer (2 vols., 1826); and lectures on æsthetics, edited by Heyse (1829).

**SOLIMAN.** See SOLYMAN.

**SOLINGEN,** a town of Rhenish Prussia, near the Wupper, 12 m. S. E. of Düsseldorf; pop. in 1871, 14,040. It contains a Catholic and two Protestant churches, a synagogue, a superior school, and a chamber of commerce. It has for centuries been celebrated for its manufacture of sword blades and other cutlery, and iron and steel ware. There are in and around Solingen more than 2,700 establishments, employing about 10,000 persons.

**SOLIS, Antonio de,** a Spanish historian, born in Alcalá de Henares, July 18, 1610, died in Madrid, April 19, 1686. After becoming celebrated as a dramatist and poet, he was appointed official historiographer, and entered holy orders in 1667. His principal historical work is *Historia de la conquista de México* (fol., Madrid, 1684; new ed., Paris, 1858; English translation by Townsend, 2 vols, London, 1724, reprinted in 1738 and 1753). His most celebrated play, *La Gitanilla*, or "The Pretty Gypsy Girl," is founded on Montalvan's piece borrowed from the story of Cervantes. A collection of his plays appeared at Madrid in 1732.

**SOLIS, Juan Diaz de,** a Spanish navigator, born in the latter half of the 15th century, killed in South America in 1516. In conjunction with Yañez Pinzon, he discovered Yucatan in 1506. In 1508 they unitedly explored the coast of South America from Cape St. Augustine to lat. 40° S., and took possession of the continent for Spain. Having quarrelled, they returned to Spain in 1509; a lawsuit followed, and Solis was beaten and imprisoned, and Pinzon received important grants in the island of San Juan. Afterward Solis was released, was paid 34,000 maravedis indemnity, and on the death of Amerigo Vespucci became pilot major. In 1515, with three ships, he explored the coast from Cape San Roque to Rio de Janeiro, entered the estuary of La Plata, which he called the Mar Dulce, and ascended the river. He was kindly received by the Indians, but afterward ambuscaded, killed, and eaten. According to some authorities, he discovered the Plata in 1512, and made a second voyage to it.

**SOLLY, Samuel,** an English surgeon, born in 1805, died in London, Sept. 24, 1871. He became a member of the London college of surgeons in 1828, lecturer on practical anatomy and assistant surgeon to St. Thomas's hospital in 1833, and subsequently attending surgeon. He was also for many years lecturer on surgery. His principal work is "Anatomy and Pathology of the Brain" (2d ed., 1847), which was for a long time a valuable and standard book. He also published "Surgical Experiences" (1865). He was fellow, member of the council, and for two years vice president of the college of surgeons.

**SOLMIZATION,** in singing, the application to the seven notes of the musical scale of the syllables *ut* (or *do*), *re*, *mi*, *fa*, *sol*, *la*, *si*, to enable the singer to acquire full command of the vowel sounds. (See MUSIC, vol. xii., p. 76.)

**SOLOMON.** See HEBREWS, vol. viii., p. 586.

**SOLOMON, Song of.** See CANTICLES.

**SOLOMON, Wisdom of.** See WISDOM, BOOK OF.

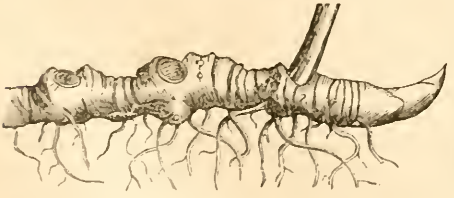
**SOLOMON BEN GABIROL** (properly perhaps Solomon ben Judah ben Gabirol, and popularly Gabirol), a Jewish philosopher and poet, born in Malaga, Spain, about 1020, died in Valencia or Ocaña about 1075. Almost all that is known of his life is that he lived for a time in Saragossa, and was intimate with Samuel Hallevi. As a Hebrew poet he immortalized himself by his *Kether malkhuth* ("Crown of Royalty"), a didactic hymn on the cosmos, which has been incorporated in the Jewish liturgy. His philosophical works he wrote in Arabic, and only incomplete Hebrew translations of them are extant. His "Source of Life," in which he appears as a bold Aristotelian, is cited by Albertus Magnus and other mediæval Christian philosophers, the name of the author appearing in the corrupt forms of Avicebron, Avencebrol, &c., derived from the Arabic Aben Gebrol. The identity of the names has but recently been established.—See Munk, *Mélanges de philosophie juive* (Paris, 1857).

**SOLOMON BEN ISAAC,** rabbi, erroneously surnamed YARHI or JARCHI, and generally known

under the abbreviation Rashi (the initials of the Hebrew *Rabbi Shelomoh Yitz'haki*), a Jewish commentator of the Bible and Talmud, born in Troyes, France, about 1040, died there, July 13, 1105. His comments on the Talmud have never been excelled, and they accompany all editions of the text. Those on the Bible have been translated into Latin by Breithaupt (3 vols., Gotha, 1710–'14). A German translation of the commentary on Genesis was made by Hayman (Bonn, 1833), and one of the whole Pentateuch by Lucas (Prague, 1833–'8).

**SOLOMON ISLANDS**, a group of the S. Pacific lying S. E. of New Britain and E. of New Guinea, extending in a S. E. direction from lat. 4° 50′ to 11° 50′ S., and from lon. 154° 30′ to 162° 30′ E. The group is composed of the islands Bougainville, Choiseul, Malayta, Santa Isabella, New Georgia, Guadalcanar, San Cristoval, and several smaller ones, the area of the whole being estimated at 10,000 sq. m. Mountains, often of considerable height, traverse them. The shores are generally low, and in some places bordered with mangrove swamps. They are watered by numerous streams, and the temperature is cooled by copious rains. They are very fertile; bananas, yams, sugar cane, and ginger are cultivated; and the breadfruit, cacao, and clove trees abound. They are inhabited by negrillos and Malays. The population is very irregularly distributed, the northern islands being more populous than the others.—The islands were discovered and explored in 1568 by the Spanish navigator Mendaña, sent out by his uncle Lope de Castro, viceroy of Peru. He named them Solomon islands on the pretence that the riches of Solomon's temple were brought from them. He died in Santa Cruz group in 1595, while on his way to colonize them, and they were not again visited till rediscovered by Carteret in 1767. Some partially successful missionary efforts have recently been made there.

**SOLOMON'S SEAL**, the common name for species of *polygonatum* (Gr. πολύς, many, and γόνυ, knee, the stems having numerous joints), a genus of the lily family, closely related to asparagus, and having thick, knotted, horizontal rootstocks, which show upon their upper



Solomon's Seal. Rhizome, showing stem, bud, and scars of former stems.

surface deep scars left by the falling away of the stems of previous years, a character which gave rise to the popular name. Each rootstock bears a single leafy stem; in front of it is a bud to continue the growth another year, and behind it are the scars of former stems; the stems, 1 to 4 ft. high, are gracefully curved, and clothed with nearly sessile or half clasping, strongly nerved leaves, from the axils of which appear the drooping greenish flowers; the perianth is cylindrical, six-lobed at the summit, with six stamens inserted near the middle of the tube; the three-celled ovary ripens to a globular black or blue berry with two to six seeds. The great Solomon's seal (*P. giganteum*) and the smaller (*P. biflorum*) are common species, while the remaining one, the broad-leaved (*P. latifolium*), is very local. Several species are found in Europe, which were formerly used medicinally, and ours have a reputed value as diuretics. The young shoots are cooked and eaten in Turkey like asparagus, and the roots, which contain a considerable quantity of starch, have been used in Europe as food in times of scarcity. They are interesting but not showy garden plants. Species of the related genus *smilacina* are called false Solomon's seal; they have their flowers in terminal racemes, and mostly red berries.

**SOLON**, the Athenian lawgiver, born about 638 B. C., died in Athens about 559. He was a lineal descendant of Codrus. In his youth he visited many parts of Greece and Asia as a merchant, gained distinction by his poems, and from his reputation for political wisdom was reckoned one of the seven sages. Returning to Athens, he began his political career by recovering Salamis from the Megarians. The Athenians had repeatedly failed in their attempts upon this island, and had prohibited any citizen on pain of death from proposing a renewal of the enterprise. Solon counterfeited madness, and in apparent frenzy read in the agora a short poem, the effect of which was that the law was rescinded, war was declared, and he himself was appointed to the command of it. In a single campaign (about 600) the Megarians were expelled from the island, but a tedious conflict ensued, which was finally settled in favor of Athens by the arbitration of Sparta. Soon after, in the Amphictyonic council, he moved the decree by which the Athenians espoused the cause of the Delphian oracle against Cirrha. In 594 he was called by all parties to the archonship, with powers substantially dictatorial, and chiefly with authority to confirm, repeal, or modify the Draconian laws. The constitution of Solon (see Athens, vol. ii., p. 55), which made property instead of birth the title of citizenship, and which was the prelude to the subsequent democracy, was by a solemn oath of the government and people declared valid without alteration for ten years. He obtained leave of absence for that period, visited Egypt, and went thence to Cyprus, where he persuaded the prince of Æpea to change the site of the town, and himself made the regulations for the prosperity of the new establishment, which in his honor was called Soli. He returned to

Athens prior to the first usurpation of Pisistratus (560), and amid violent dissensions was respected by all parties, but was unable to overrule the popular favor of his kinsman.—The chief sources for the biography of Solon are the compilations of Plutarch and Diogenes Laërtius. The extant fragments of his verses are usually contained in the collections of the Greek gnomic poets, and there is a separate edition of them by Bach (Leyden, 1825).

**SOLOTHURN** (Fr. *Soleure*), a N. W. canton of Switzerland, bordering on Basel Country, Aargau, and Bern; area, 303 sq. m.; pop. in 1870, 74,713, of whom 62,078 were Roman Catholics. The Jura mountains occupy a part of the canton, and the remainder of the surface is level and fertile. It is traversed by the river Aar, a tributary of the Rhine. Gold, silver, iron, and lignite are found. The soil is remarkably fertile. A great deal of the surface is occupied by meadows and pastures, upon which large numbers of cattle are kept. The forests are extensive, and afford valuable timber. German is the language of the canton. The government was formerly aristocratic, but democratic principles have been largely introduced into it, especially by the revision of the constitution in 1841.—SOLOTHURN, the capital, is at the foot of the Weissenstein, on the Aar, 17 m. N. by E. of Bern; pop. in 1870, 7,054. It has one of the finest cathedrals of Switzerland, an arsenal with a large collection of ancient armor, and a museum containing a rich collection of Jura fossils. Till 1874 it was the seat of the bishop of Basel.

**SOLSTICE** (Lat. *sol*, the sun, and *stare*, to stand), the period in the annual revolution of the earth round the sun when he is at that point in the ecliptic furthest north or south from the equator, or in other words reaches his greatest northern or southern declination. There are two solstices in the year: the summer solstice, June 22, when the sun seems to traverse the tropic of Cancer; and the winter solstice, Dec. 22, when he reaches his greatest southern declination, and appears to traverse the tropic of Capricorn. For several days before and after the solstice there is but a slight variation in the sun's apparent declination, and so far as his motion from and toward the ecliptic is concerned he may be said to stand still. The solstitial points are the two points of the sun's greatest elevation above or depression below the equator; and a circle through these points and the poles of the earth is called the solstitial colure.

**SOLUBLE GLASS.** See GLASS, SOLUBLE.

**SOLWAY FRITH,** an arm of the Irish sea, which extends 40 m. N. E. between England and Scotland, with a breadth varying from 24 m., between St. Bees Head in Cumberland and Rayberry Head in Kirkcudbrightshire, to 2 m. It receives on the English side the rivers Derwent, Ellen, Waver, Wampool, and Eden; and on the Scottish side, the Urr, Nith, and Annan. Whitehaven, Maryport, and Allonby are on the English side, and Annan and Kirkcudbright on the Scottish. At ebb tide the broad sands which occupy a considerable portion of the frith are left dry.

**SOLYMAN II.,** or **Soleiman,** called the MAGNIFICENT, an Ottoman sultan, born about 1495, died before Sziget in Hungary, Sept. 5, 1566. He was the son of Selim I., whom he succeeded in 1520. In 1521 he subdued the rebellion of Ghazali Bey in Syria, and in Hungary took Belgrade and other fortified towns. After an arduous siege he took Rhodes from the knights of St. John in 1522. He invaded Hungary a second time in 1526, won the decisive battle of Mohács (Aug. 29), in which Louis II. of Hungary lost his life, overran a part of the kingdom, and recognized as king John Zápolya, who put himself under Solyman's protection. This embroiled the sultan with Ferdinand I. of Hapsburg, who was elected king by the majority of the Hungarians, and began the first of the Turkish wars against Germany. In 1529 Solyman took Buda, and appeared before Vienna with a vast army; but after a number of assaults he retired with a loss of 80,000 men. A second attempt in 1532 was baffled by the resistance of Güns under Jurisics. In 1534 he invaded Persia, and subdued Armenia and Irak, with the cities of Tabriz and Bagdad; in 1536 formed an alliance with Francis I. of France against Charles V., the brother of Ferdinand; in the same year created the Barbary corsair Khair ed-Din or Barbarossa a Turkish admiral, and thus swept the Mediterranean and Italian coasts; conquered Croatia in 1537 by a great victory over the imperialists at Eszék; and in 1538 made the conquest of Yemen. An attempt in 1537 on Corfu failed. Upon the death of John Zápolya in 1540, he supported his son John Sigismund, and continued the war with Ferdinand till 1547, when a truce humiliating to that prince was agreed upon. He now again invaded Persia, in 1548 gained a victory at Van in Armenia, and in 1549–'50 conquered the provinces of Shirvan and Georgia. Hostilities in Hungary were renewed in 1552. John Sigismund was established in Transylvania under Turkish protection, and Solyman's fleets under Piali, the successor of Khair ed-Din, gained a victory over the combined fleets of the emperor at Jerba on the African coast. A truce made in 1562 left the Turks in possession of their Hungarian conquests. In an attempt upon Malta in 1565, the whole naval force of Solyman was repulsed. In 1566 he again led a vast army to the invasion of Hungary, crossed the Drave, and laid siege to the fortress of Sziget, which was defended by a small garrison under Zrinyi; but a paroxysm of anger at the terrible repulses he encountered induced an attack of apoplexy, in which he died a few days before the last and fatal assault was made. Under this sultan the Ottoman empire attained its greatest military power, and it began immediately to decline under his succes-

sor, Selim II. By the Turks he was surnamed the Legislator (*Kanuni*), and the *Kanun Nameh*, or code of laws and regulations, drawn up under his direction, formed the basis for a long period of the Turkish administration of government and justice. He was also a patron of literature and art; in his reign the use of the Turkish language in literature superseded that of the Persian.

**SOMAULI,** or **Somal,** the general name of the tribes inhabiting that portion of Africa S. of the gulf of Aden, and extending from Cape Guardafui and the straits of Bab-el-Mandeb to the Doho river. The eastern tribes are called Burri, the western Gulbedh. The principal eastern tribes are the Midjertheyn, the Wursumgalli, and Dulbhanta; the principal western, the Habr Awal, the Habr Tul Jaala, and the Habr Gerhajis. The eastern tribes are generally peaceable and orderly, the western savage and warlike. They are all Mohammedans, and are very superstitious, believing in charms and witchcraft. They live generally in houses made of mats. Slavery exists among them. In war they use shields, spears, bows, and poisoned arrows. Their principal articles of trade are various kinds of gums, tragacanth, myrrh, and especially frankincense. They are generally governed by chiefs, who however have little power. The characters and modes of life of the various tribes differ greatly. Their language is a mixture of Arabic and Galla words, and the race is supposed to be of the same mixed origin.

**SOMERS, John,** lord, an English statesman, born in Worcester, March 4, 1651, died April 26, 1716. He was educated at Trinity college, Oxford, and in 1676 was called to the bar at the Middle Temple, but remained some years longer at the university, publishing several political pamphlets, and a variety of metrical and prose versions from classical authors. He began to practise law in London in 1682, acquired great professional eminence, and became a leader of the whig party. He represented Worcester in the convention which met in January, 1689, and was a member of the two committees (acting as chairman of the second) which prepared the "Declaration of Right." In 1689 he was appointed solicitor general and knighted, in 1692 attorney general, in 1693 lord keeper of the great seal, and in 1697 lord chancellor, when he was raised to the peerage as Baron Somers of Evesham. After ineffectual attempts to fasten upon him a charge of maladministration, and also of complicity in the piracies of Capt. Kidd, whom he had helped fit out a ship to capture pirates, an unsuccessful motion was made in the house of commons, April 10, 1700, that the king should be requested to dismiss him. But his absence by illness from the debates upon a measure distasteful to William, assumed to be by design, induced the king on the 17th of the same month to remove him. In the next year an attempt was made to impeach Somers on 14 distinct charges, the most important of which referred to an illegal issue at the king's request of blank commissions under the great seal for the purpose of negotiating certain treaties, to his alleged complicity with Kidd, and to his acquisition of various unreasonable grants from the crown in addition to the salary and fees of his office; but the commons declined to prosecute the impeachment, and he recovered the favor of the king, whose last speech to parliament was written by him. On the accession of the whigs to power in 1708, Somers was appointed president of the council, and held the office until the return of Harley and the tories in 1710. Subsequently he participated in legislative duties until his death, which happened from apoplexy. A number of original letters and papers, illustrating his life and character, perished by fire in 1752. The so-called "Somers Tracts" (16 vols. 4to, 1748–'52; new ed. by Sir Walter Scott, 13 vols. 4to, 1809–'15) consist of pamphlets selected chiefly from his library. R. Cooksey wrote "Life and Character of Lord Somers" (4to, 1791).

**SOMERS ISLANDS.** See Bermudas.

**SOMERSET,** the name of four counties in the United States. **I.** A W. county of Maine, bordering on Canada, intersected by the Kennebec river, and drained by the head streams of the Penobscot and Walloostook rivers; area, 3,800 sq. m.; pop. in 1870, 34,611. The surface is diversified, and the soil generally good. There are several small lakes, and the N. part is covered with forests, affording vast quantities of timber for export. The Maine Central and the Somerset railroads enter it. The chief productions in 1870 were 31,202 bushels of wheat, 106,657 of Indian corn, 296,185 of oats, 92,767 of barley, 20,536 of buckwheat, 31,408 of peas and beans, 988,179 of potatoes, 113,481 tons of hay, 366,442 lbs. of wool, 796,238 of butter, and 169,349 of cheese. There were 7,222 horses, 11,132 milch cows, 5,886 working oxen, 14,954 other cattle, 78,400 sheep, and 3,590 swine; 23 manufactories of carriages and wagons, 2 of edge tools and axes, 5 of furniture, 8 of tanned and 5 of curried leather, 1 of paints, 1 of paper, 6 of sash, doors, and blinds, 6 of turned and carved wood, 3 of woollen goods, 9 wool-carding and cloth-dressing establishments, 5 flour mills, and 39 saw mills. Capital, Skowhegan. **II.** A N. central county of New Jersey, bounded N. E. by the Passaic and W. by the Lamington river, intersected by the Raritan, and traversed by the Delaware and Raritan canal and several railroads; area, 275 sq. m.; pop. in 1870, 25,510. The surface in some parts is very hilly, and the soil generally fertile, especially along the streams. The chief productions in 1870 were 218,766 bushels of wheat, 561,136 of Indian corn, 700,515 of oats, 86,684 of potatoes, 42,034 tons of hay, 22,457 lbs. of wool, 3,800 of flax, and 587,093 of butter. There were 6,263 horses, 9,992 milch cows, 4,922 other cattle, 7,302 sheep, and 7,883 swine;

2 manufactories of agricultural implements, 8 of cheese, 1 of pig iron, 3 of castings, 10 tanneries, 6 distilleries, 18 flour mills, and 7 saw mills. Capital, Somerville. **III.** A S. W. county of Pennsylvania, bordering on Maryland, bounded W. by the Youghiogheny river and Laurel ridge, and intersected in the south by Castleman's river; area, 1,000 sq. m.; pop. in 1870, 28,226. The surface is generally mountainous, and the soil fertile. The glades are admirably adapted to grazing. The county abounds in bituminous coal, and iron ore, fire clay, and cannel coal of excellent quality are found. It is traversed by the Pittsburgh, Washington, and Baltimore railroad. The chief productions in 1870 were 134,641 bushels of wheat, 142,515 of rye, 92,277 of Indian corn, 559,616 of oats, 49,779 of buckwheat, 84,476 of potatoes, 51,327 tons of hay, 80,177 lbs. of wool, 1,344,522 of butter, 11,005 of flax, and 674,326 of maple sugar. There were 8,273 horses, 13,811 milch cows, 15,157 other cattle, 32,343 sheep, and 10,748 swine; 43 tanneries, 16 saw mills, and 14 woollen mills. Capital, Somerset. **IV.** A S. E. county of Maryland, on the E. shore of Chesapeake bay, and bounded S. E. by the Pocomoke river and sound; area, about 400 sq. m.; pop. in 1870, 18,190, of whom 7,274 were colored. The surface is level and the soil generally fertile. It is intersected by the Eastern Shore railroad. The chief productions in 1870 were 40,719 bushels of wheat, 251,883 of Indian corn, 100,110 of oats, 105,009 of Irish and 42,026 of sweet potatoes, and 9,090 lbs. of wool. There were 1,235 horses, 1,693 milch cows, 4,427 other cattle, 3,199 sheep, and 7,628 swine. Capital, Princess Anne.

**SOMERSET, Edward Seymour,** duke of. See Seymour.

**SOMERSET, Robert Carr,** earl of. See Overbury, Sir Thomas.

**SOMERSETSHIRE,** a S. W. county of England, bordering on the counties of Gloucester, Wilts, Dorset, and Devon, and the Bristol channel; area, 1,636 sq. m.; pop. in 1871, 463,412. The coast is indented by several bays, the chief of which is Bridgewater bay. The principal rivers are the Avon, Frome, Yeo, Axe, Brue, and Parret. The Avon, Bridgewater, and other canals, and the Great Western railway intersect the county. The surface is hilly, but there is also a great extent of marshy land, and much of the soil is very fertile. Wheat and potatoes are the principal crops, and large numbers of cattle and sheep are reared. Coal, iron, and lead are largely produced. Woollen cloth, canvas, gloves, silk, lace, paper, glass, and various kinds of iron ware are manufactured. Somersetshire contains many remains of antiquity. Bristol is partly in this county, and the other principal towns are Bath, the capital, Wells, Taunton, Bridgewater, and Frome.

**SOMERSWORTH,** a town of Strafford co., New Hampshire, on the Salmon Falls river, which separates it from Maine, and on the Eastern and Boston and Maine railroads, 33 m. E. of Concord and 65 m. N. of Boston; pop. in 1870, 4,504. It is the fifth town in the state in point of manufactures, the principal village being Great Falls, near the falls of that name in Salmon Falls river. The Great Falls manufacturing company, with a capital of $1,500,000, controls the water power (reckoned at 3,200 horse power), and employs about 1,800 hands, manufacturing about 20,000,000 yards of cotton goods annually. The Great Falls woollen company manufactures cassimeres, and the Somersworth machine company stoves and castings of all kinds; these have a capital of $100,000 each. There are several smaller manufactories, including a flour mill with a capital of $30,000. The village contains three banks, two hotels, about 60 stores, 15 schools, a public library of 6,000 volumes, a weekly newspaper, and six churches.

**SOMERVILLE,** a N. E. central co. of Texas, intersected by the Brazos river; area, about 300 sq. m. It was formed in 1875 from Hood co. The surface is rolling and the soil fertile. Wheat, Indian corn, and cotton grow well. Capital, Glen Rose.

**SOMERVILLE,** a city of Middlesex co., Massachusetts, on the Mystic river, 2 m. N. W. of the state house, Boston; pop. in 1850, 3,540; in 1860, 8,025; in 1870, 14,685; in 1875, 21,868. It borders S. W. on Cambridge. The surface is uneven; the principal elevations are Prospect, Spring, Central, and Winter hills. A public park of about 16 acres has been laid out in the N. E. part of the city. It is lighted with gas and supplied with water from Mystic pond. It is connected with Boston by three lines of horse cars and four steam railroads. A large portion of the inhabitants do business in Boston. The principal manufacturing establishments are five brick yards, a bleachery and dye works, a leather-currying establishment, an iron foundery, an art foundery, several carriage factories, two manufactories of glassware, and one each of earthenware, grate bars, ice tools, ladders, mats, spikes, brass and copper tubes, steam boilers, &c. The city is divided into four wards, and is governed by a mayor, 8 aldermen, and 16 councilmen. The valuation of property in 1874 was $30,837,700, and the funded debt at the close of the year was $1,419,854. There are 18 public school houses, including a high school, under the control of a committee of three members from each ward; average attendance in 1874, 3,022; expenditures, $86,705 13, of which $55,990 62 were for teachers' wages. The free public library contains about 5,000 volumes. There are two weekly newspapers and 15 churches, viz.: 3 Baptist, 3 Congregational, 2 Episcopal, 4 Methodist, 1 Roman Catholic, 1 Unitarian, and 1 Universalist. The McLean asylum for the insane is in the E. part of the city.—Somerville was set off from Charlestown in 1842, and incorporated as a city in 1872.

**SOMERVILLE, Mary**, a British physicist, born in Jedburgh, Roxburghshire, Scotland, Dec. 26, 1780, died in Naples, Italy, Nov. 29, 1872. She was the daughter of Vice Admiral Sir William Fairfax, and chiefly through her own efforts acquired a thorough education, particularly in mathematics and landscape painting. In 1804 she married Samuel Greig, then Russian consular agent in London, where she went to reside. Left a widow in 1807, she returned to Edinburgh, and in 1812 married her cousin William Somerville, M. D., who in 1816 was appointed a member of the army medical board, and removed to London. Here she attracted attention by some experiments on the magnetic influence of the violet rays in the solar spectrum, the results of which were published in the "Philosophical Transactions" of 1826; and Lord Brougham suggested that she should prepare for the "Library of Useful Knowledge" a summary of the *Mécanique céleste* of Laplace, which proved too voluminous for its original destination, and was published under the title "Mechanism of the Heavens" (8vo, Cambridge, 1831). This work led to her election as an honorary member of the royal astronomical society, and her bust by Chantrey was placed in their hall. In 1834 she published "The Connection of the Physical Sciences" (9th ed., 1858). In 1835 she received a pension of £200, subsequently increased to £300. Soon afterward she went to Italy on account of the health of her husband, and there resided during the rest of her life, principally in Florence, Rome, and Naples. Her next work was "Physical Geography" (2 vols., 1848; 6th ed., 1870), a history of the earth in its whole material organization, and of animal and vegetable life; and her last, "Molecular and Microscopic Science" (2 vols., 1869). She was a member of many foreign societies, and in 1869 received the Victoria medal of the royal geographical society, and in the same year the first gold medal ever awarded by the Italian geographical society. She warmly favored what are popularly known as "women's rights," and was a member of the general committee for woman suffrage in London. In her 92d year she read books in the higher mathematics four or five hours daily, solved the problems, and to the day of her death was occupied in the revision and completion of a treatise on the "Thêory of Differences." During her last few years she noted down some recollections of her life, which have been published under the title "Personal Recollections, from Early Life to Old Age, of Mary Somerville," by her daughter, Martha Somerville (8vo, London, 1873).

**SOMERVILLE, William**, an English poet, born at Edstone, Warwickshire, in 1692, died July 19, 1742. He was educated at Winchester school and New college, Oxford, and settled on a paternal estate in Warwickshire. He lived beyond his means, and finally became intemperate. His "Chase," in blank verse, has often been reprinted. He wrote "Field Sports," describing hawking, and "Hobbinol, or Rural Games," a mock heroic poem.

**SOMME**, a N. department of France, in Picardy, bordering on the departments of Pas-de-Calais, Le Nord, Aisne, Oise, and Seine-Inférieure, and the English channel; area, 2,379 sq. m.; pop. in 1872, 557,015. The surface is generally level, but occasionally diversified. It is divided into two nearly equal portions by the river Somme, which flows through it in a W. N. W. direction. The soil is carefully cultivated, but not naturally fertile. Cider is an important product. Cotton, linen, and woollen goods, iron ware, and beet sugar are manufactured. It is divided into the arrondissements of Amiens, Abbeville, Doullens, Montdidier, and Péronne. Capital, Amiens.

**SÖMMERING, Samuel Thomas von**, a German physiologist, born in Thorn, Jan. 18, 1755, died in Frankfort, March 2, 1830. He studied medicine at Göttingen, and became professor of anatomy at Cassel in 1778, and at Mentz in 1784. In 1790 he began to practise medicine at Frankfort, and returned to that city in 1820 after spending 15 years in Munich as physician to the king of Bavaria, who ennobled him. His works include *Vom Baue des menschlichen Körpers* (5 vols., 1791–'6; new ed., 9 vols., 1839–'44); *De Corporis Humani Fabrica* (6 vols., 1794–1801); and *Ueber das Organ der Seele* (1796), teaching that the soul has its seat in a vapor-like fluid in the cavities of the brain.

**SOMNAMBULISM** (Lat. *somnus*, sleep, and *ambulare*, to walk), literally, the act of walking in sleep, but usually applied to all the movements of a person who while in a condition of sleep acts his dreams. There are three kinds of somnambulism, viz.: 1, simple, where the somnambulist is apparently in ordinary health, but rises from his bed, walks, runs, or climbs, or sometimes talks or writes, while asleep; 2, morbid, where there is a diseased condition, which admits the manifestation of the duality of the human system, the somnambulist sometimes being alternately in the natural and the morbid condition, and frequently while in the latter performing acts of which while awake he is incapable; and 3, artificial, which is treated under ANIMAL MAGNETISM. The first class of somnambulists are usually persons of nervous temperament, and the phenomena are generally induced in them either by some violent excitement, or oftener by a morbid condition of the stomach, late suppers, indigestible food, or the like. Some writers advise the placing a wet cloth before their beds, on which they may step, or waking them suddenly in some other way; but such a course is fraught with great danger, as the shock may prove fatal, or at least permanently injurious.—Morbid somnambulism is a condition concerning which we have little positive knowledge, but the phenomena of which are often very striking. A shy, diffident girl of 14, for instance, of a nervous temperament, but who has exhibited no

extraordinary intellectual powers, and has had but very ordinary education, becomes languid, listless, and pale; complains of pain in the side, and perhaps of an unpleasant feeling in the frontal region; after a while, falling asleep in the daytime, she will rise from her chair, and, imagining herself a preacher to a large audience, go through the preliminary exercises of a religious service, and deliver an extempore sermon, the arrangement and language of which far transcend her waking capacity; and this performance may be repeated daily or every other day. In the case we are describing, which in its general features is similar to a considerable number which have occurred in recent times, the subject recovered her health, and the phenomena ceased after two or three years. In some instances they have been followed by the death of the somnambulist.—The development of the double existence is another of the phenomena of morbid somnambulism, not less remarkable than the preceding, and equally well authenticated. The history of the celebrated seeress of Prevorst, by Dr. Kerner, will be readily recalled; and in many cases the two states are strongly marked, and the subject remains in each for some weeks, being utterly unconscious while in the one of any event which has occurred while in the other. Though resembling it in some particulars, these cases are not to be confounded with those in a state of ecstasy (see CATALEPSY), there being none of the physical insensibility or muscular rigidity. The causes and cure of this form of somnambulism are alike obscure.—See Dr. A. J. Kerner, *Geschichte zweier Somnambulen* (Carlsruhe, 1824), and "The Seeress of Prevorst," translated into English by Mrs. Catharine Crowe (New York, 1845); Macnish's "Philosophy of Sleep" (1830); Abercrombie "On the Intellectual Powers" (1830); Deleuze's "Critical History of Animal Magnetism" (revised ed., New York, 1846); Colquhoun's "Animal Magnetism" (1851); Reichenbach's "Animal Magnetism;" Dr. Sonderis's "Narrative of the Religious Excitement in Sweden;" and Dr. Gibson's "Year of Grace, an Account of the great Irish Revival in 1859" (1860).

**SOMNAUTH,** or **Somnath Pattan,** a walled town of British India, in the peninsula of Cattywar, in the political agency of the same name under the Bombay government, on the N. E. shore of the Arabian sea, 28 m. W. N. W. of Cape Diu, and about 200 m. N.W. of Bombay; pop. about 5,000. Somnauth is celebrated in the mythological legends of ancient Hindostan, and is now chiefly remarkable as the site of a magnificent temple dedicated to Siva, which formerly attracted many pilgrims, and was supported by the revenues of 10,000 villages. It was stormed and robbed of immense treasure by Mahmoud of Ghuzni in 1024, and its gates were carried away as a trophy. They were brought back to India in 1842 by the English, on the evacuation of Afghanistan, and deposited in the magazine at Agra.

**SOMOGY** (Ger. *Schümegh*), a county of S. W. Hungary, bordering on the counties of Zala, Veszprém, Tolna, and Baranya, and on Croatia and Slavonia; area, 2,538 sq. m.; pop. in 1870, 289,555. It is mountainous, and is drained in the south by the Drave. Lake Balaton on the northwest is partly within its limits. The products include grain, wine, tobacco, and timber. Capital, Kaposvár.

**SONATA,** a form of musical composition consisting of several independent movements, each of which is developed in accordance with certain accepted rules. The great body of instrumental music is based upon the sonata form. When first used, in the latter part of the 16th century, the word simply signified a composition for instruments, and conveyed no idea of any determined form. Gradually composers applied it to a composition for one or two instruments, consisting of three movements of contrasted character and time. Philipp Emmanuel Bach contributed greatly to the development of the sonata. His works of this class consisted of a first movement, *allegro*, a second, *adagio*, and a third, *rondo*, which was more vivacious than the others. Haydn adopted Bach's general plan, though in his 44 sonatas he developed the movements in a broader manner. Mozart and Beethoven composed some of their best works in this form; in their day it was the favorite kind of pianoforte composition. It has also been used by Von Weber, Schubert, Schumann, and other later composers. Haydn added a fourth movement, the *minuetto*, and this, or its equivalent the *scherzo*, with the three previously existing movements, constitutes the form upon which all the quartet and quintet music for stringed instruments and the symphony are based.

**SONDERSHAUSEN.** See SCHWARZBURG-SONDERSHAUSEN.

**SONDRIO,** a N. province of Italy, in Lombardy, bounded N. W. and N. by Switzerland, N. E. by Tyrol, and S. by Brescia, Bergamo, and Como; area, 1,262 sq. m.; pop. in 1872, 111,-241. It includes the valleys of the Valtellina (*Val Tellina*), 45 m. long, and its continuation the former county of Bormio, and the valley of Chiavenna, and forms only one district. It is surrounded by branches of the Rhætian Alps, including some of their highest summits, and the carriage roads over the Splügen, Bernina, and Stelvio passes, the last the highest of the Alpine roads, run through the province. The province abounds in picturesque localities. The principal river is the Adda. Excepting along the marshes near the lake of Como, the country is exceedingly fertile in grain and fruit, and especially in wine. The cheese is among the best in Lombardy. Iron and marble abound. The principal towns are Chiavenna, Bormio, and Sondrio, the capital, which has a population of about 5,000, and a fine cathedral. (See VALTELLINA.)

**SONE,** a river of British India, a southern tributary of the Ganges, rises in the high-

lands of the Central Provinces, in lat. 22° 41′ N., lon. 82° 7′ E., near the source of the Nerbudda, and falls into the Ganges 28 m. above Patna, after a course of upward of 450 m. The general direction of its flow is northeasterly, through Jubbulpore, Rewah, and Behar. All its important tributaries come from the south. In the highlands it flows through narrow valleys, but lower down they widen into alluvial plains, which are well cultivated, and yield cotton, indigo, and sugar cane. It is about 3 m. wide at its junction with the Ganges, but the navigation is of little importance above Daudnugur, about 60 m. from that point, where the river is 10 or 12 ft. deep in the rainy season, but at other times nearly dry. Coal is found upon the banks of its upper course, and agates and carnelians occur. Work is now (1876) in progress on the Sone irrigation project for supplying water to about 2,000,000 acres in the Patna division of Bengal, by a dam across the river, and other works.

**SONNEBERG,** a town of Germany, in Saxe-Meiningen, 35 m. S. E. of Meiningen; pop. in 1871, 6,764. It is the centre of an important manufacturing district, and has a fine church, a new town hall, and a new government building. Dolls and toys of wood and papier maché, china goods, cotton hose, and kid gloves are made here in great perfection. The shipments to the United States amounted in 1873–'4 to $938,332 in gold. In the vicinity are marble and other quarries, and there are many breweries. An American consul is stationed here.

**SONNET** (It. *sonetto*), a poem consisting of 14 iambic decasyllabic or endecasyllabic lines, rhyming in a peculiar manner. The first 8 lines make two quatrains, and the remaining 6 two tercets. There are two rhymes in the quatrains, the 1st, 4th, 5th, and 8th lines rhyming together, and also the 2d, 3d, 6th, and 7th. This is the best arrangement, as the Italians hold, but others occur, and sometimes, even in Petrarch, the rhymes are alternate. In the tercets great liberty is allowed; the rhymes may be either two or three, and they may be arranged at the will of the poet, but never in couplets. There are but few Italian precedents for the form which the English poets prior to Milton gave to the sonnet. From the difficulty of continuing the same rhyme, they made it consist of three quatrains and a final couplet, each quatrain usually having its own two alternate and independent rhymes. The Anacreontic sonnet is composed of octo-syllabic lines. It is doubtful whether the sonnet was the invention of the Italians, or was derived by them from earlier Provençal poets. The oldest extant specimens are in Italian, by Lodovico Vernaccia (about A. D. 1200), and by Piero delle Vigne, chancellor of the emperor Frederick II., who flourished early in the 13th century; the first who gave to it the arrangement which was subsequently adopted as its legitimate form was Guittone d'Arezzo (died in 1294); and it was carried to its highest excellence by Petrarch. The Italian sonnet was introduced into Spain by the marquis of Santillana in the 15th century, and during the two following centuries it was regarded there with extravagant favor. It never found much favor in France, and fell into ridicule in the 17th century through the *bouts rimés*, or blank sonnets, in which the rhyming words were first chosen and arranged, while the subject was to be selected and the body of the sonnet to be written afterward. In Germany the sonnet has been chiefly cultivated by the poets of the romantic school. The earlier English form of the sonnet was introduced by Surrey and Wyatt in the reign of Henry VIII.; and there are numerous sonnets by Sidney, Spenser, Shakespeare, Daniel, Drayton, Drummond, and others. Milton returned to the genuine Italian form, but did not always adhere to it. From the time of Milton for nearly a century few sonnets were written in England. It was revived in the Italian form by Edwards, Gray, and T. Wharton, while Bowles, Charlotte Smith, and Helen Maria Williams reverted to the easier form of the old English sonnets.—See "The Sonnet: its Origin, Structure, and Place in Poetry, with original Translations from the Sonnets of Dante and Petrarch," by Charles Tomlinson (London, 1874).

**SONNINI DE MANONCOURT, Charles Nicolas Sigisbert,** a French naturalist, born in Lunéville, Feb. 1, 1751, died in Paris, May 29, 1812. Being commissioned as a marine engineer, he spent several years in Cayenne and on the W. coast of Africa, afterward passed some time with Buffon, and in 1777 joined the African expedition under Baron de Tott. After visiting Egypt, Greece, and Asia Minor, he returned to France in 1780. He contributed to Buffon's *Histoire naturelle* 13 volumes of fishes, 1 of cetacea, and with Latreille 4 of reptiles. He lost his fortune by the revolution, and afterward edited a *Bibliothèque physico-économique* (1801–'12), and *Nouveau dictionnaire d'histoire naturelle* (24 vols. 8vo, 1803 *et seq.*), and published accounts of his travels.

**SONNTAG, William Louis.** See p. 891.

**SONOMA,** a N. W. county of California, bounded S. E. by San Pablo bay and W. by the Pacific ocean, and watered by Russian, Santa Rosa, Petaluma, and Sonoma rivers; area, 1,400 sq. m.; pop. in 1870, 19,819, of whom 473 were Chinese. The N. part is traversed by well timbered spurs of the Coast range. The valleys are very fertile, and Sonoma valley is celebrated for its vineyards. In the N. E. part of the county are the geysers, a collection of hot springs. Gold, silver, copper, quicksilver, and coal occur, but not generally in paying quantities. The county is traversed by the San Francisco and North Pacific railroad. The chief productions in 1870 were 618,425 bushels of wheat, 145,792 of Indian corn, 323,961 of oats, 195,456 of barley, 369,154 of potatoes, 308,496 gallons of wine, 230,394 lbs. of wool, 1,060,266 of butter, 246,900 of cheese, and

35,571 tons of hay. There were 10,616 horses, 1,110 mules and asses, 14,960 milch cows, 16,592 other cattle, 58,387 sheep, and 28,588 swine; 4 manufactories of carriages and wagons, 5 of cooperage, 5 of cabinet furniture, 1 of iron castings, 5 of wine, 13 of saddlery and harness, 2 of sash, doors, and blinds, 8 of tin, copper, and sheet-iron ware, 5 flour mills, 4 tanneries, 3 currying establishments, 3 breweries, and 18 saw mills. Capital, Santa Rosa.

**SONORA,** a N. W. state of Mexico, bounded N. by the United States, E. by Chihuahua, S. by Sinaloa, and W. by the gulf of California and Lower California; area, 81,022 sq. m.; pop. in 1869, 109,388. The eastern portion of the state is extremely mountainous, being traversed by a branch of the Sierra Madre; the western is composed mainly of extensive plains. The principal rivers are the Mayo, Yaqui, and San José, the second having a course of 450 m., and all three emptying into the gulf of California. The most important mineral productions are gold and silver, of which there were 144 mines in 1870; the coinage of the mints of Hermosillo and Álamos in 1869 amounted to $1,116,397. Copperas occurs in some places, as do also amianthus, alabaster, and jasper; and carbonate of soda and nitrate of potash are found. The climate is hot on the coast, mild in the central portions, and cool in the elevated region of the east. Much of the soil is fertile, but agriculture is chiefly confined to the southern districts watered by the Mayo and Yaqui rivers. The staple productions are wheat, maize, barley, oats, beans, sugar, cotton, and tobacco; coffee is raised, and fruits are very abundant. There are extensive forests, but little of the timber is suitable for building; copal, gum arabic, archil moss, cochineal, and many other dyes and drugs are produced. Seals, turtles, oysters (including pearl oysters), and fish of good quality are found in inexhaustible quantities. There are seven steam and a large number of other flour mills; coarse cotton fabrics are manufactured in a mill of 60 looms at San Miguel, the only factory of any kind in the state; and large quantities of cigars are made. Cattle rearing is extensively carried on, despite the depredations of the Apache and other Indians. The exports include hides, gold and silver coin and bullion, ores, hog skins, pepper and gum, flour, and cigars. In 1870 there were 105 schools, with an attendance of 3,871. The state is divided into eight districts: Ures, Hermosillo, Guaymas, Álamos, Montezuma, Zaguarita, Arispe, Altar, and Magdalena. The capital is Ures; the chief seaport, Guaymas.

**SONTAG, Henriette,** Countess Rossi, a German singer, born in Coblentz, Jan. 3, 1806, died in Vera Cruz, Mexico, June 18, 1854. She appeared upon the stage in children's parts as early as her sixth year, at 15 made her début at Prague in Boïeldieu's "John of Paris," and soon rose to a foremost place among European vocalists. In 1828 she privately married Count Rossi, an Italian nobleman, and in 1830 retired from the stage. She was induced by her husband's pecuniary misfortunes to resume her profession in 1849, sang for several seasons in Europe, then made a successful tour in the United States, and died while returning from a professional visit to Mexico.

**SOOCHOW,** or **Suchau,** a city of China, in the province of Kiangsu, on a lake through which the imperial canal passes, 112 m. E. S. E. of Nanking, and 53 m. W. by N. of Shanghai; pop. variously estimated from 500,000 to 2,000,000. It consists of the town proper, surrounded by a wall 10 m. in extent, and four extensive suburbs. Silk, linen, cotton hardware, and glass are manufactured. There are many beautiful gardens in the neighborhood. It suffered severely during the Taeping rebellion, the insurgents occupying it and driving out the merchants and wealthy inhabitants. It succumbed with other cities of the delta to the imperialists in 1864, and since then has recovered much of its prosperity.

**SOODAN,** or **Soudan** (Arab. *Biled es-Sudan*, the country of the blacks). **I.** A vast continental belt of territory (also called Nigritia), stretching nearly across Africa, mainly between the 6th and 15th parallels of N. latitude, from the Nile provinces of Egypt on the east to the Mandingo country and Senegambia on the west. In Waday and near Timbuctoo its northerly boundary is not far from lat. 17° N. This region is occupied by a large number of native states, of which the most important are Adamawa, Baghirmi, Bambarra, Bornoo, Darfoor, Gando, Houssa, Sackatoo, and Waday, each described under its own title. The altitude of Soodan and the aspect of the surface vary greatly in the different districts. The portion W. of the Niger is bounded S. by the Kong mountains, which curve northward into the highlands of Senegambia, forming the W. boundary. The region enclosed within the great bend of the Niger is of moderate elevation, and consists of a series of well watered and fertile plains, in some places densely populated. The central portion of the country extends E. from the river as far as Lake Tchad, in which centres the hydrographic system of this part of Soodan. The surface is hilly except in the vicinity of the lake, but the altitude is believed not to exceed 2,000 ft., and probably does not average more than half as much. Among the hills are numerous torrent beds filled only in the rainy season. There are swamps in the lower districts, and an abundant forest growth, but the cleared area is sufficient to render central Soodan both populous and productive. Lake Tchad, which is intersected by the 14th parallel of N. latitude and the 15th meridian of E. longitude, is bordered N. E. by the native state of Kanem, beyond which lies the Sahara, S. E. by Baghirmi, and on all other sides by Bornoo. It is about 840 ft. above the sea level, and its numerous affluents drain the vast alluvial plain surrounding

it, which slopes gently toward its shores. (See TCHAD, LAKE.) The principal tributary is the Shary, flowing into the lake from the south. The plain is subject to frequent inundation in the vicinity of the streams, but is fertile and thickly inhabited. In Waday, which borders it on the east, the country becomes hilly again, and so continues some distance beyond the confines of Darfoor. The Nyam-Nyam country, lying principally S. of lat. 5° 30′ N. and E. of the 25th meridian, is drained by the westward-moving river Welle, discovered by Schweinfurth, and belongs geographically to Soodan, if that stream is connected with the system of Lake Tchad.—The geology of Soodan is but little understood, and the mineral wealth seems limited to iron, which appears to be widely diffused, and gold, which is found in the rivers. The climate is everywhere characterized by extreme heat and moisture. The maximum temperature is attained in the level region of central Soodan, where the annual mean is over 83° F., while the more western hilly country is remarkable for its excessive moisture and a greater range of the thermometer. The rainy season, which abounds in thunder storms and tornadoes, lasts from the middle of May or June, varying with the region, to November, when the northerly winds set in, and the weather becomes fair and dry. The natural products comprise palm oil, cocoanuts, dates, figs, and many other tropical fruits. The chief cultivated crops are maize, millet, yams, rice, wheat, beans, tobacco, cotton, indigo, and various vegetables. The fauna of Soodan embraces the larger mammalia, such as the elephant, hippopotamus, and rhinoceros; the lion, leopard, and spotted hyæna, among the carnivorous animals; numerous species of antelopes; and the ostrich, on the borders of the desert. Domestic animals are extensively raised, including several breeds of horses and innumerable cattle, as well as goats, sheep, asses, and poultry. The honey made by wild bees is gathered in large quantities, and forms an important article of native traffic. The external trade of Soodan is carried on principally by means of caravans, which journey to and from Algeria and Morocco. The exports comprise attar of roses, gold dust, gum arabic, indigo, ivory, and ostrich feathers and skins, of which about £1,500,000 worth annually reaches Algeria; the imports from that country average about the same amount, mainly in cotton goods, cutlery, and weapons. Inferior iron utensils and coarse cotton cloth are the only noteworthy articles of native manufacture. The population consists chiefly of negroes, but in the west the Mandingoes predominate, and the Foolahs are the ruling people in Gando, Sackatoo, and Adamawa. In many parts of the country the Arabs are extremely influential.—Soodan has yet to be thoroughly and exhaustively explored throughout. Among the more prominent European travellers who have visited or traversed some portion of the country are Mungo Park, Denham and Clapperton, Caillié, Lander, Barth, Vogel, Rohlfs, and Nachtigal (1869–'74). The last named entered Bornoo from the Sahara N. of Lake Tchad, and made his way thence eastward through Waday and Darfoor to the Nile, an undertaking never before accomplished. The explorations of Petherick and Schweinfurth relate to regions S. of the limits usually assigned to Soodan. **II.** A province of Egypt, distinguished from the preceding, of which it is but a continuation eastward, by prefixing the definite article (the Soodan). It comprises Kordofan, Nubia proper, Sennaar, Taka on the east, and some Nile districts further south; pop. estimated by Sir Samuel Baker at over 1,000,000. The soil is fertile, and would be productive under just rule, but the exactions of the government have been so excessive as greatly to retard the development of the province. The khedive has undertaken the construction of a railway from Shendy, N. of Khartoom, the capital, down the Nile a distance of about 220 m., to a point below the second cataract. The products of the Soodan have hitherto found their way to Cairo mainly by means of caravans occupying four months on the journey. According to an official statement of such products sold in that city in 1873–'4, they were valued at £1,550,600, and comprised ostrich feathers (worth £824,013), gums, ivory, calf skins, coffee, senna, wax, tamarinds, and many other articles. This statement did not include exports from the Soodan through the Red sea ports. The province has been gradually annexed by Egypt since 1821.

**SOOFEES.** See SUFIS.

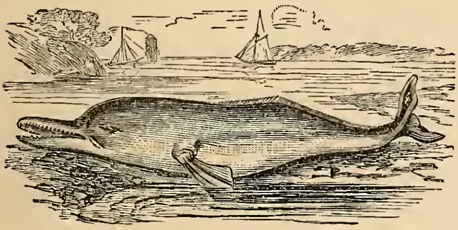
**SOOLOO,** or **Sulu**, the general name of a picturesque chain of islands in the Indian archipelago, known also as the Sooloo archipelago, extending about 250 m. from S. W. to N. E., between Borneo and Mindanao, from lat. 4° 40′ to 6° 45′ N., and from lon. 119° to 122° 20′ E., separating the Celebes sea on the south from the Sooloo or Mindoro sea on the north; estimated area, 1,300 sq. m.; pop. about 200,000. They lie outside the volcanic belt of the Indian archipelago. The entire number of islands is about 150, most of which are small and uninhabited. There are three large islands: Tawi, near the coast of Borneo; Basilan, close to the S. W. extremity of Mindanao; and Sooloo, about midway between them. Each is about 40 m. long and from 6 to 20 m. wide, richly clothed with tropical vegetation, and rising into peaks of considerable height, those in Sooloo being 2,000 ft. above the sea. The island of Cagayan Sooloo, 140 m. N. W. of the main chain, is sometimes included within the Sooloo archipelago, although it does not properly belong to it. Balambangan island, further west, near Maludu bay in Borneo, is noted for the two unsuccessful attempts of the British to establish themselves there. It was ceded to England in 1763, but the fortifications were destroyed by the Spaniards in 1775; it was re-

settled in 1803, but abandoned in 1804. The Sooloo archipelago lies within the influence of the monsoons. The thermometer ranges between 75° and 87°. The chief productions consist of teak and sandal wood, rice, tortoise shell, pearls, mother of pearl, fish, tripang, and edible birds' nests. According to Mr. St. John, this archipelago furnishes probably a greater number of valuable oyster beds than any other part of the world. The islands are subject to the sultan of Sooloo, and are governed by numerous petty chiefs. The fortified town of Sugh or Sooloo, on the island of the same name, is the capital and chief port of the group, and carries on considerable trade with the other islands and Manila. Its population is about 6,000, and that of the whole island is estimated at 100,000. The inhabitants are Mohammedan Malays, and were renowned for their piratical habits prior to the repression of piracy in these waters by the Spanish in 1851. They write their language, which appears to resemble the Philippine tongue, in the Arabic character.

**SOONGARIA,** or **Dzungaria.** See TURKISTAN.

**SOONNA.** See SUNNA.

**SOOSOO,** or **Sousou,** the native name of the dolphin of the Ganges, a fresh-water cetacean of the genus *platanista* (F. Cuv.). In this, the only described species (*P. Gangetica*, F. Cuv.),



Soosoo, or Dolphin of the Ganges (Platanista Gangetica).

the body is from 20 to 24 ft. long, thickest in front and gradually tapering to the tail; the head obtuse; the jaws nearly equal, almost straight, slender, compressed at the sides, expanded at the end, and from 3 to 4 ft. long; the teeth are $\frac{30}{30}-\frac{30}{30}$, conical, projecting from the gums, largest, nearest together, and most curved in front, interlocking in the two jaws, and laterally near together in the lower jaw; the symphysis very long; the blow-hole a longitudinal fissure, an unusual form; eyes very small, shining black, deeply sunk, and 4 in. above the angle of the mouth; auditory foramina open but small; the pectorals fan-shaped, 1½ ft. long and 1 ft. broad posteriorly; dorsal much depressed and nearest the tail; caudal 2½ ft. wide and festooned. The color is shining pearly gray, with a few lighter colored spots; the fat under the skin is highly prized by the Hindoos as an external application in painful diseases. It is carnivorous, feeding principally on fish, in the pursuit of which it is very active, but at other times is rather slow. It inhabits the Ganges as far as the head of navigation, but is most abundant where its numerous mouths open into the sea.

**SOOTHSAYER.** See MANTIS.

**SOPHIA** (Bulg. *Triaditza*), a town of European Turkey, in Bulgaria, on a small affluent of the Isker, 310 m. W. N. W. of Constantinople; pop. estimated from 18,000 to 30,000, including Bulgarians, Turks, Greeks, and Armenians. It is beautifully situated on the road to Belgrade and surrounded by mountains. The old castle was fortified in 1854. The principal mosque was formerly the magnificent church of St. Sophia. A Greek archbishop and a Catholic bishop reside here. S. of the city are extensive ruins of the ancient Sardica or Ulpia Sardica, an important town of Mœsia, in which a council was held in 347. Sophia was founded by Justinian, and conquered by the Bulgarians in 809 and by the Turks in 1382. For a long time it was the capital of Bulgaria.

**SOPHIA ALEXEYEVNA.** See PETER I.

**SOPHIA DOROTHEA,** crown princess of Hanover, born Sept. 15, 1666, died Nov. 13, 1726. She was a daughter of Duke George William of Brunswick, of the Lüneburg-Celle line; her mother was a French lady. In 1676 she was affianced to a prince of the house of Brunswick, who died in the same year. She was married in 1682 to her cousin, the future George I. of England, and became the mother of George II. and of the queen of Frederick William I. of Prussia. She lived unhappily with her husband, from whom she was divorced in December, 1694, after being suspected of an intrigue with Count Königsmark. The latter had disappeared in the night of July 1–2 of that year on leaving Sophia's apartment, and it was generally believed that he had been assassinated at her father-in-law's instigation. She was banished for the rest of her life to the castle of Ahlden, near Celle, whence her popular designation as princess of Ahlden.

**SOPHISTS.** See PHILOSOPHY, vol. xiii., p. 437.

**SOPHOCLES,** a Greek tragic poet, born in the Attic village of Colonus in 496 or 495 B. C., died probably in 406. He was about 30 years younger than Æschylus, and 15 years older than Euripides. Having gained the prize of a garland both in music and gymnastics, he was selected for his beauty and musical skill in his 16th year to lead, naked, anointed, and with lyre in hand, the chorus which danced and sang around the trophy in the celebration of the victory of Salamis. In 468 he first came forward as a competitor in a dramatic contest, having Æschylus for his rival. The representation was at the great Dionysia, presided over by the first archon; the judges were Cimon and his colleagues who had just returned from the conquest of Scyros, bringing with them the bones of Theseus; the play presented by Sophocles was probably the "Triptolemus," celebrating the Eleusinian hero as a patriot and civilizer; the public interest and expecta-

tion were strongly excited; and the first prize, which for a whole generation had belonged to Æschylus, was now awarded to his youthful rival. From this time to 441 he is said to have written 31 plays. In 440 "Antigone," his earliest extant drama, gained the prize, and so delighted the Athenians that they elected him one of the ten strategi for the ensuing year. He engaged as the colleague of Pericles in the Samian expedition, but neither achieved nor sought military reputation. He was familiar with Herodotus, and wrote a poem in his honor. Ruhnken supposes that it was not the poet, but an orator of the same name, who after the destruction of the Sicilian army in 413 favored the oligarchical movement and was appointed one of the ten *πρόβουλοι.* Sophocles refused repeated invitations to leave Athens and reside at foreign courts. During the 34 years following the success of "Antigone" he produced 81 dramas. Contending, besides Æschylus, with Euripides, Chœrilus, Aristias, Agathon, and his own son Iophon, he gained the first prize 20 or 24 times, and the second in all other cases. At an advanced age he filled the office of priest to the native hero Halon. There is no certain authority for any of the accounts of his death, that he was choked by a grape, that he sustained his voice so long in publicly reading the "Antigone" as to lose his breath and life together, or that he died of joy on obtaining a dramatic victory. It has been said that he combined all the qualities which, in the judgment of a Greek, would make up a perfect character: beauty and symmetry of person, mastery alike in music and gymnastics, spontaneity of genius and faultlessness of taste, constitutional repose, a habit of tranquil meditation, a ready wit, and an amiable demeanor.—Sophocles is placed by the universal consent of ancient and modern critics at the head of the Greek drama. His tragedies hold the just mean between the vague and solemn sublimity of Æschylus and the familiar scenes and rhetorical pathos of Euripides, presenting the characters of men worthy of sympathy and admiration, while the former delighted in religious themes fit to inspire awe, and the latter abounds in unpoetical disquisition and immoral vehemence of passion. He illustrates the age of Pericles, intervening between that of the heroes of Marathon and Salamis and that of the sophists. Of all his dramas only seven have been preserved, to which Müller assigns the following chronological order: "Antigone," "Electra," "Trachinian Women," "King Œdipus," "Ajax," "Philoctetes," and "Œdipus at Colonus." They all belong to the latter period of his life and reveal his art in its full maturity, and several of them were esteemed by the ancients among his greatest works. The "Œdipus at Colonus" was first brought out by his grandson after his death. There are also fragments and titles of his lost plays. The *editio princeps* of Sophocles is that of Aldus (1502). The text of Turnebus's edition (1533) served as a basis for the subsequent editions of Henry Stephens (1568), Canterus (1579), and others, until the edition of Brunck (2 vols., Strasburg, 1786), which is the basis of all later editions. Among the best are those of Hermann (4th ed., Leipsic, 1851), Dindorf (new ed., Leipsic, 1867), Tourneur (Paris, 1873), Schneidewin (4th ed. by Nauck, Berlin, 1873), Campbell (Oxford, 1873–'4), Blaydes (London, 1873–'4), and White (Boston, 1874). The best translations are: in German, by Jordan (Berlin, 1862), Schöll (new ed., Leipsic, 1871), and Donner (7th ed., Leipsic, 1873); in French, by Fayart (Paris, 1849), Artaud (6th ed., 1862), and Personneaux (2d ed., 1874); and in English, by Adams (London, 1729), Franklin (1758–'9), Potter (1788), Dale (1824), Buckley (Bohn's "Classical Library," 1849), Plumptre (1866–'71), Collins ("Ancient Classics for English Readers," London and Philadelphia, 1873), and Campbell (1874).

**SOPHOCLES, Evangelinus Apostolides,** an American scholar, born near Mt. Pelion, in Thessaly, March 8, 1807. He studied in the convent on Mt. Sinai, emigrated to the United States, entered Amherst college in 1829, taught school, and was tutor in Greek in Harvard college in 1842–'5 and 1847–'59. He was then appointed assistant professor of Greek there, and in 1860 professor of ancient, Byzantine, and modern Greek. He received the degree of A. M. from Yale college in 1837 and from Harvard college in 1847, and that of LL. D. from the Western Reserve college in 1862 and from Harvard college in 1868. He has published "A Greek Grammar" (Hartford, 1838; 3d ed., 1847); "First Lessons in Greek" (1839); "Greek Exercises" (1841; 3d ed., 1848); "A Romaic Grammar" (1842; 2d ed., Boston, 1857, and London, 1866); "Greek Lessons for Beginners" (Hartford, 1843); "Catalogue of Greek Verbs" (1844); "History of the Greek Alphabet, with Remarks on Greek Orthography and Pronunciation" (Cambridge, 1848; 2d ed., 1854); "A Glossary of Later and Byzantine Greek" (4to, Boston, 1860, forming vol. vii., new series, of the "Memoirs of the American Academy"); and "Greek Lexicon of the Roman and Byzantine Periods" (8vo, Boston, 1870), his chief work.

**SOPHONISBA.** See Masinissa.

**SORACTE** (now *Monte di Sant' Oreste*, and sometimes *Monte di San Silvestro*), a mountain of ancient Etruria, in the territory of the Falisci, visible from and about 25 m. N. of Rome. It rises in an abrupt mass to a height of about 2,250 ft. It was consecrated to Apollo, who had a temple on its summit, where the present monastery of San Silvestro stands.

**SORBONNE,** the principal school of theology in the ancient university of Paris. It was founded in 1253 by Robert de Sorbonne or Sorbon, so called from his birthplace in Champagne. He had been a poor student, but became chaplain to Louis IX. in 1252, and found-

ed with the king's aid a collegiate school for the gratuitous education of poor students in theology. He secured the services of three secular professors, Guillaume de Saint-Amour, Eudes de Douai, and Laurent Langlois, and formed with them, and 16 poor students under his own direction, a community which served as a model for similar collegiate schools in the universities of France and England. The charter granted in 1253 by Louis IX. was confirmed and enlarged by Pope Clement IV. in 1268. Before 1253 theological instruction was given in the bishop's school near the cathedral of Notre Dame; thenceforward it was given exclusively at the Sorbonne. Robert also founded near the college a preparatory seminary called "the little Sorbonne," which was destroyed in 1635, when the present church of the Sorbonne was erected on its site. He provided a library of 1,000 volumes, which was increased by subsequent benefactors, especially by Cardinal Richelieu. The members of the college (*maison de Sorbonne*) were divided into fellows (*socii*) and commoners (*hospites*). The fellows, composing the faculty, were all secular priests, doctors or bachelors in divinity, selected for their eminent learning, after undergoing the test of a severe public examination, a triple ballot, and teaching a course of mental philosophy. Besides the strict necessaries of life provided in the college, the poorest among them received a trifling stipend. The commoners were required to be bachelors in divinity, were chosen from among the most talented of their class after the most rigorous ordeal, and were maintained by the college, but had no voice in its government. The fellows were nominated for life, and were officially designated "fellows or bachelors of the house and society of the Sorbonne;" the commoners were styled "bachelors of the house of the Sorbonne," and their membership ceased on their graduating as doctors. The college property was vested in the fellows, and all business was managed in their name. A perfect equality reigned among them; the holding of office implied no superiority or power of one over another. No member of a religious order was admitted into their body, and a fellowship was forfeited by entering such an order. The exceeding rigor exercised in the selection both of fellows and of commoners was for the purpose of maintaining a high standard of intellectual culture among the secular priesthood. But the vast lecture halls attached to the college were open to all poor scholars indiscriminately, and the professors were pledged never to refuse to teach any such, while students who had means were required to pay the usual university fees. From 1253 to 1789 at least six doctors of the Sorbonne were constantly employed in giving gratuitous instruction. The high standard of excellence thus maintained by the faculty, and the large number of distinguished scholars who went out from the Sorbonne to fill the highest ecclesiastical and civil offices in every European country, raised this celebrated school to an unrivalled pitch of fame and influence all through the middle ages and down almost to its suppression. Its controlling power was felt in the contests between the university of Paris and the mendicant orders, Guillaume de Saint-Amour being the chosen advocate of the former and the uncompromising foe of the friars; the Sorbonne was appealed to in the disputes between the civil powers and the papacy, and in the great theological controversies and long schisms that divided the church. It opposed the claims of ultramontanism, decided against the divorce of Henry VIII. from Catharine of Aragon, condemned the docrines of Luther, Calvin, Baius, Jansenius, and Quesnel, sustained the Catholic league against Henry of Navarre, and declared in 1588 that Henry III. had forfeited the crown. The Sorbonne was specially favored by Cardinal Richelieu, who rebuilt on a magnificent scale the college, lecture halls, and church, besides enlarging the library. The first works printed in France were from the presses of the Sorbonne. These were established in 1469 by Jean de la Pierre, prior of the Sorbonne, and Guillaume Fichet, rector of the university. In 1470 they published *Gasparini Pergamensis Epistolarum Liber*, followed by other publications in Latin, French, Greek, and Hebrew. The Sorbonne was suppressed in 1789, and at the organization of the modern university of France by Napoleon I. its buildings became the seat of the faculties of science, letters, and theology of the *académie universitaire;* but the faculty of theology is scarcely a shadow of its predecessor.

**SOREL,** a town and the capital of Richelieu co., Quebec, Canada, on the E. bank of the Richelieu river, at its mouth in the St. Lawrence, 45 m. below Montreal; pop. in 1861, 4,778; in 1871, 5,636. It occupies the site of a fort built by the French in 1665, and was for many years the summer residence of the governors of Canada. Nearly all the shipping plying between Quebec and Montreal winters here. Ship building is largely carried on. The town contains manufactories of engines, mill machinery, stoves, ploughs, leather, bricks, &c., several saw and grist mills, two branch banks, a tri-weekly (French) and two weekly (one French) newspapers, a monthly periodical (French), and three or four churches.

**SOREL, Agnes.** See AGNES SOREL.

**SORGHUM,** a genus of grasses, of the tribe *andropogoneæ*, and by some authors included in *andropogon*. In grasses of this genus the flowers are in open panicles, the spikelets two or three together, the lateral ones sterile, or reduced to mere pedicels, the central or terminal one fertile; the stems not hollow, as in most grasses. A single species, *S. nutans*, known as Indian grass and wood grass, having a stalk 3 to 5 ft. high, and a panicle of shining russet-brown flowers, is common throughout most of the states. The name sorghum is in

common use for a sugar-producing grass which is a variety of *S. vulgare.* Sugar cane, *saccharum officinarum*, is a grass closely related to *sorghum*, and neither plant is known in the wild state. The common sorghum, *S. vulgare*, is a poorly defined species, and presents varieties so marked that, did not intermediate forms connect them, it would be difficult to regard them as belonging to the same species. One form, known as Indian millet, and in the East as *durra*, is cultivated in southern Europe, and in Asia Minor, India, and other parts of the East, where it takes the place of the cereals of northern climates; the abundant round, hard seeds afford a very white flour, which makes good bread; the seeds are also used for feeding domestic animals. In the West Indies it is cultivated as food for laborers under the name of Guinea corn, but the grass called by that name in our southern states belongs to a different species. The Indian millet is sometimes cultivated in this country as food for poultry; half a century ago it was introduced as chocolate corn, its seeds being roasted and used as a substitute for coffee; and the seeds are sometimes offered by speculators as Egyptian wheat, or with some other attractive name, at high prices. Another variety, with long straight branches to the panicle and small seeds, is the broom corn. The variety generally known as sorghum (also called sorgho and Chinese sugar cane) is *S. vulgare*, var. *saccharatum*, and is remarkable for its very sweet juice; this has been in cultivation in China, and especially in Africa, from very early times; in Africa, where it is called *imphee*, there are numerous subvarieties known to the natives by such names as *vim-bis-chu-a-pa*, *nee-a-za-na*, *oom-see-a-na*, &c., differing in size, productiveness, and shape of seed cluster, much as do our varieties of maize. An attempt was made to introduce sorghum into Europe as early as 1786, by Prof. Arduino of Florence, but it did not receive much attention until 1851, when Count de Montigny, French consul at Shanghai, sent seeds to Paris; it is said that only one seed out of this lot germinated, and the product of this supplied all the seed sown at first in Europe and America. In 1856 some of this seed was obtained from France by the United States patent office, and distributed; but a much greater dissemination was made by Mr. Orange Judd of New York, who imported a large quantity and distributed 25,000 packets to the subscribers to his paper, the "American Agriculturist," in all parts of the country. In 1857 Mr. Leonard Wray, an Englishman, arrived in New York with the seeds of several varieties of imphee from the south of Africa, some of which are named above; they were tested by several persons, especially in the southern states, and were found to be a promiscuous and carelessly collected lot, which at once brought all kinds of imphee into disrepute; and though one or two selections from these varieties have been cultivated, the main crop is of the Chinese variety. The plant grows from 8 to 18 ft. high, and before the seed cluster shows has much the appearance of maize. In some varieties the branches of the panicle are long, slender, and spreading, in others short and erect, and in some long and drooping to one side; the color of the seed varies from white, through shades of brown, to nearly black; in the true Chinese the panicle is pyramidal, with long, not crowded branches, and the clear brown seeds enclosed in a shining black hull. It will grow wherever Indian corn can be cultivated, but it does not usually ripen its seeds

Chinese Sugar Cane (Sorghum vulgare, var. saccharatum).

north of lat. 41°; it does best on a light warm soil, which should be well fertilized, but not with coarse manures: it is sown in drills or in hills the same as corn, and the crop should be kept clean in the same manner; the plants when they first come up are small, and may be mistaken for some worthless grass. The stalks are cut up at the ground before hard frosts, stripped of their leaves by the use of a fork or machine made for the purpose, and taken to the mill, or stored until they can be pressed. Its sugar, at least soon after pressing, is almost wholly a form of glucose, and the yield of cane sugar, at least in the plant as

grown in this country, is much too small to make its extraction profitable; and the plant is now cultivated for the sirup or molasses. Well ripened canes yield about one half their weight in juice, of which from 5 to 10 gallons, according to the soil and climate, will make one gallon of sirup; the yield of sirup averages from 150 to 175 gallons to the acre, though in exceptional cases the returns are much larger. The sirup varies, according to the care and skill given to its manufacture, from a dark greenish brown color with a repulsive grassy flavor, to a fine amber-colored, honey-like fluid, which, having no characteristic flavor, is preferred by many to any other sirup. The evaporators now in use allow the juice to be concentrated without undue exposure to heat, while the scum is readily removed; lime is used in correcting the acidity of the juice, which for the finest product is filtered through animal charcoal. The total production of sorghum molasses in the United States was 6,749,123 gallons in 1860, and 16,050,089 in 1870. Of the latter amount Indiana produced 2,026,212 gallons, Ohio 2,023,427, Illinois 1,960,473, Kentucky 1,740,453, Missouri 1,730,171, Tennessee 1,254,701, and Iowa 1,218,635. As fodder it is not always relished by cattle, and it is now regarded as less valuable than maize. The seeds are fed to poultry, cattle, and hogs, and bread has been made from the flour. The begasse, or refuse from the press, has been used to make the coarser kinds of wrapping paper; the scum and washings of the evaporators are converted into vinegar. In France sorghum has been cultivated as a source of alcohol.

**SORIA.** **I.** A N. province of Spain, in Old Castile, bordering on Burgos, Logroño, Saragossa, Guadalajara, and Segovia; area, 3,836 sq. m.; pop. in 1870 (estimated), 158,699. Mountains border three sides, and the surface is broken. The Douro rises near the N. boundary, and flows first mainly S. and then W. into the province of Burgos. There are large forests of pine, oak, and beech. The roads are mere tracks, only practicable for mules. **II.** A city, capital of the province, on an irregular eminence on the right bank of the Douro, 113 m. N. E. of Madrid; pop. about 5,500. It is surrounded by old walls. The site of ancient Numantia is supposed to have been a few miles N. of Soria, but no positive traces of it remain.

**SORREL,** the plant *rumex acetosa*, a native of Europe, Asia, and arctic America, which has long been in cultivation. The genus *rumex* (the ancient Latin name) belongs to the *polygonaceæ* or buckwheat family, and consists of more than 100 species, several of which, either indigenous or introduced, are found all over this country and are popularly known as docks. Sorrel is a perennial, with a tuft of radical leaves which are 4 in. or more long, and arrow-shaped at the base; its flower stalks are 2 ft. or more high, bearing leafless panicles of unisexual, diœcious, or sometimes monœcious flowers, which are apetalous, small, and greenish, often turning red; the calyx deeply six-cleft, the three inner segments en-

Sorrel (Rumex acetosa)—the variety called "Belleville."

larging in fruit, orbicular, and somewhat petal-like, enclosing the triangular nut. The leaves are pleasantly sour, owing to the presence of the acid oxalate of potash. In France half a dozen varieties of this are cultivated, of which the Belleville is the most popular. Though sorrel is rarely eaten by the English, the French regard it as one of the necessaries of life. It is used in salads and in soups, but more commonly it is dressed in the same manner as spinach; if too strongly acid when pure to suit the taste, it is mixed with spinach or patience dock. While it is comparatively little known in this country, its use is increasing, and it is now quite regularly found in the markets.—Sheep sorrel belongs to the

Sheep Sorrel (Rumex acetosella).

same genus, and is *R. acetosella*, introduced from Europe, and one of the well known weeds of agriculture; it grows from a few inches to a foot or more high; the lower leaves are

halberd-shaped; its diœcious flowers in slender panicles, the fertile ones turning reddish. The herbage of this is also sour, and where it is abundant and luxuriant is sometimes used by Europeans as a substitute for the garden sorrel; children often eat the pleasantly sour leaves. In some countries the juice of this, as well as of the preceding, is used to curdle milk. As a weed the plant is most abundant upon worn-out soils. Wood sorrel is described under OXALIS. (See also TREE SORREL.)

**SORRENTO** (anc. *Surrentum*), a city of S. Italy, in the province, on the S. side of the gulf, and 16 m. S. E. of the city of Naples; pop. about 4,300, besides many strangers attracted by the climate and the picturesque situation. Deep ravines around the city are excavated in the volcanic tufa. In the vicinity are sea baths, curious grottoes, and relics of antiquity, the principal of which is a reservoir still used. Sorrento is the seat of an archbishop, and has a fine cathedral. The house in which Tasso was born, on the cliff overhanging the sea, is now a favorite hotel. Celebrated inlaid woodwork and silk and other goods are made here. —Under the Romans Surrentum was chiefly known as a fashionable resort, and for its pottery and medicinal wines. In A. D. 79 the eruption of Vesuvius caused great damage to it. In the middle ages it had considerable commerce. The geology of Sorrento has been described by Puggaard (Copenhagen and Leipsic, 1858).

**SOTHERN, Edward Askew**, an American actor, born in Liverpool, Eng., April 1, 1830. He first appeared on the stage in the United States as Dr. Pangloss at the Boston National theatre, in September, 1852. He was a stock actor in Barnum's museum, New York, till 1854, when he joined Wallack's company. For years he was known as Douglas Stewart, and it was not till 1858 that he used his own name. On Oct. 18, 1858, in Tom Taylor's comedy "Our American Cousin," the character of Lord Dundreary was assigned to Sothern. The part as originally written consisted of a few lines, and was assumed by Sothern under protest; but his lisp, drawl, peculiar skip, and many absurdities were very successful, and the part being enlarged, the play ran for 140 consecutive nights. On Nov. 11, 1861, he appeared as Lord Dundreary at the Haymarket theatre, London, and repeated the part 496 consecutive nights. He returned to the United States, and for many months performed Dundreary in the leading cities. On Oct. 10, 1874, he reappeared in the Haymarket, and during a short engagement presented the part of "Brother Sam," written for him by John Oxenford. He returned to New York for the season of 1874-'5, playing Dundreary and Garrick in Wallack's theatre.

**SOTO.** See DE SOTO.

**SOTWELL, Nathaniel.** See SOUTHWELL.

**SOUBISE. I. Benjamin de Rohan**, seigneur de, a French soldier, born in La Rochelle in 1583, died in London, Oct. 9, 1642. He was a son of René II. de Rohan by Catharine Parthenay, the heiress of the house of Soubise, and the brother of Henri de Rohan (1579-1638), the celebrated Huguenot leader. After serving in Holland under Maurice of Nassau he was appointed in 1621, by the Protestant assembly at La Rochelle, commander of Poitou, Brittany, and Anjou. When the other chiefs had laid down their arms, he boldly but unsuccessfully defended St. Jean d'Angély; and his attempts to renew the war during the winter of 1622, and his mission to England to obtain help from James I., were equally abortive. In 1625, after taking a royal squadron and keeping at bay for several weeks the united French and Dutch fleets, he was defeated by Duke Henry II. of Montmorency and driven from the islands of Ré and Oléron (Sept. 15), which he had occupied for some time. Having secured through the medium of Charles I. the hollow peace of April 6, 1626, he joined in 1627 the English in the fruitless attempt to relieve La Rochelle, and some time after the surrender of that stronghold he went to England, although permitted to remain in France. He was buried in Westminster abbey. **II. Charles de Rohan**, prince de, a French soldier, a descendant of the preceding, born in Paris, July 16, 1715, died there, July 4, 1787. He was notorious for his dissipation, and was a favorite of Louis XV. and his adjutant in Flanders, where he was appointed governor in 1748. In 1751 his governorship was extended over Hainaut. Through the influence of Mme. de Pompadour he became in 1753 allied to the royal family by the marriage of his daughter to the prince de Condé, who obtained for him a high command in the army of the Rhine (1756). He was surprised and routed at Gotha with 8,000 men by Seydlitz with 1,500 troops, and soon afterward he was ignominiously defeated by Frederick the Great at Rossbach (Nov. 5, 1757), where he commanded the united French and allied armies. Nevertheless he was appointed to other high commands and offices, and after varied successes and quarrels with fellow commanders, especially with the duke de Broglie, over whom he triumphed through his influence at court, his career in the army ended disastrously with his loss of Cassel, Nov. 1, 1761.

**SOULANGES**, a W. county of Quebec, Canada, on the N. bank of the St. Lawrence, above Montreal; area, 137 sq. m.; pop. in 1871, 10,808, of whom 9,724 were of French and 732 of Scotch origin. It is traversed by the Grand Trunk railway. Capital, Coteau Landing.

**SOULE, Joshua**, an American clergyman, born in Bristol, Me., Aug. 1, 1781, died in Nashville, Tenn., March 6, 1867. He was licensed to preach in 1798, joined the Methodist conference in 1799, was ordained in 1802, and in 1804 appointed presiding elder of the Maine district, which embraced 13 circuits and one station. In 1808, at the general conference in Baltimore, he drew up the plan of a delegated general conference which now appears in the "Discipline." After presiding over various

other districts in Maine and Massachusetts, he was elected in 1816 book agent and editor of the "Methodist Magazine." In 1820 he was stationed in the city of New York; in 1821 he was preacher in charge of the station in that city, and in 1822–'3 of the Baltimore city station. In 1824 he was elected bishop. He was delegate from the general conference to the British Wesleyan Methodist conference in 1842; and afterward he travelled extensively in the British islands and in France. On the division of the church, Bishop Soule adhered to the southern portion, and removed from Lebanon, O., to Nashville, Tenn. In 1853–'4 he made an episcopal tour in California.

**SOULÉ, Pierre,** an American statesman, born in Castillon, France, in 1801, died in New Orleans, March 16, 1870. He studied in the Jesuits' college at Toulouse, was implicated in a plot against the Bourbons, fled to a village in Navarre, and became a shepherd. He was afterward an advocate in Paris, and for an attack upon the ministry in the *Nain* newspaper he was fined 10,000 francs and sentenced to prison. He escaped to England, and in 1825 emigrated to New Orleans, where he rose to eminence at the bar. In 1847 he was elected United States senator from Louisiana to fill a vacancy, and in 1849 was reëlected for a full term. In 1853 he was appointed minister to Spain, where he fought a duel with M. Turgot, the French ambassador, and wounded him. He participated in the Ostend conference in 1854 (see BUCHANAN, JAMES), and came home in 1855. In 1861 he visited Europe as diplomatic agent of the confederate government, and in 1862 was arrested in New Orleans by Gen. Butler, and imprisoned, but was released on condition of leaving the country. He returned to New Orleans shortly before his death.

**SOULIÉ, Melchior Frédéric,** a French novelist, born at Foix, Dec. 23, 1800, died at Biévre, near Paris, Sept. 23, 1847. He was expelled from the law school in Paris on account of his radicalism, and after publishing in 1824 *Amours français*, an unsuccessful volume of poems, he supported himself as the foreman of an upholsterer till 1828, when his drama *Roméo et Juliette* proved successful at the Odéon. Most of his subsequent pieces failed, excepting *Clotilde* in 1832. He achieved greater celebrity as a novelist, especially by *Diane et Louise* (1836), which he dramatized under several titles. He published more than 150 volumes of novels, including *Le maître d'école* (1839), *Si jeunesse savait, si vieillesse pouvait* (1842), and his *Mémoires du diable* (1844), which had a prodigious circulation. His monument in Père Lachaise was unveiled Feb. 20, 1875.

**SOULOUQUE, Faustin,** a Haytian emperor under the title of Faustin I., born in the district of Petit Goave, in the southern peninsula of Hayti, about 1785, died there in July, 1867. He was born a slave, but became free by the decree of 1790, took part in the negro insurrection against the French in 1803, served as captain under President Boyer in 1820, as colonel under Hérard in 1844, as brigadier general under Guerrier in 1845, and was commander of a division at the time of the death of Riché in February, 1847. While the generals Souffran and Paul were disputing and plotting for the succession, the senate unexpectedly elected Soulouque to the presidency, March 1, 1847. He belonged to the party of the mulattoes, but, jealous of their power, he began to attach the blacks to his interest, and to pursue a system of terror toward the citizens, whom he decimated in 1848 by confiscations, proscriptions, and executions. Like his predecessors he vainly sought to subjugate the republic of Dominica. In 1849 he caused the restoration of monarchy, ostensibly by the will of the people and the action of the chambers, was almost unanimously chosen emperor (Aug. 26), assumed the title of Faustin I., surrounded himself with a numerous court, founded a military and civil order and an order of nobility, and issued a constitution, reserving to himself the right at any juncture to rule as he pleased. He was crowned in 1850, and a second time, with greater pomp, on April 18, 1852. In 1855 he repeated his attempt to conquer the neighboring republic, and took the field with a considerable army, but was so completely defeated by a few hundred Dominicans under Santana that he barely escaped capture, and his treasure and throne fell into the hands of the enemy. A campaign in the following year also terminated in his defeat. A commercial crisis in 1858 increased the general discontent, and Gen. Geffrard led a revolt, and was recognized as president of the republic of Hayti. Soulouque was, however, allowed to depart (Jan. 15, 1859) with his wife and child for Jamaica. After the fall of Geffrard in 1867, he returned to Hayti.

**SOULT, Nicolas Jean de Dieu,** duke of Dalmatia, a French soldier, born at St. Amans-la-Bastide, Guienne, March 29, 1769, died there, Nov. 26, 1851. He enlisted in 1785, became a captain in 1793, and reached in one year the rank of brigadier general after the battle of Fleurus (June 26, 1794). In 1799 he was made general of division by Masséna, with whom he distinguished himself at the battle of Zürich, Sept. 25, which saved France from invasion, and at the siege of Genoa, during which he was surrounded and captured by the Austrians, May 15, 1800, but was speedily exchanged, after the battle of Marengo. In 1804 Napoleon made him a marshal. In 1805 he increased his reputation at the head of the fourth corps in Germany, especially at Austerlitz, Dec. 2, where Napoleon declared him to be the first strategist of Europe. In 1806–'7 he won additional fame in the campaign against Prussia, and finally occupied Königsberg (June 16, 1807), and after the treaty of Tilsit he was made governor of Berlin and duke of Dalmatia. Next appointed commander of the second corps in Spain, he nearly annihilated the Spanish army at Burgos,

Nov. 10, 1808, took from the English Corunna (where he had been at first defeated) and Ferrol, and occupied Oporto and the northern part of Portugal, whence he was expelled by Wellington. After his retreat to Spain he gained several advantages, and on March 11, 1811, he obtained possession of Badajoz through the treachery of the Spanish commander; but he was defeated by Beresford at Albuera, May 16, and Wellington carried Badajoz by assault with fearful loss on the night of April 6, 1812. Disapproving of King Joseph's proceedings, Soult asked to be relieved; but soon after reaching France Napoleon ordered him to assume the chief command of the army in Spain, and retrieve Joseph's crushing defeat at Vitoria, June 21, 1813. But despite his wonderful efforts, after various engagements in the mountain passes with the main body of the allies, he was cut off from Bayonne by Wellington, defeated at Orthez, Feb. 27, 1814, and forced back to Toulouse, which was taken by Wellington, April 10. Soult offered a heroic resistance, and consented only to an honorable capitulation after the full confirmation of Napoleon's first abdication, and led his troops safely out of the city. His conduct during this memorable campaign received the warm commendation of Napier, the English historian of the peninsular war; and when 26 years later Soult officially attended the coronation of Queen Victoria, he was most cordially received by Wellington and his other former adversaries. Under the first restoration he was for a short time minister of war; but as he rejoined Napoleon on his return from Elba, and served as major general at Waterloo, he was banished from 1816 to 1819. In 1820 he was reinstated as a marshal and received a pension of 200,000 francs, and in 1827 he became a peer. Under Louis Philippe he was minister of war in 1830–'31, prime minister in 1832–'4, and again (with the portfolio of foreign affairs in 1839–'40, and of war in 1840–'45) from 1839 till 1847, when the extraordinary title of marshal-general was given to him on his retirement. He left memoirs, of which only the first part was published (3 vols., 1854) by his son Napoléon Hector, who died in 1857.

**SOUND**, the sensation peculiar to the organ of hearing. This sensation is the final effect of a closely connected series of mechanical actions, which have their origin in some rapidly vibrating body, whence they are propagated progressively through the air to the membrane of the drum of the ear, and thence, through a series of small articulated bones, into the inner cavity. This cavity, tunnelled in the hard petrous bone, is filled with liquid and contains the delicate terminal fibrils of the auditory nerve. Each of these fibrils appears to be attached to the centre of a delicate rod or chord. These chords are stretched, and being of different lengths and diameters are generally supposed to be tuned to sounds extending through a range of several octaves. By the sympathetic vibrations of these tuned bodies they shake their attached nerve fibrils and thus give rise to sensations peculiar to sounds of various pitch. From the foregoing we see that the subject of sound is naturally divided into three parts. In the first division we shall consider the manner of production of sound, and the nature of those vibrations which cause sonorous sensations. In the second part we shall explain the manner in which these vibrations are propagated through the elastic medium existing between the vibrating body and the ear. In the third part we shall consider the manner in which the ear perceives a simple sound and analyzes a composite sound into its elementary sonorous sensations.—At the place of origin of every sound there is always some solid, liquid, or gaseous body in a state of rapid vibration. This vibrating body imparts its motions to any elastic medium with which it may be in contact, and the vibrations thus given to the contiguous medium are propagated in all directions. The contiguous elastic medium may be a solid, a liquid, or a gas. Proofs of the above statements are readily afforded by the following simple experiments. A sounding tuning fork is drawn over a piece of smoked glass, so that the point of a piece of foil, attached to one of its prongs, may just touch the glass. After this experiment we observe that the point attached to the fork has laid bare the glass in a sinuous line, as seen in fig. 1, thus showing that when the fork causes

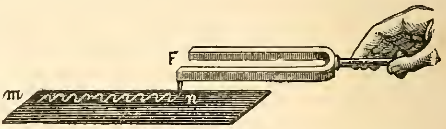


Fig. 1.

a sound its prongs are swinging to and fro in a direction perpendicular to its length. That a liquid may be the vibrating body at the source of the sound, is shown by placing a "siren" under water and forcing through it a current of water. If we take an organ pipe with glass sides and sprinkle in its interior a small portion of precipitated silica, we shall, on sounding the pipe, observe this very light powder rise in thin delicate vertical plates in certain portions of the pipe, while in intermediate places the silica remains at rest. Neither the tone of the pipe nor the positions of the plates of silica are altered in the least by pressure on the walls of the pipe; thus showing that the real vibrating body in an organ pipe is its contained column of air. It now remains to show that the medium through which the sonorous vibrations are propagated outward from the vibrating body may be either solid, liquid, or gaseous. One of the most beautiful experiments in acoustics was invented by Sir Charles Wheatstone, and shows that sounds, even the most complex, may be transmitted through solids as readily as through the air. In the lower

room of a house, or in a tightly closed box lined with felt, he placed a musical box. On the top of the musical box rests the end of a long light wooden rod which reaches to one of the rooms above. The rod is insulated from the floor of the rooms by India rubber. No sound is perceived in the upper room until we place on the top of the rod a violin, a guitar, or any instrument with a sounding board, when the sounds of the musical box fill the upper room and appear to emanate from the musical instrument on the rod. That a liquid may be the medium for the transmission of sonorous vibrations is readily proved by placing on a resonant box a long cylindrical vessel filled with water, and then bringing in contact with the surface of the water a disk of wood attached to the foot of a vibrating tuning fork. The vibrations of this instrument are sent through the water, and reaching the top of the resonant box throw the latter into vibrations of the same period as those of the fork. That the air, a gaseous body, vibrates while it is transmitting sonorous pulses, can be shown by placing in the path of these vibrations a delicate membrane strewn with a light dry powder. The powder dances on the membrane while the sound is perceived. The vibrations of the air can also be detected by means of the so-called "sensitive flames," which are formed of jets of gas, issuing from cylindrical orifices under such great pressure that they are just on the point of flaring, or roaring. These flames are so sensitive to aërial vibrations that the slightest sound, if of the proper pitch, will cause them suddenly to contract greatly in their lengths, and at the same time to give forth roaring sounds. These flames are generally most sensitive to acute sounds, such as a hiss or the jingling of a bunch of keys. (See PYROPHONE.)—An analysis of sonorous sensations reduces them to three kinds: pitch, intensity, and timbre. 1. *Pitch and the Determination of the Number of Vibrations of a Sounding Body.* Pitch is that quality of sound by which we distinguish the position of sounds in the musical scale. One sound is thus said to be higher or lower than another. Pitch depends on the number of vibrations in a second which enter the ear. The pitch rises with the increase of the number of vibrations. In England, Germany, and America a vibration is understood to be a motion to and fro, while in France it is a motion to or fro. The sound having the lowest pitch is caused by 40 vibrations in a second; a smaller number of vibrations than this does not cause a continuous sonorous sensation. The highest audible sound is caused by about 40,000 vibrations in a second; vibrations of greater frequency than this are not generally audible, though the limit of audibility of the highest sounds is different for different persons. Thus some cannot hear the chirrup of the cricket, while others perceive sounds one or two octaves above it. Dr. Wollaston discovered this variation. The pitch of a sound may be determined by several methods, some of the most precise of which are: 1. By means of an instrument called a "siren," fig. 2, invented by Cagniard de Latour. It consists of a metal cylinder the bottom of which is perforated by a tube through which air is blown into the cylinder. The top of the cylinder is perforated with a number of holes. Just over this top and nearly touching it rotates a metallic disk on a vertical axis. This disk is perforated with the same number of holes as are in the cylinder. The form of the holes is shown in the section in the figure. They do not pass perpendicularly through the plates, but

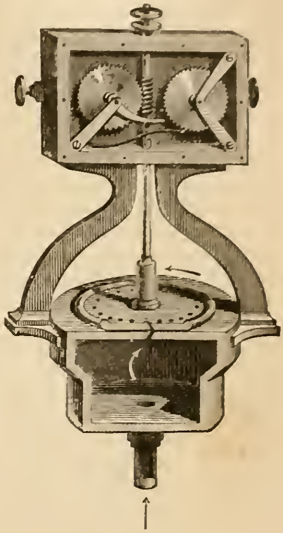

FIG. 2.

slope contrary ways, so that the air when forced through the holes in the top of the cylinder impinges upon one side of the holes in the rotating plate, and thus blows it round in a definite direction. The disk in making one revolution opens and shuts the holes as many times as there are holes in the disk and cylinder, and hence the wind escapes from the cylinder in successive puffs, the frequency of which depends upon the rate of rotation. A sound is thus produced having a pitch which rises with the increase of velocity of rotation. The vertical axis has a screw cut on it which works in a notched wheel attached to a dial, which shows the number of rotations of the disk. To determine the pitch of a sound by means of this instrument, we gradually increase the rotation of the disk until the sound emitted approaches the pitch of the sound the number of vibrations of which we would determine. When the two sounds are quite near in pitch, the ear will perceive distinct beats produced by the joint action of the two sounds on the air. The velocity is now cautiously increased until the beats disappear. At this moment the counter is put in operation, and the disk is allowed to run for a known number of seconds; then the counter is thrown out of action and the number of revolutions of the disk read off. On multiplying the number of revolutions of the disk by the number of its holes, and dividing this product by the number of seconds during

which the disk was connected with the counter, we have the number of vibrations per second corresponding to the given sound. 2. The number of vibrations per second of a tuning fork, or of any rod or plate, can be determined very precisely by the following plan. The tuning fork or rod has attached to it a piece of delicate foil, which just touches the smoked surface of paper covering a metallic cylinder. If the cylinder is turned while the fork vibrates, it is evident that the point attached to the fork will trace a sinuous line on the cylinder. Now, if by any means we can mark off seconds of time on this sinuous trace, we shall have only to count the number of sinuosities between two successive second marks to have the number of swings made by the fork in a second. The above conditions are attained in the following manner: A break-circuit clock is placed in the primary or battery circuit of an induction coil; one of the terminal wires of the secondary circuit of this induction coil is connected with the tuning fork, while the other terminal wire is connected with the revolving cylinder. At each second the break-circuit clock sends a spark from the point attached to the vibrating point, through the smoked paper, to the revolving metallic cylinder. It is evident that on counting the number of flexures contained between two successive spark holes in the fork's trace we have the number of half vibrations made by the fork in a second. When we have thus determined the exact number of vibrations, at a known temperature, given by a tuning fork, we may use the number of vibrations of this fork as a point of departure in determining the number of vibrations of any rod, plate, chord, or membrane, by means of a very simple and ingenious method recently devised by Prof. O. N. Rood, and described by him in the "American Journal of Science," August, 1874. Let us suppose that it is required to ascertain whether two tuning forks are in unison, or to determine the difference in the number of vibrations executed by them in a second. For this purpose a short piece of fine steel wire is attached to each of the forks, and they are supported in positions so that their vibrations shall be at right angles to each other, as indicated in fig. 3. The wires may have a diameter of one or two tenths of a millimetre, or even less, and are to be attached with the least possible amount of soft wax or varnish. They may be brought quite near to each other, or may if necessary be several inches apart. If the forks are now set into vibration and the intersection of the wires viewed against a bright background with a small telescope, it will be seen that an optical figure is developed, which is partly due to the same well known conditions that give rise to the acoustic figures of Lissajous, and partly to the circumstance

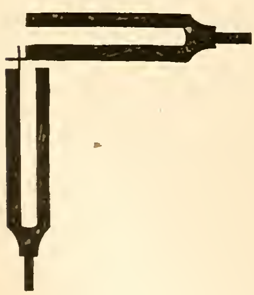

Fig. 3.

Fig. 4.

Fig. 5.

that the wires move with less velocity when near their maximum deviation from the line of rest. Hence, if the difference in phase is zero, an appearance like fig. 4 is produced, which changes into fig. 5 when the difference in phase has increased to one half a complete vibration. Fainter indications of the same figures are shown in all cases, except when the difference in phase is one fourth, three fourths, &c., of a vibration, or nearly so. This figure is characteristic then of forks in unison, and the fact of its constancy will be the evidence of perfect unison. If the forks are not exactly in unison, fig. 4 will after some time change into fig. 5, and the number of seconds necessary for this change will measure the interval required by one of the forks in gaining or losing half of a complete vibration. The focal length of the object glass of the telescope used was 120 millimetres for parallel rays, and when the aperture was reduced to two millimetres, sufficiently distinct vision of both wires could be obtained, even when their distance apart was several centimetres. With this limited aperture, the light from a white cloud answered quite well. If the forks differ by an octave, an almost equally distinct and well marked figure will be produced, such as is seen in figs. 6 and 7, which represent the characteristic appearances in this case. This figure is quite as useful for purposes of investigation as for that of unison. Somewhat less distinct and more complicated figures are given by the quint, the duodecime, and the double octave. From the foregoing it is evidently easy with this method to bring a vibrating string into

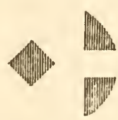

Fig. 6.

Fig. 7.

unison with a given tuning fork, or to adjust it so that the interval shall be a quint, octave, twelfth, or double octave, above or below. It is also easy to ascertain the number of vibrations made by a string in a given case, by the aid of a bridge and a properly selected fork making a known number of vibrations, the string being shortened till it furnishes one of the above mentioned figures, and therefore

executes a known number of vibrations, after which the number of vibrations made by its whole length can readily be calculated by a well known law. 3. The following method of determining the number of vibrations of a sounding body is applicable to all cases, whether the body be solid, liquid, or gaseous. After we have determined, by the method already described, the precise number of vibrations of a given fork, we make another fork higher in pitch than the former, which makes with the first eight beats a second; a third fork is then tuned until it gives eight beats with the second fork, or sixteen with the first. Thus a series containing many forks is formed, any fork of which makes eight vibrations more in a second than the fork next below it in pitch. On each fork is stamped its number of vibrations. To determine with these forks the pitch of a given sound, we find in the series of forks one which makes with this sound eight beats or fewer than eight beats in a second, and we count the number of these beats given during one minute or more. Dividing the number of beats found by the number of seconds during which the observation lasted, we have the number of beats made in one second by the fork and the given sound, and as the number of beats per second is always equal to the difference in the number of vibrations per second of the two sounds, it follows that we at once know how many vibrations per second the fork exceeds or falls short of those of the sound. To ascertain whether the fork makes more or less than the sound in a second, we place a small piece of wax on a prong of the fork, and observe whether this causes the number of beats to increase or to diminish. If the number of beats increases, then the fork was lower in pitch than the sound, while if the beats are less frequent the fork was higher in pitch than the given sound. The series of forks just described is called after its inventor a Scheibler's tonometer. 2. *The Intensity of Sound.* The intensity of sound depends on the energy of the aërial vibrations contiguous to the ear. For sounds of the same pitch the intensity varies as the square of the amplitude of the aërial oscillations. The plans generally used are unworthy the designation of measures, being only rough comparisons. The writer first succeeded in measuring the relative intensities of sounds of the same pitch, and the reader is referred to the publication on the subject in the "American Journal of Science" for February, 1873. The principle of the method depends on the fact that if two sonorous impulses meet in traversing an elastic medium, and if at their place of meeting the molecules of the medium remain at rest, then at this place of quiescence the two impulses must have opposite phases of vibration and be of equal intensities. By means of an appropriate apparatus the above conditions are brought about in the union of the two sounds whose intensities we would compare. We then measure the distances from the place of meeting of the two sounds to the points of origin of these sounds. The relative intensities of the sounds will be as the inverse ratio of the squares of these distances. But to determine the relative or absolute intensities of sounds of different pitch is one of the most difficult of experimental problems. The writer has recently succeeded in reaching approximate measures of the absolute intensities of sounds by measuring the amounts of heat produced when the sound vibrations are absorbed by India rubber. By knowing the exact fraction of the whole energy of the sound absorbed and the specific heat of the rubber, the mechanical equivalent of the entire sonorous vibrations, in fractions of a Joule's unit, can be calculated. It was thus shown that the aërial vibrations produced by a treble C fork, mounted on its resonant box and vibrated during ten seconds, will, if entirely converted into heat, raise the temperature of one pound of water $\frac{1}{100,000}$ of a degree; or, in mechanical effect, will raise 54 grains one foot high. 3. *Timbre of Sound, and Analysis of Sounds.* Timbre is a term used to designate those special characters by which we distinguish between two or more sounds having the same pitch and equal intensities. Thus, sounding the same note on a flute, a violin, a clarinet, and a piano, the ear at once distinguishes the instrument producing the note. Some preliminary knowledge as to the differences between a simple and a composite sound is necessary before giving an explanation of the cause of timbre. A simple sound is a sound which has only one pitch. Such a sound is produced when a tuning fork, mounted on a resonant box, is gently vibrated by drawing a bow across one of its prongs. All simple sounds are alike in timbre; the only differences existing between them are differences of pitch and of intensity. Thus, if simple sounds alike in pitch and in intensity were produced by four instruments differing even very much in construction, the ear could not give us the information by which we could distinguish one instrument from another. On examining closely into the nature of the aërial vibrations which produce a simple sonorous sensation, we find that this sensation is only experienced when the aërial particles swing to and fro with the same character of reciprocating motion as pertains to a freely swinging pendulum. But there are other sounds which are not simple but composite, being formed of the combination of several simple sounds of various pitch and intensities. Thus, by attentive listening one can distinguish several sounds of various pitch in the sound of a piano string, or in that of a reed organ pipe. On analyzing these composite sounds, by methods presently to be described, we find that they can always be separated into two or more simple sounds, and that if we call the number of vibrations producing the lowest in pitch unity, then the remaining sounds will, in order of ascending pitch, bear to the first the vibration ratios of

1 : 2, 1 : 3, 1 : 4, 1 : 5, &c. The lowest sound perceived is generally the most intense, and is called the "fundamental." This is the sound which is indicated in musical notation, and which designates the pitch of the composite sound. But really when we produce one of the sounds indicated by musical notation, we generally at the same time evolve a long series of sounds bearing to each other the vibration relations of 1, 2, 3, 4, 5, 6, &c. This series of sounds is called the harmonic series, and is sometimes designated as the series of overtones of the fundamental sound. But the members of this series do not always all coexist; thus the sounds of the clarinet only contain the odd numbers of the series, viz., 1, 3, 5, 7, &c. It is evident from the above facts that an indefinite number of different composite sounds can be formed by combining simple sounds and giving to them various relative intensities; and that each of these composite sounds will be characterized by its own peculiar timbre. This great discovery, that all simple sounds have one and the same timbre, and that the characteristic timbre of any other sound is due alone to the number and relative intensities of the harmonics or overtones forming the sound, was made by Helmholtz; he not only succeeded first in proving this by the experimental analysis of various composite sounds, but also by reproducing these composite sounds with their characteristic timbres by simultaneously sounding their simple sonorous components with their proper relative intensities. This explanation of timbre, as Helmholtz has shown, has a dynamic basis, and is the direct consequence of the celebrated theorem of Fourier, which may thus be rendered in the language of dynamics: Every periodic vibratory motion can always, and always in one manner, be regarded as the sum of a certain number of pendulum vibrations.—There are various methods of analyzing a composite sound. They are generally founded on the fact that if we have two bodies which give exactly the same number of vibrations in a second, and vibrate one of them, the other, although somewhat distant from the first, will be thrown into vibration by the action of the aërial pulses which have emanated from the first body. This must necessarily follow, for the pulses which the second body receives from the air synchronize with the number of vibrations in a second which this body alone can give. This phenomenon may be called "co-vibration." Helmholtz in his investigations generally used as co-vibrating bodies masses of air contained in hollow spheres of various sizes. These spheres are called resonators, and one of them, as made by König of Paris, is shown in fig. 8. These spherical masses of air are so graduated in volume that a series of resonators is formed, and each resonator will resound only to the number of vibrations in a second which is stamped on it. The manner of using these resonators is as follows: The compound sound falls upon the open mouth of the resonator, while the nipple-shaped tube opposite the mouth is placed in one ear, and the other ear is closely stopped with beeswax. If the sound, to which the

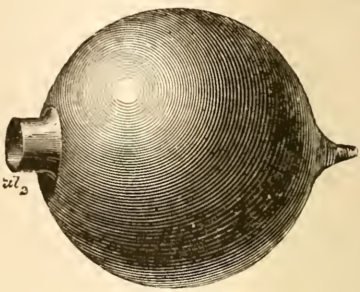

FIG. 8.

mass of air contained in this resonator enters into co-vibration, exists in the composite sound, then the ear will perceive this sound with some intensity, to the exclusion of the other component sounds. Thus by placing to the ear each resonator of the series and noting those which resound, we can readily ascertain the simple sounds, whose union forms the composite sound which we have analyzed. The writer has often replaced the resonators applied to the ear by tuning forks mounted on resonant boxes. If the mouth of one of these boxes, like fig. 9, be placed near a sounding reed pipe, and if the note of the fork on the resonant box exists in the composite sound of the reed, then this fork will be set in vibration and will continue to vibrate after the reed has ceased to sound; for the mass of air in the box acts like a resonator, and is set in vibration by the pulses of that harmonic of the reed which is in unison with it. But, as the fork is also in unison with the mass of air in the resonant box, it follows that it also is set in motion by the latter, so that, after the composite sound ceases, we find that the fork sings out alone, and thus shows that it has selected from a chorus of harmonics that one

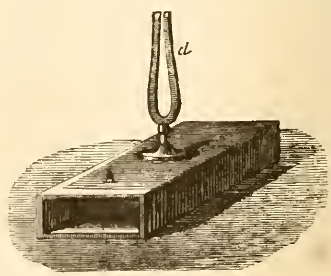

FIG. 9.

which is in unison with its own tone. It has thus been easy, by using one fork after another of the harmonic series of the reed, to show the composition of its sound to a

large audience. We have also succeeded with the following experiment. Forcibly sound the reed pipe and place around its mouth eight or more forks of the harmonic series of the sound given by the reed, with the mouths of their resonant boxes toward the reed pipe. After the reed has sounded for a few seconds, stop it, and we shall find that all of the forks are in vibration; and thus singing together, they approximately reproduce the sound of the reed. This experiment requires the resonant boxes, the forks, and the harmonics of the reed to be in exquisite unison. The reader may convince himself of the composite nature of the sound given by a piano string, by the following simple experiments. If we sound on the piano the C below the middle or treble C, if we call this note $C_2$, the harmonics of this sound will be $C_3$, $G_3$, $C_4$, $E_4$, $G_4$, $B\flat_4$, $C_5$, &c. But the seventh harmonic, or $B\flat_4$, is wanting, because the hammers of the piano strike the strings at points about one seventh of their length, and hence this harmonic cannot appear. If it did, it would cause harshness of timbre, for the seventh harmonic forms dissonant combinations with the other harmonics of the series. To show that all of the remaining harmonics exist in the sound of $C_2$, depress slowly and firmly the key of $C_3$; the hammer will rise, press against the string, and fall from it, but the damper of this string will remain raised. Now strike strongly the key of $C_2$, and after holding it for a few seconds stop its sound. We shall now hear the sound of $C_3$ very distinctly, showing that it has been set into vibration by the vibrations of $C_3$ which exist in the compound sound designated as $C_2$. In like manner one can show that $G_3$, $C_4$, $E_4$, $G_4$, $C_5$, &c., exist as components of the composite sound of the string of $C_2$. The reader who desires further information on the subject of sonorous analysis will find descriptions of six experimental methods in "Researches in Acoustics," paper No. 5, "American Journal of Science" for August and September, 1874. —*Reproduction of Sonorous Vibrations from the Curves made by Vibrating Bodies.* Experiment has established that the sensation of a simple sound is alone produced when the aërial molecules vibrate with the same reciprocating motion as pertains to a freely swinging pendulum. If we obtain the sinuous trace of a vibrating tuning fork or of a long elastic rod on a plate of smoked glass, fig. 10, we shall find, on making measures on these curves, that they are sinusoids or curves of sines, and hence can alone be produced by pendulum motions. But the curve produced by the fork can be made to reproduce the motions of the fork, only much slower, in the following manner: Cut a fine slit in a piece of paper, and slide it over the curve from right to left, as shown in fig. 10; then we shall see the portion of the curve exposed in the slit vibrating upward and downward with the same kind of motion as rules the oscillations of a pendulum. The aërial molecules and a point on the membrane of the drum of the ear vibrate thus when we experience the sensation of a simple sound. The majority

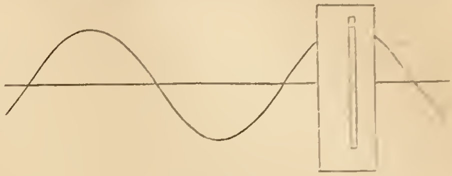

FIG. 10.

of sounds, however, are composite. It is evident that a molecule of air or a point on the tympanic membrane can have only one direction of motion at one and the same instant, and therefore that a composite sonorous vibration will give to the molecule of air a motion which must be the resultant of the combined motions of all the pendulum motions of its simple sonorous components. Hence we may suppose a molecule of air, animated with a resultant motion like the above, to trace a curve which evidently will be the resultant of all the simple sinusoidal curves belonging to the sonorous elements of the composite sonorous vibration. We can obtain this resultant curve as follows, and then we can reproduce from it the motions of a molecule of air, or of a point on the tympanic membrane, when these points are acted on by a compound sonorous vibration. Draw on the axis *a b*, fig. 11, sinusoidal curves having lengths related to each other as 1 : 2 : 3 : 4 : 5 : 6. These curves will then be the separate traces of the first six harmonics contained in a composite vibration which causes a musical sound, such as the sound of a piano string. Another axis *c d* is now drawn below *a b*, and 500 equidistant lines, perpendicular to *a b* and *c d*, are drawn through the curves on *a b* and extended below the line

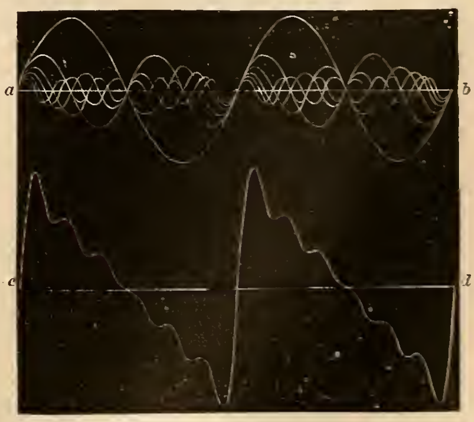

FIG. 11.

*c d*. The algebraic sums of the ordinates of the curves on *a b* are now transferred to the corresponding ordinates on *c d*, and through

points thus found is drawn the curve having the line $c\,d$ for its axis. This curve may be regarded as the trace of the composite vibration of a molecule of air, or of a point of the tympanic membrane, on a surface which moves near these points. Hence if we slide this curve along, in the direction of its axis, under a slit in a screen which allows only one point of the curve to appear at once, we shall reproduce in this slit the vibratory motion of the aërial molecule and of the point on the tympanic membrane. The writer has exhibited this motion in a continuous, or rather recurring manner, as follows: On a piece of Bristol board he drew a circle, and in one quadrant of this circle he drew 500 equidistant radii. On these radii, as ordinates, he transferred the corresponding values of the same ordinates of the resultant curve of fig. 11, diminished to one fourth of their lengths. He thus deflected the axis of the curve of fig. 11 into one fourth of a circle curve; and this, repeated four times on

FIG. 12.

the Bristol board, rendered the curve continuous and four times recurring, as shown in fig. 12. He now cut this figure out of the board and used it as a template. He placed the latter centred on a glass disk 20 in. in diameter. This disk was coated on one side with opaque black varnish, and with the template and the separated points of a pair of spring dividers he removed from the glass disk a sinuous band, as shown in fig. 12. The glass disk was now mounted on a horizontal axis and placed in front of a lantern, the diameter of whose condensing lens was somewhat greater than the amplitude of the curve. The image of that portion of the curve which was in front of the condenser was now projected on a screen, and then a piece of cardboard having a narrow slit cut in it was placed close to the disk, in the direction of one of its radii. On revolving the disk he reproduced on the screen the vibratory motion of a molecule of air, or of a point on the tympanic membrane, when these are acted on by the joint impulses of the first six harmonic or pendulum vibrations, forming a musical sound. On slowly rotating the disk one can readily follow the compound vibratory motion of the spot of light; but on a rapid revolution of the disk, persistence of visual impressions causes the vibrating spot to appear elongated into a band. This band is not equally illuminated; it has six distinct bright spots in it, beautifully revealing the six inflections in the curve. By sticking a pin in the centre of fig. 12, as an axis about which revolves a piece of paper having a fine slit, the reader can gain some idea of the complex motion we have described. Of course it is understood that in the above experiment the amplitudes of the vibrations are enormously magnified when compared with the wave lengths, and that it is really only when the amplitudes of the elementary pendulum vibrations are infinitely small that the resultant curves we have given can be rigorously taken as representing what they purport to; for the law of "the superposition of displacements" depends on the condition that the force with which a molecule returns to its position of equilibrium is directly proportional to the amount of displacement, and this condition only exists in the case of infinitely small displacements; yet the law holds good for the majority of the phenomena of sound. It is also to be remarked that in order to simplify the

FIG. 13.—Resultant Curve formed by combining the curve of a musical note with that of its octave. $\lambda : \lambda' :: 1 : \frac{1}{2}$.

consideration of the curves, they are all represented with the same phase of initial vibration. Of course the resultants have an infinite

FIG. 14.—Resultant Curve formed by combining the curve of a musical note with that of its fifth. $\lambda : \lambda' :: 1 : \frac{2}{3}$.

variety of form, depending on the differences in their initial phases, and on the amplitude of the harmonic elements. In figs. 13, 14, and

15, we have drawn the resultant curves formed by combining the curves of musical sounds corresponding to the various consonant intervals indicated below the figures. As these

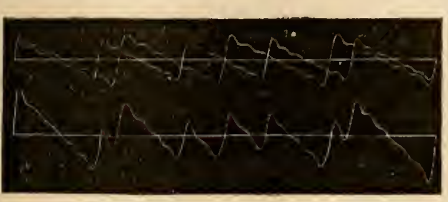

FIG. 15.—Resultant Curve formed by combining the curve of a musical note with that of its major third. $\lambda : \lambda :: 1 : \frac{4}{5}$.

curves are the resultants formed by the combination of the curves of composite musical sounds, it follows that the components of these curves are not simple sinusoidal curves, as in the case of fig. 11, but are derived from the resultant of fig. 11 by reducing to one fourth the amplitude of that curve, and by taking wave lengths corresponding to intervals indicated below the figures. From the curves of figs. 13, 14, and 15 can be reproduced their generating motions in the same manner as we have done in the case of the curve of fig. 11. As a periodic or recurring vibration can alone produce in the ear the sensation of sound, and as the duration of the period is always equal to the least common multiple of the periods of the pendulum vibrations of the components, it follows that in the case of a sound formed of a harmonic series the period equals the time of one vibration of the fundamental; but in the cases of other combinations the duration of the period increases with the complexity of the ratio of the times of vibration of the components; thus, the durations of the periods of the following combinations are placed after them in fractions of a second: $C_3+C_4=\frac{1}{256}$; $C_3+G_3=\frac{1}{128}$; $C_3+E_3=\frac{1}{64}$; $C_3+E_3+G_3=\frac{1}{25.6}$; $C_3+E_3+G_3+C_4=\frac{1}{17}$ of a second. ($C_3$ stands for the treble C; $C_4$ is the C of the octave above it.)—*Transmission of Sound.* If air were incompressible, a motion produced at any point of its mass would instantaneously be transmitted to every other point of the atmosphere. Thus, if we imagine a long tube, open at one end and closed at the other by a piston which moves in the tube without friction, it is evident that if this piston were pushed into the tube a certain distance, the air would at the same time move out of the tube at the open end. But air is compressible and elastic, and after the piston has been pushed into the cylinder, a measurable interval of time will have elapsed before the air moves out of the open end of the tube. This interval is the time taken by sound to traverse the length of the tube. The velocity of sound is 1,090 ft. in a second at 32° F., and it increases almost exactly one foot in velocity for each degree of elevation of temperature above 32°. Now imagine the piston to move forward into the tube over a minute fraction of an inch, and that it occupied $\frac{1}{10}$ of a second in making this forward motion; then the length of air compressed at the instant the piston has come to rest will be equal to $\frac{1090}{10}$, or 109 ft. If the piston makes its movement in $\frac{1}{100}$ and in $\frac{1}{1000}$ of a second, the length of air compressed in the tube will be respectively 10·9 and 1·09 ft. But such a compressed portion of air cannot remain at rest, by reason of its elasticity. It immediately expands, and in so doing presses forward on the undisturbed air in front of it and on the interior wall of the tube. The column of compressed air in thus regaining its natural density has compressed an air column of equal depth in front of it; this in its turn reacts on the back column and prevents it from rarefying, while at the same time it has compressed another column of equal depth in front of it, and so on. Thus the sonorous pulse, as it is called, is transmitted through the whole length of the tube. A beautiful illustration of the manner in which a sound pulse is propagated is afforded by attaching to a sounding board a long, elastic spiral spring of brass, while the other end is held in the hand. On separating two of the coils of the spring with a finger nail, and then allowing them suddenly to come together, a pulse or compression will be thrown through the whole length of the spring to its further end, where striking on the sounding board it will cause a sharp rap. This action against the board will be reflected from the board to the hand, and again from the hand to the board, and so on several times in succession. When the piston above spoken of makes a backward movement, it creates a vacant space in the tube, into which the air rushes by virtue of its elasticity, and thus a certain depth of air is rarefied; this first cylinder of rarefied air in retracting to its natural dimensions causes rarefaction in an equal depth of air in front of it; this second rarefied cylinder of air now reacts on the first, brings it to rest, and causes rarefaction in a third equal column of air, and so on. Thus the rarefaction, like the compression, is transmitted through the whole length of the tube. When a compression traverses the tube it successively brings the molecules of air nearer together, while a rarefaction in its progress separates the aërial molecules; hence, if we imagine the piston to move backward and forward with a regular vibratory motion we have rarefaction succeeding compression in regular order, and the effect on any one molecule of air is to give it a like regular motion backward and forward. In the above discussion we have, for simplicity, supposed the piston to have a uniform velocity during its motions; but this, as we have already seen, is not the case with freely vibrating elastic bodies, for they have the same character of reciprocating motion as that of a freely swinging pendulum. To explain what will be the effect on the air of such a motion, we will suppose that the piston vibrates through a

very small distance, $a\,a'$, fig. 16, making equal excursions on one side and the other of the position of equilibrium $m\,m'$; and as the piston vibrates like a pendulum, it will increase

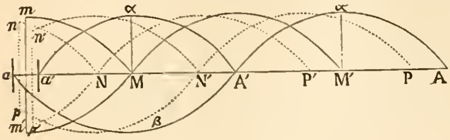

FIG. 16.

in velocity as it goes from $a$ or from $a'$ to $m\,m'$, and diminish in velocity as it goes from $m\,m'$ to $a$ or to $a'$. Let T be the time taken by the piston to make a semi-vibration, that is to say, a motion from $a$ to $a'$ or from $a'$ to $a$. Divide this time T into exceedingly small and equal parts $t$, during which the piston will also go over very small but unequal spaces, increasing with the velocity from $a$ to $m\,m'$, and diminishing with the velocity as the piston goes from $m\,m'$ to $a'$. The first very small displacement of the piston, accomplished during the time $t$, will produce in a very thin layer of air, which touches the piston, a very feeble degree of compression, and this compression will progress forward into the air of the tube. The very small succeeding motion of the piston during the next succeeding $t$ will produce a slightly greater condensation, which will travel behind the former condensation with the same velocity. The third displacement of the piston will produce a still greater condensation, and so on, until the displacement which brings the piston to the position $m\,m'$, which, being the greatest of all, will produce the greatest condensation. If the piston continues its motion to $a'$, with a velocity which is now gradually decreasing, a new series of condensations will take place, less and less in degree, which will travel behind those of the first series. These two series will be symmetrically placed on one side and the other of the maximum condensation, if we suppose that the two semi-oscillations of the piston are equal, and if we neglect the very small amplitude of oscillation $a\,a'$. If $a$ A' is the space through which the first condensation progresses in the time T, then all the condensations which have succeeded it during the movement of the piston from $a$ to $a'$ will be distributed in the space $a'$ A'. If we represent by ordinates these condensations at the moment when, the piston having arrived at $a'$, the first condensation is at A', we will form a curve $a'$ $a$ A', whose maximum ordinate M $a$ will represent the condensation produced by the piston at the moment of its passage through $m\,m'$. Let us now suppose that the vibrating piston returns on its path, it will produce by this motion a series of increasing dilatations during the time $\frac{1}{2}$T, and then decreasing dilatations until the instant when the piston reaches $a$. These dilatations will travel behind the condensations, and when the piston has returned to $a$, in which case the series of condensations will have reached the position A' $a$ A, these dilatations will be distributed in the space $a$ A', and the diminution of density of the layers of air can be represented by the negative ordinates of the curve $a\ \beta$ A', below the axis of the curve $a$ A'. The state of air in the tube at the instant when the vibrating piston, departing from $a$, arrives at $n\,p$, $m\,m'$, $n'\,p'$, $a'$, is indicated by the curves $n$ N, $m$ M, $n'$ N', $a'$ A'. If the piston makes another complete vibration from $a$ to $a'$ and from $a'$ to $a$, a new series of condensations and of dilatations, distributed in a space equal to $a$ A, will travel behind the first series already described. The dilatation and condensation contained in $a'$ A, and produced by a complete vibration of the body at the origin of sound, *i. e.*, by an oscillating motion from $a$ to $a'$ and back from $a'$ to $a$, is called a sonorous wave. A sonorous wave is always formed of two parts, one half of air in a state of condensation, the other half of rarefied air. The sum of all the condensations in the condensed half of the wave is represented by the area of the curve $a'$ $a$ A'; and if we divide this by the interval T of a half vibration of the body, we have the mean condensation of the half wave. This mean condensation can be calculated, and it has been found that for the sound given by 250 vibrations per second, which corresponds nearly with the lowest C of the violin, this compression gives for the compressed half of the wave an increase of $\frac{1}{1710}$ to the ordinary density of the atmosphere. The length of a wave is evidently the distance through which the air has been affected the moment after the first complete vibration of the sonorous body has been made. If we designate this length by $l$, we can calculate the wave length by dividing the velocity $v$ of sound in a second by $n$, the number of vibrations the sounding body makes in a second; or, $l=\frac{v}{n}$. By a sonorous wave surface is understood that surface which is at such a distance from the point or points of origin of the sound that all points in that surface have the same phase of vibration at the same instant of time. Thus, it is evident that if we have a small sphere of air which successively and rapidly increases and diminishes its volume, we shall have alternate spherical shells of compressed and of rarefied air surrounding the vibrating sphere. If we view a surface in one of these shells, in every part of which surface the particles of air are moving in the same direction with the same velocity, we shall have the sonorous wave surface. The acoustic wave lengths and wave surfaces are not mere creations of the imagination, but have a real existence. The author of this article first devised a method by which one can readily detect the phases of vibration in the air surrounding a sounding body, and

thereby has succeeded in measuring directly in the vibrating air the length of sonorous waves, and has determined in the air surrounding the vibrating body the form of the wave surface. ("American Journal of Science," November, 1872.) It is evident that the ultimate effect of the passage of sonorous waves through the atmosphere will be to cause the molecules of the air to swing to and fro with the motions of pendulums. It is also apparent that all the characteristics of the periodic motion at the source of the sound will be impressed on the surrounding air and transmitted through it to a distance.—*Reflection of Sound.* It follows from the very nature of sound pulses that if a sonorous wave meet a hard smooth surface, or encounter the surface of separation of two media of unequal elasticity, reflection of sound will take place, and the laws of reflection will be the same as in the case of light, viz.: the angle of reflection will equal the angle of incidence, and both the incident and reflected ray will lie in the same plane, which is at right angles to the reflecting surface. These laws admit of a ready experimental proof. If two concave parabolic mirrors, formed of metal backed with hard wood or plaster of Paris, be placed opposite each other at a distance of 10 or 15 ft. with the axis of the mirrors in the same line, and a watch be placed in the focus of one of the mirrors, it will be found that the sonorous pulses emanating from the watch will be reflected from the first mirror upon the surface of the second mirror, and here by a second reflection will be conveyed to the focus. This fact can be ascertained by leading to the focus a tube terminated at one end by a small funnel, while the ear is applied to the other end of the tube. In the article OPTICS it has been shown that the action just described is a necessary consequence of the laws of reflection given above.—*Refraction of Sound.* Sound waves are also refracted, and their refraction is due to the same cause which produces refraction of the rays of light; *i. e.*, to the change in velocity which occurs when the sonorous beam enters a refracting medium. When the sonorous wave surface falls upon the refracting medium so that it is parallel to the refracting surface, there will be no refraction, or change in the direction of the sound, but only a change of velocity. But when the sonorous wave surface forms an angle with the surface of the refracting medium, the change in velocity causes the refraction of the sonorous beam, so that if the velocity of the sound is less in the refracting medium than it was before it entered it, the sound will be refracted toward the perpendicular to the refracting surface. The refraction will be away from the perpendicular when the velocity of the sound is greater in the refracting medium than it was before it entered it. It follows from the above action, that for the same media there will be a constant ratio existing between the sines of the angles of incidence and refraction, and also that the incident and refracted ray will be in the same plane at right angles to the refracting surface. (See LIGHT, vol. x., p. 439.) The experimental verification of these laws, however, is not so easy as in the similar phenomena of light. The experiment

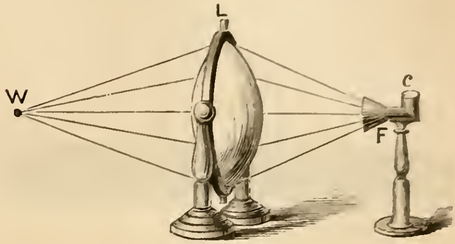

FIG. 17.

best adapted for this purpose is one devised by Sondhaus and represented in fig. 17. He constructed a lens, L, of sheets of collodion, having the form of portions of a sphere, and united these sheets to the opposite sides of a metal ring. On inflating the envelope thus formed with carbonic acid gas, a lenticular form was given to it. A watch was placed at W, on the axis of the lens, and it was found that the sound waves were refracted to the conjugate focus of the lens at F. If at F we place a bent pipe with a funnel-shaped mouth, and replace the watch at W by a small organ pipe, the refraction is detected by seeing grains of a light powder dance on the membrane closing the upper mouth of the bent pipe at *c*.—*Interference of Sound.* Another necessary consequence of the nature of sound vibrations and of the manner of their propagation is, that if the condensed half of a sonorous wave meet the rarefied half of another sonorous wave, and these waves have the same length and the same energy of vibration, there can be no vibratory motion at their place of meeting, for the directions of the vibrations in the two half waves are opposed, and the intensities of these opposed vibratory motions are equal. These conditions are fulfilled in various well known experiments, and it is one of the best established facts in acoustics that two sound vibrations may meet and produce silence at the place of their meeting; this is known as the phenomenon of the interference of sound. Dr. Thomas Young studied this phenomenon attentively, and its contemplation led to his great discovery of the similar phenomena of the interference of light, which formed the basis of his reasoning in establishing the undulatory theory of light. To Dr. Young we owe one of the simplest known means of exhibiting and studying the phenomena of interference of sound. If a vibrating tuning fork be held in a vertical position at a short distance from the ear, and then rotated around its vertical axis, it may be observed, when the

surfaces of the prongs of the fork are opposite the ear, that sound will be perceived; but when the edges of the fork formed by the meeting of those surfaces are opposite the ear, it will be found that no sound, but entire silence, occurs. This phenomenon is readily explained. First, it is necessary to know that the prongs of a vibrating fork alternately approach to and recede from each other, as is readily seen when we obtain on a piece of smoked glass the trace of two delicate wires attached to the ends of the prongs of the vibrating fork. A trace thus made is accurately shown in fig. 18. When the prongs recede

Fig. 18.

from each other, condensations will be produced in the air opposite the faces $c\,c'$ (see fig. 19, which represents a plan of the ends of the prongs); but while these condensations are thus formed rarefactions are produced in the air opposite the opening between the prongs at $r\,r'$. The reverse of these actions occurs when the prongs approach each other. The result of the actions will be evident from the figure, where the full lines show the centres of shells

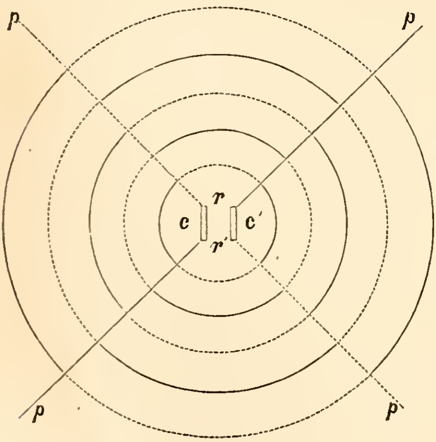

Fig. 19.

of condensed air, and the dotted lines the centres of shells of rarefied air. These shells alternate, and meeting along the planes $p, p, p, p$, passing through the vertical edges of the fork, they neutralize each other's action. W. Weber has shown that the points of quiescence in this case must lie in hyperbolic sheets. This must be so, for the difference in the distance of every point of quiescence from two fixed points must be a constant quantity, which in this experiment will be equal to the half of the wave length given by the fork. The writer has used this experiment of Young to show the reflection of sound from flames and from sheets of cold and heated gases, such as carbonic acid gas and hydrogen. Two resonators were placed as in fig. 20 with the planes of their mouths at

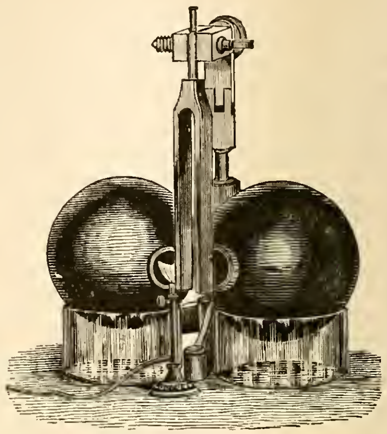

Fig. 20.

a right angle, and in this angle was firmly fixed the fork to whose note the resonator resounded. The broad face of one of its prongs faced the mouth of one resonator, while the space between the prongs faced the mouth of the other resonator. By trial the two planes of the fork are placed at such distances from the resonators that complete interference of the vibrations issuing from their mouths is obtained, and the only sound that reaches the ear is the faint one given by the action of the fork on the air outside the angle included by the mouths of the resonators. If in these circumstances we place before the mouth of one of the resonators a flat coal-gas flame, we shall find that this flame reflects part of the sound which falls upon it, and thus partially screens the resonator, so that sonorous vibrations of diminished intensity now enter this resonator, and therefore the balance of interference no longer exists, and a sound issues from the resonator which has not the gas flame opposite its mouth. But if a piece of French tracing paper be placed before the mouth of the latter resonator, the balance of interference will be restored, thus showing that the reflecting power of a gas flame is equal to that of tracing paper. In a similar manner the writer has shown and approximately measured the reflecting power of sheets of cold carbonic acid and hydrogen gases.—*Change of Pitch caused by Translation of the Sounding Body.* One of the most remarkable phenomena is the change in pitch caused by the motion of a sounding body to or from the ear; or, what is the same, by the motion of the ear to or from the source of sound. When the sounding body and the ear approach, we perceive a rise in the pitch; when they recede from each other, a fall in pitch occurs. This is a fact known to all who have listened to the rapid change in pitch of a locomotive whistle which

occurs at the instant it passes us; the same phenomenon is yet more marked when the listener is on a train which passes another going in the opposite direction while the whistle of the latter is sounding. If we suppose each train to be moving at the rate of 30 m. an hour, and the pitch of the whistle while the trains are approaching each other to be that of the C next above the treble, the pitch will fall about a tone while the trains are receding from each other. The following simple considerations will afford the means of calculating the change in wave length produced by a known velocity given to a sounding body of a given pitch, and will also serve to solve the inverse problem, viz., the velocity of the sounding body which causes an observed change in its pitch. If the sounding body moves toward the ear over a space S in one second, it is evident that in these conditions more vibrations or wave lengths will enter the ear by the number of wave lengths contained in S. If $l$ represent the wave length produced by the vibrating body when it is stationary, and $l'$ the wave length when it moves toward the ear, N the number of vibrations per second of the sounding body, and V the velocity of sound per second, we shall have $N=\frac{V}{l}$, and $l'=l\left(\frac{V}{V+S}\right)$; and S, the velocity of the sounding body per second, will be $S=V\left(\frac{l-l'}{l'}\right)$.—*Perception of Sounds and their Analysis by the Ear.* The ear may be divided into three portions: the outer, the middle, and the inner ear. (See EAR.) The organ of Corti is enclosed in the ductus cochlearis of the inner ear, a canal of triangular section which forms an ascending spiral of two and a half turns around the modiolus. It is bounded on two of its sides by the scalæ, and on its third by the membranes lining the outer wall of the cochlea. The upper wall of the ductus cochlearis is formed by the membrana Reissneri, which separates it from the scala vestibuli, and its lower wall is the lamina spiralis and the elastic membrana basilaris, which separate it from the scala tympani. The ductus is closed at its upper end, and at its lower end it communicates with the sacculus hemisphericus by a fine duct. The arch of Corti rests upon the membrana basilaris, which extends beyond the base of the arch to the membranous outer wall of the cochlea; and over the arch spreads the membrana tectoria, covering the rods of Corti and the hair-cell chords as with a roof, but leaving the outer portion of the elastic membrana basilaris exposed. The effect of these anatomical relations is to bring the sound vibrations to act with the greatest advantage on the hair-cell chords, which are supposed to be the parts of the inner ear that are tuned to the range of sounds appreciated as musical by the human ear. If a simple sonorous vibration enter the inner ear, then one of these chords, vibrating synchronously with it, will shake the nerve fibril attached to this chord, and thus give the sensation of a simple sound; but if a composite sonorous vibration enter the ear, several chords will enter into vibration, each vibrating to one of the definite simple vibrations forming the components of the compound sound. These hair-cell chords may be compared to the tuned strings in a pianoforte, which readily respond to a note sung over them. If the note be formed of a simple sound, then only one string of the piano will answer back. If the sound be composite, the strings will decompose it into its simple component sounds, and the position of these simple sounds in the musical scale can be determined by observing which of the strings of the piano have entered into vibration. This experiment shows how the ear is supposed to appreciate a simple sound, and to decompose a compound sound into its simple sonorous sensations. The relation of the various parts of the inner ear is such as to cause the chords of the organ of Corti and their attached nerve filaments to make half as many vibrations in a given time as are made in the same time by the membrane of the drum of the ear. The relations which the form of the scalæ bears to the sonorous waves traversing them will be modified according to the existence or non-existence of a communication between the scalæ. On this point there seems to be some difference of opinion; but in explaining the functions of the scalæ, first on the supposition that the scalæ are continuous, and then on the assumption that they are not continuous, but closed at the place where the passage called the helicotrema is supposed to exist, it will be made highly probable that no communication exists between the scalæ, or at least if one exist it must be by a very contracted passage. E. Weber was the first to point out the peculiar molecular actions which exist when the dimensions of a body are very small compared with the length of the sonorous waves which traverse it; and Helmholtz based his investigations on "The Mechanism of the Ossicles of the Ear" on the theory of Weber, which Helmholtz gives in these words: "The difference in displacement of two oscillating particles, whose distance from one another is infinitely small compared with the wave length, is itself infinitely small compared with the entire amplitude of displacement." It is evident that the sonorous compressions and dilatations which may exist in any body depend entirely on the differences in the phases of the vibrations constituting the sonorous wave, and when the body has a depth equal to half a wave length it can embrace the maximum amounts of condensation and of rarefaction. But condensation and rarefaction can alone produce lateral action on the walls of a straight canal traversed by sonorous vibrations; and hence, if the length of the canal be but a small fraction of the wave, there exists throughout the canal but little difference in phase of vibration, and therefore but little lateral action. The united length of the scalæ is but a small

fraction of the mean length of the sonorous waves which traverse it; for if we take $4\frac{1}{2}$ metres as the mean length of the waves which are propagated through the scalæ, and 59 millimetres as the length of the united scalæ, it follows that the latter is only $\frac{1}{75}$ of the mean wave length. Now if we imagine the scalæ straightened, and as forming one continuous tube with a free communication at the helicotrema, then the mean wave traversing them will cause only $\frac{1}{37}$ of the lateral action which this same wave would produce if the scalæ had the length of one half of the wave; and it follows that the whole liquid of the scalæ will vibrate forward and backward almost as an incompressible mass, approaching in character the oscillations of a solid piston in a cylinder; therefore, the action against the walls of the ductus cochlearis will be very slight. But now consider the change in effect on the ductus which takes place when it, together with the scalæ, is wound up into such an ascending spiral as really exists in the ear. The molecules of the liquid in the scalæ, thrown forward and backward by the vibrations of the stirrup bone, tend to move in straight lines, but the curved form of the scalæ causes them to press against the outer or peripheral part of the upper wall (membrana Reissneri) of the ductus cochlearis and against the outer part of the lower wall (membrana basilaris) when the stirrup bone moves inward, and when it moves outward this action of compression is relieved from the two opposite walls of the ductus. But these actions on the walls of the ductus, produced by the vibrations of the stirrup bone, are opposed to each other, and since they take place simultaneously and with about the same intensity (by reason of the assumption of the free communication of the scalæ), the hair-cell chords cannot vibrate, but will only experience compressions and dilatations like the fluid in which they are immersed. Therefore, there appears a physical basis for the opinion that either there is no communication between the scalæ, or if one exist it must be through a very constricted passage. Indeed, if we adopt the latter view, then everything works to produce the maximum effect upon the co-vibrating chords of the organ of Corti; for, when the stirrup bone moves inward, the pressure is thrown upon the outer border of the upper wall or roof of the ductus, thence across to the peripheral portion of the basilar membrane. This action, we may say, takes place simultaneously throughout the whole length of the ductus, moves downward the floor of the basilar membrane, and thus presses the fluid of the scala tympani against the sound membrane and moves this membrane outward. But when the stirrup bone moves outward, the pressure is relieved from the elastic basilar membrane which is now moved upward, while the round membrane moves inward. There are also other anatomical facts besides the inclination of the membrana Reissneri to the plane of the membrana basilaris, and the inclination of both these membranes to the plane perpendicular to the axis of the cochlea, which favors an opinion that the outer or peripheral part of the basilar membrane receives the main part of the vibrations which enter the ductus cochlearis. The auditory nerve fibrils are not attached to the Corti rods or pillars, as was formerly imagined; and hence these bodies cannot be the co-vibrating parts of the ductus; but the Corti pillars appear to act as supports for the lamina reticularis, between which and the basilar membrane are steadily and tensely stretched the hair-cell chords, and to these chords are attached the auditory nerve fibrils. The very fact that the number of these hair-cell chords increases with the higher development of the ear, shows their important functions; for, while in man they are arranged alternately in five rows and number 18,000, in other mammalia there are only two or three rows. These hair-cell chords are more perpendicular to the basilar membrane than the Corti rods, and are also different in their forms, having swellings in the middle of their lengths. These swellings must cause them to act like loaded strings, and thus each hair-cell chord is peculiarly well adapted to co-vibrate with only one special sound. And these hair-cell chords are so directed in reference to the sound pulses which enter the ductus that their lengths are in the direction of these pulses, and therefore they cannot be directly set in motion by these vibrations. Indeed, they appear to hold the same relation to those vibrations as the antennal fibrils of the mosquito bear to sound vibrations which exist in the directions of these fibrils. The writer has shown by direct experiment ("American Journal of Science," August, 1874) that in these conditions the fibrils of the mosquito remain at rest, although when the same sound pulses fall athwart the fibril it may be set into energetic vibrations. The hair-cell chords, therefore, cannot be set into vibration by the action of the feeble pulses which may reach them directly through the membrana Reissneri from the scala vestibuli; and furthermore, the shielding influence of the membrana tectoria tends to prevent this direct action on the chords. If this view be correct, that these chords receive their vibrations from the basilar membrane, to which their ends are attached, and not directly from the impulses sent into the ductus, it necessarily follows that these chords bear to the membrane to which they are stretched the same relation as stretched strings bear to the vibrating tuning forks to which they are stretched in directions perpendicular to the lengths of the forks. Hence it follows that a chord in the ductus will vibrate only half as often as the basilar membrane to which it is fastened. As the basilar membrane, the tympanic membrane, and the air contiguous to the latter vibrate together, it follows that the auditory nerve fibrils vibrate as frequently as the tympanic membrane and the molecules of air outside of the

head. The following experiment illustrates very well the foregoing explanation of the mode of audition. A membrane, loosely stretched on a frame, is placed in a vertical position near a reed pipe, which, as we have already seen, gives a highly composite sound. Strings of various lengths and diameters, loaded at their centres, are fastened to the membrane and stretched to a fixed support. On sounding the reed pipe, only those strings in tune with the harmonics, or simple sounds, existing in the sound of the reed pipe, will enter into vibration; similarly, when the sound of the same reed pipe enters the ear and vibrates the basilar membrane, the only hair-cell chords which enter into vibration are those which are in tune with the elementary vibrations existing in the composite sonorous vibration produced by the reed pipe. And it is to be observed that as the loaded string makes one vibration to two of the membrane, so the hair-cell chord makes only one vibration to two of the basilar membrane or of the membrane of the drum of the ear. If it be true that when simple vibrations impinge on the ear the tympanic and basilar membranes vibrate twice, while the co-vibrating body only vibrates once, it follows that if the same simple vibrations be sent directly to the co-vibrating parts of the ear, without the intervention of the basilar membrane, we shall perceive a sound which is the octave of the one experienced when the same simple vibrations entered the ear through the tympanic membrane. Hence it appears that this hypothesis can be brought to the test of experiment in the following manner: If we vibrate a fork near the ear, and closely apprehend the character of its sound, we experience a sensation which certainly does not contain that corresponding to the higher octave of the fork. Now press the foot of the fork firmly against the zygomatic process, close to the ear, directing it somewhat backward, and we shall distinctly hear the higher octave of the fork singing in concert with its real note. If the auditory canal be now closed by gently placing the tip of the finger over it, we shall perceive the higher octave with an intensity almost equal to that of the fundamental note. The same sensation, though less intense, may be obtained by placing the fork on any part of the temporal bone. One can also perceive distinctly the higher octave when the fork is placed on the parietal bone, about two inches in front and an inch or so to the side of the foramen, with its foot directed toward the opposite inner ear, while the auditory canal of this ear is gently closed with the finger. In these circumstances the higher octave is often heard, with some persons, to the almost entire exclusion of the lower, or of the proper note of the fork. These experiments have been made on the ears of several accomplished musicians, and the results have invariably agreed with those described above.—*Duration of residual Sonorous Sensations.* For a long time it has been known that the sensation of light endures an appreciable time after the cessation of the entrance of light into the eye. The durations of the residual sensations corresponding to lights of different colors and intensities have been generally determined by finding the number of flashes of a given light in a second required to blend and produce a continuous sensation. The durations of the residual sonorous sensations had never been made the subject of investigation until the writer began the study of these phenomena, and succeeded in determining the law connecting the pitch of a sound with the duration of its residual sonorous sensation. The manner of determining the data of this law is similar to the method employed in the study of the analogical phenomena of light. Intermittent sonorous pulses were sent into the ear by means of perforated revolving disks, and the rotation of the disk was brought just to that velocity required to blend the separated pulses. It was thus found that if we represent by N the number of vibrations per second producing a given sound, and by D the duration of the residual sonorous sensation of this sound, then the law connecting the pitch, or number of vibrations per second, with the duration of the sonorous sensation, will be expressed by $D=\left(\frac{53248}{N+23}+24\right)\cdot 0001$. This is the expression of the law given in the article HARMONY. Besides the application of this law to the elucidation of the fundamental facts of musical harmony, there are other and new classes of phenomena which it has served to point out. For instance, as the duration of the residual sonorous sensation is less as the pitch of the sound is higher, it follows that at the instant of the cessation of the aërial vibration, producing a given composite sound, the timbre of this sound must instantly begin to change; for the residual sensations of the higher harmonics will disappear one after another, in the order of descending pitch, until there remains in the ear only the sensation corresponding to that of the lowest or fundamental harmonic. The knowledge of the law given above led to a new method of analyzing a composite sound by means of a perforated rotating disk. Thus, on rotating with great velocity a large disk, with sections cut out of it, before a reed pipe, and placing the ear close to the disk, we have the composite sound reaching the ear in a series of impacts which succeed each other so rapidly that even those of the highest harmonic of the reed blend into a continuous sensation; but on gradually lowering the velocity of rotation, the impacts of this highest harmonic can no longer blend, and we perceive this harmonic beating alone on the ear. This fact can more readily be confirmed by the aid of the resonator corresponding to this harmonic. A further slight lowering of the velocity of rotation brings out the beats of the next lower har-

monic, and so on, until the velocity has been so diminished that the beats of the lowest or fundamental harmonic are perceived. Then all the component sounds of the reed are beating on the ear in unison, but the effects they severally produce on the ear are very different; for the higher harmonics, notwithstanding their feebler intensities, must be heard more distinctly, because their intermittences are the furthest removed from the number that cause the blending of their separate impulses. In other words, the number of impacts of the highest harmonics approaches nearer than the lower to the number of beats required to cause them to give their greatest dissonant effects; it having been determined that it requires about $\frac{4}{10}$ of the number of sonorous impacts, which blend into a continuous sound, to produce the most dissonant sensation that can be obtained by a series of separated beats falling on the ear.—The following are the most important works on sound: Chladni, *Traité d'acoustique* (Paris, 1809); Peirce, "An Elementary Treatise on Sound" (Boston, 1836), which contains an excellent catalogue of works and memoirs on the subject; Airy, "On Sound and Atmospheric Vibrations, with the Mathematical Elements of Music" (London, 1868); Donkin, "Acoustics" (Oxford, 1870); *Acoustique*, in Daguin's *Traité de physique* (Paris, 1870); *Akustik*, in vol. i. of Wüllner's *Lehrbuch der Experimentalphysik* (Leipsic, 1870); Helmholtz, *Die Lehre von den Tonempfindungen* (Brunswick, 3d ed., 1870; English translation, by A. J. Ellis, 1875); Sedley Taylor, "Sound and Harmony" (1873); Tyndall, "On Sound" (new ed., 1875); and A. Guillemin, *Le son: notions d'acoustique physique et musicale* (1875).

**SOUND, The**, a narrow strait, forming one of the passages between the Cattegat and the Baltic, and separating the Danish island of Seeland from the coast of Sweden. In its largest sense it extends N. and S. 66 m., and opposite Copenhagen it is about 15 m. wide. But the name is properly confined to the narrowest part of the passage, which between Elsinore and Helsingborg is not more than 3 m. wide. The Great Belt gives a wider and deeper communication between the Cattegat and the Baltic, but the Sound is most frequented because shorter and favored with better winds. The depth ranges from 4 to 20 fathoms. The Danish kings formerly owned the territory on both sides of the strait, and from time immemorial levied duties on all vessels passing through it; but this is done no longer, the right having been bought off by other nations, under treaties concluded in 1857.

**SOUNDING.** See ATLANTIC OCEAN, vol. ii., p. 69, and DREDGING, DEEP-SEA.

**SOUR GUM.** See TUPELO.

**SOUTH, Robert**, an English clergyman, born at Hackney, Middlesex, in 1633, died in London, July 8, 1716. He graduated at Christ Church college, Oxford, in 1655, was ordained in 1658, was elected public orator of the university in 1660, soon afterward became chaplain to the chancellor Clarendon, and was made a prebendary of Westminster in 1663, and a canon of Christ church, Oxford, in 1670. He was a zealous champion of passive obedience and the divine right, and was opposed alike to Protestant dissent and to Roman Catholicism. When Sherlock published his "Vindication of the Holy and Ever Blessed Trinity," South attacked him for inculcating tritheism (1693). His sermons have passed through many editions (6 vols., 1692; 5 vols. additional, 1744; 4 vols., London, 1843; 2 vols. royal 8vo, Edinburgh, 1843; abridged, London, 1851 and 1859); and a volume of his posthumous works appeared in 1717.

**SOUTH ADAMS.** See ADAMS, Mass.

**SOUTH AMERICA.** See AMERICA.

**SOUTHAMPTON**, a S. E. county of Virginia, bordering on North Carolina, bounded E. by the Blackwater river and S. W. by the Meherrin, and intersected by the Nottaway; area, 600 sq. m.; pop. in 1870, 12,285, of whom 6,795 were colored. The surface is nearly level and diversified by large forests of cypress and pine, and the soil is tolerably productive. Tar and turpentine are largely exported. It is traversed by the Seaboard and Roanoke and the Atlantic, Mississippi, and Ohio railroads. The chief productions in 1870 were 218,858 bushels of Indian corn, 13,683 of oats, 24,927 of sweet potatoes, 3,587 lbs. of wool, and 18,660 of butter. There were 909 horses, 1,385 milch cows, 3,308 other cattle, 2,576 sheep, and 12,978 swine. Capital, Jerusalem.

**SOUTHAMPTON**, a seaport town of Hampshire, England, and a county of itself, on the peninsula formed by the estuary of the river Itchen and the larger estuary of the Test, called the Southampton water, 70 m. S. W. of London; pop. in 1871, 53,741. The Southampton water varies in breadth from 1½ to 2 m., and extends inland from Calshot castle, 7 m. below Southampton, to Red Bridge, 4 m. above. The entrance is well sheltered by the isle of Wight, and the channel is deep and straight, with good anchorage. It has the advantage of four tides in the 24 hours; a peculiarity caused by the isle of Wight intercepting a portion of the tidal wave in its progress both ways through the English channel. The mean rise of the spring tides is 18 ft., and of the neap tides 8 ft. The town is well built, and supplied with pure spring water from an artesian well 910 ft. deep. It has a well wooded park of 365 acres, 5 parish churches, 13 other churches, a public library and museum, and several charitable, literary, and scientific institutions. Among the noteworthy public buildings are the custom house, the ordnance survey office, the royal Victoria hospital for 1,200 invalid soldiers, and the royal southern yacht club house. For many years Southampton was mainly a watering place, but since the opening of the docks in 1842 it has become the principal port of departure

for several East and West India, China, Australia, North German, and American steamship lines, besides having a large trade coastwise and with the continent. There are five docks, paved with granite and lined with warehouses, viz.: one of 10 acres, two of 16 acres each, and two of 22 acres each; and further shipping accommodations, begun in 1873, include a quay 1,500 ft. long on the right bank of the Itchen, which is ultimately to form the E. arm of a dock of 30 acres. The entrances in 1873 were 6,920 British vessels, tonnage 852,461, and 578 foreign vessels, tonnage 376,964; clearances, 6,839 British vessels, tonnage 832,617, and 543 foreign vessels, tonnage 347,710. The total value of exports was £11,459,889. The principal industries are brewing, sugar refining, iron casting, coach building, and ship building; many large steamships have been built here. The annual cattle fair is important.—Southampton is a very ancient place. Remains of the Roman camp Clausentum, 1 m. N. E. of the present town, are still seen. The bar across High street and the W. and S. gates, now standing, are parts of the Saxon walls around the old town. In 980 the Danes sacked the place. After 1016 it was the occasional residence of Canute, and the shore is said to be the scene of his rebuke to his courtiers. The town was destroyed by French, Spanish, and Genoese allies in 1338, was rebuilt and fortified by Richard II., and was erected into a county of itself by Henry VI.

**SOUTHAMPTON, Henry Wriothesley,** third earl of, an English statesman, born Oct. 6, 1573, died in Holland, Nov. 10, 1624. When he was 20 years old Shakespeare dedicated to him his poem of "Venus and Adonis," and in the next year "The Rape of Lucrece." Sir Edwin Sandys converted him to Protestantism. In 1596 he took part in the expedition of the earl of Essex against Cadiz. In 1599, accompanying Essex to Ireland, he was made general of horse. From that command he was recalled by the queen, and went speedily into the Netherlands. On his recall from that country he confederated with Essex and appeared with him in the insurrection which he then made in London. On his trial for treason he protested that he had never entertained a thought against the queen; sentence of death and attainder was passed against him, but he was immediately relieved of the former by the queen, and in the first year of James I. the attainder was removed by act of parliament. As an assign of Sir Walter Raleigh he took part in colonizing America, and in 1602 sent out the Concord under Gosnold. He interested those connected with him, Lord Arundel, his brother-in-law, and Cecil Calvert, afterward Lord Baltimore, who was Lord Arundel's son-in-law. In 1605, in conjunction with Lord Arundel, he despatched Waymouth to New England. The secretary of Virginia ascribes to him the principal part in obtaining the first charter for the London company of Virginia, though his name does not appear in the charter itself. In the second charter his name stands next to those of the high officers of state. The firm friend of Sir Edwin Sandys, when the latter retired from the office of treasurer (governor) of the company, Southampton was unanimously chosen in his stead, and he remained in the chair till the charter was taken away. In parliament he was one of the firmest supporters of liberty. In June, 1621, he was committed to close custody by the king, and he asked to know the charges against him and to see his accusers. The tendency of his mind in religious affairs appears from the charge made against him of corresponding with the Independents. The duke of Buckingham visited him in prison and caused him to be set free, but he was watched till near the end of August, when by the king's direction Sir George Calvert as secretary of state gave him his liberty. After the suppression of the Virginia company he went to the Netherlands to fight for Dutch independence, and took command of a regiment. In their winter quarters at Rozendaal he and his son were both seized with burning fever. The son died; the father recovered enough to depart from Rozendaal with the intention to bring his son's body to England, but died at Bergen-op-Zoom. He is the only man from whom Shakespeare acknowledges having received a benefit.

**SOUTHAMPTONSHIRE.** See HAMPSHIRE.

**SOUTH AUSTRALIA,** a British colony in Australia, comprising all of the continent between the 129th and 138th meridians of E. longitude N. of lat. 26° S., and between the 129th and 141st meridians S. of that latitude, bounded N. by the gulf of Carpentaria and the Indian ocean, E. by Queensland, New South Wales, and Victoria, S. by the S. Pacific ocean, and W. by Western Australia; area, according to latest estimates, about 900.000 sq. m.; pop. (exclusive of about 3,000 aborigines) in 1871, 185,626; in 1874 (estimated), 202,185. Capital, Adelaide. In the article AUSTRALIA, South Australia and the Northern Territory are treated as distinct; but the latter is now an integral part of South Australia, or rather a subcolony, as it is governed directly by the executive of that colony and has no representation in its parliament. It embraces the larger and almost uninhabited half of the colony, N. of lat. 24°. Within the limits of South Australia are included Kangaroo island, about 100 m. long and 30 broad, on the S. coast, and Melville island, 1,800 sq. m., and several smaller islands, on the N. coast.—The S. coast, which forms the E. and a part of the N. shore of the Great Australian bight, has a general N. W. and S. E. direction. Its principal inlets are Encounter bay, St. Vincent gulf, in the mouth of which lies Kangaroo island, and Spencer gulf, which extends more than 200 m. inland. It has many good harbors, of which Port Lincoln on Spencer gulf is the best. The N. coast, as far as Cape Arnhem, forms the W. shore of the gulf of

Carpentaria. Beyond that the chief inlets are Arnhem bay, Castlereagh bay, Mt. Morris bay, Port Essington, Van Diemen's gulf, Port Darwin, Anson bay, and Queen's channel. South Australia contains a great variety of soils and scenery, almost every kind of landscape being found within its limits. Much of it, particularly in the north, is sterile and uninviting, consisting largely of scrub and rock, but at least a third of its surface is agricultural and pastoral land, and another third wooded ranges suitable for pasturage. The scrub land is valuable only for its mineral wealth, some of the richest mines having been discovered in it. The principal chain of mountains is the Flinders range, which extends from Cape Jervis northward to the vicinity of Lake Blanche, about lat. 29°; its highest peak is Mt. Remarkable, 3,179 ft. The Gawler range, in the peninsula W. of Spencer gulf, has a height in its W. part of about 2,000 ft. N. of this are the Warburton and Stuart ranges, and there are many others stretching across the continent to the N. coast.—The Murray river enters the colony about lat. 34° S., and after a course of about 250 m., all of which is navigable, flows into Lake Alexandrina, and thence into Encounter bay by a narrow opening called the Murray mouth. The Wakefield and Gawler rivers flow W. into the gulf of St. Vincent. From the Torrens, which loses itself in reed swamps, the city of Adelaide derives its supply of water. On the N. coast the principal rivers are the Liverpool, the East and the South Alligator, the Adelaide, the Daly, and the Victoria. The Roper, which flows into the gulf of Carpentaria, is navigable for large vessels for nearly 100 m. There are many lakes, particularly in the S. E. part, which is called the lake district. Lakes Eyre, Torrens, and Gairdner are large bodies of salt water, each more than 150 m. long. Lake Eyre is only 70 ft. above the sea, while Gairdner, which lies N. of the Gawler range, is 366 ft. high. Lake Alexandrina is about 30 m. long and 15 m. wide. From its E. side a narrow lagoon, called the Coorong, extends about 85 m. parallel to the coast, from which it is separated by a narrow strip of land.—South Australia is rich in mineral resources. Iron ore abounds, but copper constitutes its chief wealth. The famous Burra-Burra mine, near Kooringa, about 100 m. N. by E. of Adelaide, was discovered in 1844 and opened in the same year. From 10,000 to 13,000 tons of ore are raised annually, yielding about 2,500 tons of pure copper. In 1860 the Wallaroo mines were opened near Kadina, on the shore of Spencer gulf, 91 m. N. W. of Adelaide. In 1861 the Moonta mines, about 12 m. distant, were discovered. They yield 25 per cent. of pure copper; in the first half of 1874 11,000 tons of ore were raised from them. In 1872 61 copper mines were worked, giving an aggregate annual yield of more than 150,000 tons. Gold has been discovered in several places, and 438 reefs were registered in 1870, giving an annual yield of 10,500 oz. Many small diamonds have been found near Echunga; and jasper, chalcedony, and opal abound. Silver, lead, and bismuth have also been found, and salt is abundant.—The climate of the inhabited part of the country is very fine, but that of the scrub land in the north is exceedingly hot and dry. In the southeast the seasons are the wet and the dry; the latter begins about the end of August and continues till the end of March. In December and January the heat is very great, and when the wind blows from the north the thermometer often rises to 115°. These winds are accompanied by clouds of dust, but seldom last more than a few hours, when they shift to the southwest and south, and the temperature falls. The average temperature is 67°, and the lowest in the level country 44°. The average annual rainfall is about 21 inches. Between March and August heavy rain falls, and the country becomes covered with luxuriant verdure; but during the summer months the ground is completely parched and the grass withered. The settled parts of South Australia, however, are not subject to the long continued droughts which are sometimes so destructive in New South Wales. No epidemic diseases prevail, affections of the lungs are infrequent, and scrofulous complaints are rare; but diseases of the eyes are common in summer. —The forests contain much large timber, but wood for cabinet and other fine work is imported. There are many species of *eucalypti* and acacias, and the pandanus, cycas, and *Adansonia* or gouty stem tree, the fruit of the last of which is eaten by the natives. In the northern parts three kinds of wild fig, a species of wild grape, and wild yams have been found. Native wheat and oats, rye grass, and rice grass also grow in the north. All the fruits common to temperate climates succeed remarkably well, and particularly the grape, many varieties of which are cultivated. Agriculture has made great advances of late, and the colony promises to become a large grain-producing country, enough wheat being grown in some years to supply the neighboring colonies and to ship many cargoes to England, where it brings high prices. The extent of land under cultivation in the year ending March 31, 1873, was 1,164,846 acres, an increase of 120,190 acres over the preceding year. The number of acres in wheat in the same year was 759,811, and in the year ending in March, 1874, 784,784; the product in the last named year was 6,178,816 bushels. In 1873 there were 5,424 acres of vineyards, and 2,901 in orchards. The return of live stock in 1873 was: sheep, 4,900,687; cattle, 151,662; horses, 82,215; goats, 17,492; pigs, 98,436; poultry, 513,883. The kangaroo dog, a cross between the greyhound and the English bulldog, often exceeding 3 ft. in height, is valuable to the inhabitants of this as well as the other Australian colonies. Much damage is sometimes done to the green crops by locusts.

For the indigenous fauna see AUSTRALIA.—The government of South Australia consists of a governor appointed by the crown, an executive council, and two houses of legislature, one called the legislative council and the other the house of assembly. The legislative council is composed of 18 members, elected by general vote for twelve years, one third retiring every four years. The president is elected by the members. The governor has no power to dissolve the council. The house of assembly has now 46 members, who are elected for three years. This body is liable to dissolution by the executive. The revenue of the colony in 1873 was £972,813, and the expenditure £839,152. The colonial debt on Dec. 31, 1873, was £2,174,900.—In 1871 there were 3,372 aborigines, who are of the same general type as those of other parts of Australia, but four different dialects are spoken by them within the limits of the colony, three of which are not intelligible to the natives of the country about the mouth of the Murray river. The tribes within the settled districts are inoffensive, and some of the boys are employed as herdsmen. The leading religious denominations in 1871 were: Church of England, 50,849; Roman Catholics, 28,668; Wesleyans, 17,075; Lutherans, 15,412; Presbyterians, 13,371; Baptists, 8,731; Primitive Methodists, 8,207; Congregationalists, 7,969; Bible Christians, 7,758; and several others were represented. The aggregate number of churches and chapels in the colony in 1872 was 607, with seats for 119,087 persons. The educational system is under the control of a central board consisting of seven members. The total number of licensed schools at the close of 1872 was 307; the number of scholars on the rolls was 15,123. A university is about to be established at Adelaide.—The exports of South Australia consist of grain, flour, wool, tallow, bark, fruit, wine, spirits, hides, beef, copper ore, copper, lead, and gold; their value in 1873 was £4,285,191. The imports consist principally of manufactured goods and articles of luxury; they amounted in the same year to £3,829,831. The entrances in 1873 were 457 vessels of 190,036 tons, and the clearances 363 vessels of 160,414 tons. In 1873 about 200 m. of railway had been completed, the principal line being the north line from Adelaide to Burra, about 100 m., with a branch line of 48 m. to Kapunda. A line connecting Narracoorte with Kingston is now constructing, and several others (one from Kadina to Port Wakefield, 32 m.) are authorized. There is telegraphic communication with the principal places in Victoria, New South Wales, and Queensland, and by the great overland line with Port Darwin on the N. coast, which is connected with Java by a submarine cable. The aggregate length of the lines in 1873 was 1,718 m.—In 1835 a company, styled the "South Australian Colonization Association," obtained a grant from the British government of the great tract of land which forms the colony of South Australia, and their first settlement was formed in December, 1836. Their operations gave rise to speculation in the lands of the colony, both there and in England, town allotments which had been originally sold at £2 10*s.* an acre soon rising to £2,000 or £3,000, and country sections from £1 to £100 an acre. Building speculations equally extravagant were carried on, and laborers' wages rose to 15*s.* and £1 a day. In 1839 a reaction took place which brought about the ruin of the land owners and most of the small moneyed settlers. Emigration turned to the other colonies, and South Australia became greatly depressed; but soon afterward the discovery of copper caused a reaction, and the colony prospered till 1851, when the discovery of gold in Victoria drew off thousands of its population and again retarded its growth. Since 1855 it has gradually recovered, and it is now once more prosperous.

**SOUTH BEND,** a city and the county seat of St. Joseph co., Indiana, on the S. bank of the St. Joseph river, at its most southern bend, 130 m. N. of Indianapolis and 85 m. E. by S. of Chicago; pop. in 1850, 1,652; in 1860, 3,832; in 1870, 7,206; in 1875, estimated by local authorities at 11,000. It is regularly laid out and substantially built, and is noted for its salubrity. It is well drained, and lighted with gas, and has water works and a good fire department. The court house is one of the finest buildings in the state. The river is navigable to this point, and affords good water power. The Lake Shore and Michigan Southern, the Michigan Central, and the Chicago and Lake Huron railroads meet here. An active trade is carried on in produce, lumber, and manufactured articles. Manufacturing is the chief interest; there were 2,183 hands employed in 1874, producing articles to the value of $4,318,722. The principal items were: flour, $385,000; carriages, wagons, &c., $1,266,000; farm machinery, $145,500; furniture, $256,000; doors, sash, and blinds, $163,000; foundery products, $440,620; sewing machines, $1,100,000; woollens, $80,000; paper, $330,402; brick, $75,000. The city has two national banks, a savings bank, and a life insurance company. There are six public school houses, with a high school; attendance in 1874, about 1,400. Other educational institutions are the university of Notre Dame and St. Mary's academy in the outskirts, and St. Joseph's academy within the city limits; these are Roman Catholic institutions, the last two for females. Three daily and four weekly (one German) newspapers and a monthly periodical are published. There are 11 churches. South Bend was laid out in 1831.

**SOUTH CAROLINA,** one of the original states of the American Union, lying between lat. 32° and 35° 10′ N., and lon. 78° 25′ and 83° 19′ W. It has the form of an irregular triangle, with the coast line for its base, and Georgia and North Carolina for its converging sides. Its extreme length, from Little River inlet on the

east to Chattooga river on the west, is about 275 m., and its greatest breadth, from the mouth of Savannah river on the south to the North Carolina line on the north, about 210 m.; area, about 34,000 sq. m. It is bounded N. and N. E. by North Carolina, S. E. by the Atlantic ocean,

State Seal of South Carolina.

and S. W. by Georgia, from which it is separated by the Savannah river and its upper branches. It is divided into 32 counties (called districts prior to 1868), viz.: Abbeville, Aiken, Anderson, Barnwell, Beaufort, Charleston, Chester, Chesterfield, Clarendon, Colleton, Darlington, Edgefield, Fairfield, Georgetown, Greenville, Horry, Kershaw, Lancaster, Laurens, Lexington, Marion, Marlborough, Newberry, Oconee, Orangeburg, Pickens, Richland, Spartanburg, Sumter, Union, Williamsburg, and York. The chief city is Charleston, which had 48,956 inhabitants in 1870 and 56,540 in 1875. Columbia (pop. in 1870, 9,298; in 1875, 14,449) is the capital. The chief towns having, according to the census of 1870, from 1,000 to 3,000 inhabitants are Abbeville, Greenville, Aiken, Georgetown, Newberry, Sumter, Beaufort, Anderson, Pickensville, Winnsborough, Spartanburg, and Camden. Other less important towns are Rock Hill, Cheraw, Cokesbury, Conwayborough, Edgefield, Greenwood, Lancaster, Marion, Pendleton, Walterboro, and Walhalla. The population of the state at decennial periods since 1790, according to the federal census, and in 1875 as reported by the state census, and its rank in the Union, have been as follows:

| YEARS. | White. | Free colored. | Slave. | Aggregate. | Rank. |
|---|---|---|---|---|---|
| 1790.... | 140,178 | 1,801 | 107,094 | 249,073 | 7 |
| 1800.... | 196,255 | 3,185 | 146,151 | 345,591 | 6 |
| 1810.... | 214,196 | 4,554 | 196,365 | 415,115 | 6 |
| 1820 ... | 237,440 | 6,826 | 258,475 | 502,741 | 8 |
| 1830.... | 257,863 | 7,921 | 315,401 | 581,185 | 9 |
| 1840.... | 259,084 | 8,276 | 327,038 | 594,398 | 11 |
| 1850.... | 274,563 | 8,960 | 384,984 | 668,507 | 14 |
| 1860.... | 291,300 | 9,914 | 402,406 | 703,708 | 18 |
| 1870.... | 289,667 | 415,814 | ...... | 705,606 | 22 |
| 1875.... | 350,721 | 572,726 | ...... | 923,447 | .. |

Included in the aggregate of 1860 were 88 Indians, and in that of 1870 124 Indians and 1 Chinaman. Of the total population in 1870, 343,902 were males and 361,704 females; 697,532 were of native and 8,074 of foreign birth. Of the natives, 678,708 were born in the state, 8,282 in North Carolina, 3,254 in Virginia and West Virginia, 2,874 in Georgia, and 945 in New York; 246,066 persons born in the state were living in other parts of the United States. Of the foreigners, 3,262 were born in Ireland, 2,754 in Germany, 617 in England, and 310 in Scotland. The density of population was 20·75 to a square mile. There were 151,105 families, with an average of 4·67 persons to each, and 143,485 dwellings, with an average of 4·92 to each. There were 233,915 persons from 5 to 18 years of age, 120,150 males from 18 to 45, and 146,614 male citizens 21 years old and upward. The increase of population from 1860 to 1870 was ·27 per cent. There were 265,892 persons 10 years old and over who could not read, and 290,379 unable to write; of the latter, 55,167 were white and 235,164 colored, 137,246 males and 153,085 females, and 179,145 were 21 years old and over. The number of paupers supported during the year ending June 1, 1870, was 2,343, at a cost of $224,805. Of the total number (2,071) receiving support at the end of the year, 965 were white and 1,106 colored. The number of persons convicted of crime during the year was 1,399. Of the 732 persons in prison at the end of the year, 148 were white and 584 colored. The state contained 451 blind, 212 deaf and dumb, 333 insane, and 465 idiotic. Of the total population (503,763) 10 years old and over, there were engaged in all occupations 263,301; in agriculture, 206,654, of whom 163,528 were laborers and 42,546 farmers and planters; in professional and personal services, 34,383, including 553 clergymen, 16,214 domestic servants, 10,654 laborers not specified, 387 lawyers, 789 physicians and surgeons, and 1,074 teachers not specified; in trade and transportation, 8,470; and in manufactures and mechanical and mining industries, 13,794. The total number of deaths from all causes was 7,380, being 1·05 per cent. of the entire population; from consumption, 657, there being 11·2 deaths from all causes to one from this disease. There were 255 deaths from cholera infantum, 273 from measles, 709 from pneumonia (or 10·4 deaths from all causes to one from this disease), 367 from intermittent and remittent fevers, 515 from enteric fever, and 537 from diarrhœa, dysentery, and enteritis.—The topography of the state resembles that of North Carolina and Georgia. The coast for about 100 m. inward is flat and sandy, with a light soil, covered by pitch-pine forests, traversed by sluggish streams, and interspersed with numerous swamps. This portion of the state is of alluvial formation. Beyond this plain is a belt of low sand hills called the middle country, which is moderately productive. West of

the middle country is a belt called the ridge, where the land rises abruptly, and thence continues to ascend, exhibiting beautiful alternations of hill and dale, till it terminates at the extreme N. W. part of the state in the Blue Ridge, the highest peak of which in South Carolina is Table mountain, 4,000 ft. above the Atlantic. The coast line extends from Little River inlet, in a S. W. direction, to the mouth of the Savannah river, about 200 m. The coast presents numerous inlets, bays, shallow sounds and lagoons, and a few good harbors. Winyaw bay, the easternmost harbor of any note, is 14 m. long and about 2 m. wide. Georgetown is at the head of this bay, to which vessels of light draught ascend. Passing S. W., Bull's bay is next in order, then Charleston harbor, St. Helena sound, and Beaufort harbor, or Port Royal entrance, besides a number of small inlets. Beaufort harbor, which admits vessels of 24 ft. draught, is one of the best in the southern states. Stono inlet, a few miles S. of Charleston, admits vessels drawing 9 or 10 ft. of water. St. Helena sound is a spacious opening 10 m. long and 3 m. broad. Small islands skirt the S. portion of the coast, shut off from the mainland by narrow channels, which afford inland steamboat communication between Charleston and Savannah. These islands are low and flat, and produce sea island cotton. Rice is also here produced in large quantities, and tropical fruits flourish.—Savannah river, which forms the boundary between South Carolina and Georgia, is formed by the confluence of the Tugaloo and Keowee, which rise in the mountains near the line of North Carolina and unite at Anderson, in the W. part of South Carolina; flowing thence in a S. S. E. direction 450 m., it empties into the Atlantic 18 m. below Savannah, near lat. 32° N. and lon. 81° W. The Savannah is navigable for large vessels to the city of Savannah, and for steamers of 150 tons to Augusta, 230 m. further, and by means of a canal round the falls at Augusta smaller boats ascend 150 m. further. The other principal rivers are the Great Pedee, the Santee, and the Edisto. The first, which rises in the Blue Ridge, flows E. S. E. and S. S. E. through North Carolina, where it is called the Yadkin, passes through the E. portion of South Carolina, receives the Black river and Lynch's creek on the right, and the Little Pedee and Waccamaw on the left, and empties into Winyaw bay. It is navigable for steamboats to Cheraw, a distance of about 150 m., above which navigation is obstructed by a fall. The Santee is formed by the junction of the Congaree and Wateree, which by their tributaries rise in the Blue Ridge (W. part of North Carolina), flow S., and unite in the central part of South Carolina; the stream thus formed, flowing upward of 120 m. in a S. E. direction, reaches the Atlantic by two mouths, North and South Santee, a few miles S. W. of Winyaw bay. The principal tributaries of the Congaree are the Saluda and Broad rivers. The Santee is navigable for its entire length, and its tributaries, the Wateree and Congaree, by aid of canals, are navigable for small boats nearly to the mountains, about 200 or 300 m. from the ocean. The Edisto and Combahee rise in the interior, and flowing S. reach the Atlantic near the southernmost point of the state. These streams are navigable for very small boats. The state is remarkably well watered, and almost every county abounds in good water power.—Geologically South Carolina is nearly equally divided between the primitive and the alluvial formations; the former prevailing in the upper portion, the latter along the coast. Among the beautiful granites of the state, the porphyritic granite of Camden and Buffalo creek, and the red granite near Columbia, are conspicuous. Of the syenites, those found in Abbeville, Fairfield, and Lexington counties are the most beautiful. The first resembles the Quincy granite, and the last is remarkable for its white feldspar, contrasting so strikingly with the black crystals of hornblende. White and variegated marbles are found in Spartanburg and Laurens. Gneiss, sufficiently slaty to be split into flagging stones, has been discovered in Pickens and in the lower part of York. Porcelain earth abounds through the primary regions, wherever the feldspathic granite is found in a state of disintegration. Soapstone of fine quality exists in several localities. Red and yellow ochres abound in Chesterfield co. Limestone is most abundant in Laurens and Spartanburg, while the white feldspathic sandstone, buhrstone, and flagstone are found in many of the upper counties. Manganese occurs in nearly every county N. of Columbia. Coal is found in Chesterfield and Marlboro. The gold-bearing rocks of the Atlantic slope extend through the N. W. corner of South Carolina, the metal being found in Abbeville, Edgefield, Lancaster, Pickens, Spartanburg, Union, and York counties. There are mines in Abbeville, Edgefield, and Union. The first mint deposits from South Carolina were $3,500 in 1827; the aggregate of such deposits to June 30, 1874, was $1,379,077. In several cases large nuggets of pure gold have been found, and gold-bearing veins have been successfully worked; but the largest quantities of gold have been obtained from surface washings. Copper occurs in some counties, while iron ore is found in the N. part of the state, above the King's mountain range, but no extensive efforts have been made to develop the deposits. Lead is found in Pickens co., bismuth in Chesterfield and Lancaster, and black lead in Spartanburg and Pickens. The limestones of the Blue Ridge may be used as fertilizers, while the richest deposits of bone phosphates on the continent, if not in the world, have recently been discovered in Charleston co., near the Ashley and Cooper rivers. These deposits underlie many square miles of surface

continuously, at a depth ranging from 6 in. to 12 ft., and exist in such quantities that from 500 to 1,000 tons underlie each acre. In fact, it seems there are no rocks in this section which are not phosphates. In 1870 it was officially estimated that $2,500,000 capital was invested in the business of converting the phosphates into forms available to agriculturists. The production of crude phosphates from 1867 to 1872 was valued at about $1,700,000.—Among the natural curiosities, the most prominent is Table mountain, 20 m. from Greenville, 4,000 ft. above the sea, which looms up perpendicularly on one of its faces 1,100 ft. above the surrounding country. "Cæsar's Head," a rock projection resembling a human skull, near Table mountain, is a place of summer resort. Glenn's Spring, the waters of which are impregnated with magnesia and sulphur, is a watering place of some note in Spartanburg. The falls of the Saluda among the mountains have a descent of from 300 to 400 ft., and the region presents much grand and picturesque scenery. Aiken has since the war become a place of resort for consumptives and other invalids, on account of its comparatively dry and equable climate. The mean temperature of Charleston (lat. 32° 45′, lon. 79° 57′) is: spring, 65·8°; summer, 80·6°; autumn, 68·1°; winter, 51·7°; year, 66·6°. The average rainfall is: spring, 8·60 inches; summer, 18·68; autumn, 11·61; winter, 9·40; year, 48·29. Prevailing wind, S. W. The following tables exhibit the result of observations taken at Aiken, Aiken co., 120 m. N. W. of Charleston, in lat. 33° 30′, lon. 81° 40′, and Gowdeysville, Union co., during the year 1870:

MEAN TEMPERATURE.

| PLACES. | Spring. | Summer. | Autumn. | Winter. | Year. |
|---|---|---|---|---|---|
| Aiken......... | 63·4° | 79·1° | 63·7° | 46·4° | 63·1¼° |
| Gowdeysville.. | 62·6 | 79·7 | 63·5 | 44·3 | 62·5 |

RAINFALL IN INCHES.

| PLACES. | Spring. | Summer. | Autumn. | Winter. | Year. |
|---|---|---|---|---|---|
| Aiken......... | 11·97 | 13·89 | 7·34 | 7·16 | 40·36 |
| Gowdeysville.. | 15·05 | 10·67 | 7·55 | 14·00 | 47·27 |

The maximum temperature at Aiken was 96° in July; minimum, 10° in December and 15° in February; maximum at Gowdeysville, 94° in July and August; minimum, 7° in December and 16° in February. Yellow fever occasionally occurs as an epidemic at Charleston.—South Carolina has very little waste land, and produces cotton, rice, tobacco, maize, oats, rye, barley, sweet and Irish potatoes, peas, beans, &c. The soil comprises six varieties: 1, tide swamp, appropriated to the culture of rice; 2, inland swamp, to rice, cotton, corn, peas, &c.; 3, salt marsh, to long cotton; 4, oak and pine, to long cotton, corn, potatoes, &c.; 5, oak and hickory, to short cotton, corn, &c.; 6, pine barren, to fruits, vegetables, &c. The pine lands, embracing about 6,000,000 acres, are perhaps the most neglected section of the state. The swamps, covering 2,000 sq. m. (1,280,000 acres), of inexhaustible fertility, are capable of drainage. The soil of much the larger portion of the state is clay, which, except in the immediate vicinity of the ocean, is almost the universal substratum. In the N. part of the state, particularly that portion bordering on the Blue Ridge, corn, wheat, oats, and barley flourish, while cotton is liable to suffer from early frosts. This region is also well adapted to the production of apples, pears, peaches, plums, grapes, and other small fruits. The central and lower portions of the state are better fitted to the culture of cotton, corn, and rice. Strawberries are abundant. The English walnut and Spanish mavson chestnut bear good crops, beginning to produce six or seven years after planting. On the sea islands grow the live oak and palmetto. In 1870 the state contained in farms 3,010,539 acres of improved land, 6,443,851 of woodland, and 2,650,890 of other unimproved land. The total number of farms was 51,889; average size, 233 acres. There were 10,286 containing from 3 to 10 acres, 9,146 from 10 to 20, 16,415 from 20 to 50, 8,148 from 50 to 100, 7,112 from 100 to 500, 465 from 500 to 1,000, and 418 of 1,000 and over. The cash value of farms was $44,808,763; of farming implements and machinery, $2,282,946; total amount of wages paid during the year, including value of board, $7,404,297; total (estimated) value of all farm productions, including betterments and additions to stock, $41,909,402; orchard products, $47,960; produce of market gardens, $127,459; forest products, $167,253; home manufactures, $312,191; animals slaughtered or sold for slaughter, $2,507,149; value of live stock, $12,443,510. There were 44,105 horses, 41,327 mules and asses, 98,693 milch cows, 17,685 working oxen, 132,925 other cattle, 124,594 sheep, and 395,999 swine. The productions were 317,700 bushels of spring and 465,910 of winter wheat, 36,165 of rye, 7,614,207 of Indian corn, 613,593 of oats, 4,752 of barley, 460,378 of peas and beans, 83,252 of Irish and 1,342,165 of sweet potatoes, 5,830 of clover seed, 10,665 tons of hay, 224,500 bales of cotton, 32,304,825 lbs. of rice, 34,805 of tobacco, 1,461,980 of butter, 194,253 of honey, 11,404 of wax, 1,055 hogsheads of cane sugar, 13,179 gallons of wine, 241,815 of milk sold, 436,882 of cane and 183,585 of sorghum molasses. The production of cotton in 1873–'4 amounted to 438,194 bales of 468 lbs. each, including 8,759 bales of sea island.—The total number of manufacturing establishments in 1870 was 1,584, having 210 steam engines of 4,537 horse power, and 700 water wheels of 10,395 horse power, and employing 8,141 hands, of whom 7,099 were males above 16, 578 females above 15, and 464 youth. The capital invested amounted to $5,400,418; wages paid during the year, $1,543,715; value of materials used, $5,855,736; of products, $9,858,981. The leading industries were as follows:

| INDUSTRIES. | No. of establishments. | No. of hands employed. | Capital. | Value of products. |
|---|---|---|---|---|
| Blacksmithing | 147 | 845 | $39,960 | $151,329 |
| Bread, crackers, &c. | 17 | 71 | 36,200 | 142,045 |
| Carpentering and building | 64 | 481 | 286,135 | 813,850 |
| Carriages and wagons | 77 | 288 | 81,820 | 186,114 |
| Cotton goods | 12 | 1,123 | 1,337,000 | 1,529,937 |
| Fertilizers | 2 | 825 | 350,000 | 425,000 |
| Flouring and grist-mill products | 624 | 1,138 | 835,814 | 3,180,247 |
| Iron, forged and rolled | 2 | 15 | 20,000 | 22,190 |
| " castings | 7 | 85 | 64,251 | 119,750 |
| Leather, tanned | 34 | 72 | 24,125 | 85,778 |
| " curried | 31 | 55 | 16,075 | 80,247 |
| Lumber, planed | 2 | 19 | 19,000 | 35,000 |
| " sawed | 227 | 1,212 | 583,425 | 1,197,005 |
| Machinery | 21 | 415 | 443,702 | 496,425 |
| Oil, cotton-seed | 1 | 24 | 40,000 | 27,200 |
| Paper, printing | 2 | 43 | 109,000 | 79,000 |
| Printing and publishing, newspapers | 11 | 164 | 102,550 | 237,930 |
| Printing, job | 2 | 18 | 27,000 | 19,225 |
| Ship building, repairing, and ship materials | 7 | 27 | 26,800 | 45,650 |
| Tar and turpentine | 54 | 876 | 205,425 | 774,077 |
| Tin, copper, and sheet-iron ware | 20 | 63 | 37,650 | 87,294 |
| Wool-carding and cloth-dressing | 12 | 40 | 17,200 | 21,259 |
| Woollen goods | 3 | 13 | 8,700 | 13,200 |

The number of cotton mills in 1874 was 18, having 1,238 looms and 62,872 spindles; the amount of cotton used during the year was 7,134,558 lbs. South Carolina has three United States customs districts, indicated in the following statement of foreign commerce for the year ending June 30, 1875, with the number of vessels registered, enrolled, and licensed:

| PORTS OF ENTRY. | Imports. | Exports. | Registered, &c. | |
|---|---|---|---|---|
| | | | Vessels. | Tons. |

The chief article of export is cotton. During the fiscal year 259,053 bales were exported from Charleston, valued at $17,930,603, besides 6,357 bales of sea island, valued at $779,346. The shipments of cotton, rice, naval stores, phosphates, and lumber to ports of the United States constitute an extensive trade. The amount of shipping in 1875 was as follows:

| DISTRICTS. | FOREIGN PORTS. | | | | COASTWISE. | | | |
|---|---|---|---|---|---|---|---|---|

The state had 204 m. of railroad in 1845, 759 in 1855, 1,007 in 1865, and 1,298 in 1875. The following table shows the railroads lying wholly or partly within the state:

| NAMES OF CORPORATIONS. | TERMINI. | | Miles in operation in South Carolina in 1875. | Total length of line when different from preceding. |
|---|---|---|---|---|
| | FROM | TO | | |
| Atlanta and Richmond Air Line | Atlanta, Ga | Charlotte, N. C. | 125 | 265 |
| Charlotte, Columbia, and Augusta | Charlotte, N. C. | Augusta, Ga | 183 | 195 |
| Cheraw and Darlington | Florence | Cheraw | 40 | .... |
| Chester and Lenoir | Chester | Yorkville | 22 | .... |
| Cheraw and Salisbury | Cheraw | Salisbury, N. C. | 12 | 80 |

| Spartanburg and Union | Alston | Spartanburg | 68 | .... |
| Wilmington, Columbia, and Augusta | Wilmington, N. C | Columbia | 124 | 189 |

The Santee canal, 22 m. long, connects Charleston, through Cooper river, with the Santee. There are also several short canals, having an aggregate length of about 30 m. At the beginning of 1875 there were 12 national banks in operation, with a capital stock of $3,135,000; circulation, $2,167,420; circulation per capita, $3 07; ratio of circulation to the wealth of the state, 1 per cent.; to bank capital, 69·1 per cent.—The government is administered under the constitution adopted in 1868, which provides that slavery shall never exist in the state; that every citizen owes paramount allegiance to the United States; that the state shall ever remain a member of the American Union; no property qualification shall be necessary to eligibility to office; distinctions on account of race or color shall be prohibited, and all citizens shall enjoy all common public, legal, and political privileges; no debt contracted by

the state in behalf of the rebellion shall ever be paid; presidential electors shall be elected by the people; the distinction between actions at law and suits in equity is abolished. The right of suffrage is bestowed upon every male citizen of the United States, 21 years old and upward, who has resided in the state one year, and in the county where he shall offer to vote 60 days preceding the election. Elections are by ballot, and a plurality only of the votes cast is necessary to a choice. Qualified electors, who acknowledge the existence of the Supreme Being, are entitled to hold office, with unimportant exceptions. The legislative power is vested in a general assembly, consisting of a senate composed of one member from each county except Charleston, which elects two senators, and a house of 124 representatives apportioned among the counties according to population, each county having at least one. The senators hold office for four years and the representatives for two. They receive $6 a day during the session, and 20 cents a mile for travel to and from the capital. The sessions of the legislature are annual, beginning on the fourth Tuesday of November. The state election is held on the third Wednesday of October in even years. The executive power is vested in a governor (annual salary $3,500 with a furnished residence) and a lieutenant governor ($2,500), *ex officio* president of the senate, who hold office for two years; a comptroller general ($3,000), treasurer ($2,500), secretary of state ($3,000), and attorney general ($3,000), who hold office for four years; a superintendent of education ($2,500), and an adjutant and inspector general ($2,500). These officers are elected by the people. The governor and lieutenant governor must have been two years resident in the state. The governor's veto may be overcome by a two-thirds vote of the legislature. The judicial power is vested in a supreme court, circuit courts (each of which is subdivided into a court of common pleas with civil jurisdiction, and a court of general sessions with criminal jurisdiction), probate courts, and courts of justices of the peace. The supreme court consists of a chief and two associate justices, elected by joint vote of the two houses of the legislature for six years. The chief justice receives an annual salary of $4,000, and the associates $3,500 each. The state is divided into eight circuits, for each of which a judge is elected by joint vote of the legislature for four years; each receives a salary of $3,500 a year. The supreme court has in general appellate jurisdiction only. The courts of common pleas have exclusive jurisdiction in matters of divorce, exclusive original jurisdiction in civil cases not cognizable by justices of the peace, and appellate jurisdiction in cases provided for by law. The courts of sessions have exclusive jurisdiction in criminal cases not otherwise provided for by law. A judge of probate is elected for each county by the people for two years. Trial justices appointed by the governor have jurisdiction of civil cases where the amount involved does not exceed $100, and of criminal proceedings for minor offences. A homestead not exceeding $1,000 in value is exempt from sale under execution, to every head of a family. A poll tax not exceeding $1 may be levied for school purposes. Provision is made for taking decennial censuses, beginning in 1875. The property of a married woman is not liable for the debts of her husband, and she may deal with it in all respects as if unmarried. Before the adoption of the present constitution, divorce was unknown in the state. Divorces are now granted for adultery or desertion for two years; and the one deserting may obtain a divorce if the desertion is justified by cruel treatment, or by neglect of the husband to provide maintenance. The death penalty is abolished, except in cases of wilful murder. Arson and rape are punishable by imprisonment for life or for a period not less than 10 years; the penalty of manslaughter and of burglary is imprisonment for a period not exceeding 30 years. The legal rate of interest, in the absence of agreement, is 7 per cent., but any rate may be contracted for. A convention to revise the constitution may be called by vote of the people, the question having been submitted to them by a two-thirds vote of each house of the legislature. Specific amendments must be proposed by two thirds of each house, voted for by a majority of the people at the next general election, and afterward ratified by a two-thirds vote of each house of the next general assembly. The state has two senators and five representatives in congress, and is therefore entitled to seven votes in the electoral college.—The state debt on Nov. 1, 1874, was reported at $17,017,651, including $9,540,750 bonded debt, $2,679,293 floating debt, and $4,797,608 contingent liabilities. Not included in this statement are bonds to the amount of $5,965,000 issued under the act of March 23, 1869, for the conversion of state securities, which have been declared by the legislature to have been issued without authority, and to be therefore null and void; but the statement includes interest on these bonds, amounting to $894,750, which it is asserted is illegal and should be deducted from the state's liabilities. The bonded debt falls due at different dates between 1877 and 1893; the rate of interest on most of it is 6 per cent. The floating debt consists of unpaid appropriations and over-due interest. The contingent liabilities were created by the indorsement by the state of the following railroad bonds, the state being secured by mortgages on the roads:

| | |
|---|---|
| South Carolina railroad | $2,093,312 |
| Northeastern | 92,000 |
| Charleston and Savannah | 505,000 |
| Savannah and Charleston | 245,750 |
| Laurens | 75,000 |
| Spartanburg and Union | 350,000 |
| Greenville and Columbia | 1,436,546 |
| Total | $4,797,608 |

The receipts from all sources during the year ending Oct. 31, 1874, amounted to $1,712,268, and the expenditures to $1,599,232. The assessed valuation of taxable property in 1874 was $141,624,952, viz.: real estate, $87,794,305; personal property, $43,944,070; railroad property, $9,886,577. The total valuation in 1873 was $176,956,502. The rate of the tax levy for state purposes in 1874 was 10$\frac{23}{60}$ mills. —The constitution of 1868 provides for a uniform system of free common schools to be supported by a tax on property and polls, and for the establishment of a state normal school, a state reform school, a state university, and educational institutions for the deaf and dumb and the blind. It also declares that all public schools, colleges, and universities, supported wholly or partly by the public funds, shall be free to all the children of the state without regard to color; but separate schools are generally provided. Provision was made for the compulsory attendance upon public or private schools of all children between the ages of 6 and 16 years, but no law for this purpose has yet (1876) been passed by the legislature. The state superintendent, who is elected by the people for four years, has general supervision of the public schools. The state board of education consists of the superintendent and the several county school commissioners. There are 32 of the latter officers (one in each county), elected for two years by the people, at an annual salary of $1,000, except in Charleston county, where the salary is $1,200. Each county has a board of school examiners, composed of the commissioner and two members appointed by him; their chief duties are the examination of teachers and the appointment of district trustees. There are no graded schools except in Charleston. The sources of school revenue are: 1, state school tax; 2, poll tax; 3, district taxes. The common school statistics for 1873–'4 were as follows:

| | |
|---|---|
| School population, 6 to 16 years of age, inclusive | 230,102 |
| White males | 43,474 |
| " females | 41,501 |
| Colored males | 73,442 |
| " females | 71,685 |
| Number of school districts | 429 |
| " of schools | 2,353 |
| School attendance | 104,738 |

| Net school revenue | $483,145 |

The state normal school was opened in Columbia in September, 1874, with two instructors and 32 students. The course of study occupies two years. In 1874 there were ten teachers' institutes held in eight counties. The university of South Carolina, in Columbia, has preparatory, academical, law, and medical departments, which are open to white and colored pupils. In 1874–'5 there were 166 students, viz.: 17 in the law, 4 in the medical, and 79 in the preparatory school, 64 in the academical department, and 2 in a special course. State scholarships were established in the university in 1874, and $6,400 appropriated for that purpose. In 1874–'5 57 students were holding state scholarships. The state appropriations for the university during the year ending Oct. 31, 1874, amounted to $41,750. The library of the university in 1875 had 30,000 volumes. Claflin university, at Orangeburg, was opened in 1870 for the education of colored persons of both sexes. In 1872 the state college of agriculture and the mechanic arts was established in connection with this institution, which was then named "Claflin University and South Carolina Agricultural College and Mechanical Institute." The departments which have been organized are: 1, common English; 2, classical preparatory and higher English; 3, agricultural and scientific. In 1874–'5 there were 5 instructors and 188 students, including 65 pursuing scientific, agricultural, and military studies. Furman university (Baptist), opened in 1851 at Greenville, in 1874–'5 had 5 professors and 55 students in the collegiate department. The institution has an endowment of $200,000, contributed by the Baptists of South Carolina; and for ten years from Jan. 1, 1876, tuition is to be free. Newberry college (Lutheran), at Walhalla, Oconee co., opened in 1858, in 1874–'5 had 6 instructors and 101 pupils, including 70 in the preparatory department. Wofford college (Methodist Episcopal church, South), opened in 1853, is at Spartanburg Court House; it has collegiate and preparatory departments, and in 1874–'5 there were 7 instructors. The principal institutions for the higher instruction of women are Columbia female college in Columbia, which in 1874–'5 had 7 teachers and 97 students; Due West female college, at Due West, Abbeville co., with 9 teachers and 113 pupils; the Greenville Baptist female college, at Greenville, with 10 teachers and 117 pupils; and the Williamston female college, at Williamston, with 8 instructors and 119 pupils. The Southern Baptist theological seminary at Greenville, established in 1859, in 1874–'5 had 5 professors and 66 students. The theological seminary of the general assembly of the Presbyterian church in the United States was opened at Lexington, Ga., in 1829, and was removed to Columbia, its present seat, in 1830. It has a library of about 19,000 volumes, and endowments, not including buildings and library, amounting to $164,000. In 1873–'4 there were 5 instructors and 57 students. The medical college of the state of South Carolina, in Charleston, was

opened in 1832, and in 1875 had 8 instructors and 60 students.—The state institution for the education of the deaf, dumb, and blind is at Cedar Springs in Spartanburg co.; but it is now (1876) suspended. The state orphan asylum, in Columbia, had in 1874 an average of 80 inmates, of whom 38 were girls. The legislature appropriated $25,000 for this institution in 1874; the expenditures amounted to $18,900. The state lunatic asylum, in Columbia, opened in 1828, had an average of 312 patients during the year ending Oct. 31, 1874, and 311 at the end of the year. The average annual cost of maintenance is $250 for each patient; $65,000 was appropriated for it in 1874, and the expenditures were $71,590. The state penitentiary, in Columbia, had in 1874 an average of 250 prisoners, who were chiefly employed upon public buildings on account of the state; their earnings amounted to $23,774. The expenses of the institution were $69,838; the state appropriation was $50,000. Religious exercises are held on Sunday. There is a day school for all convicts, and a reformatory school for those under 18 years of age, who are kept separate from the other convicts.—The total number of libraries reported by the census of 1870 was 1,663, containing 546,244 volumes. Of these, 922 with 397,020 volumes were private, and 741 with 149,224 volumes other than private; among the latter were one state library, with 2,700 volumes; 3 court and law, 6,324; 4 school, college, &c., 20,800; 647 Sunday school, 93,200; 84 church, 25,100; and 2 circulating, 1,100. The total number of newspapers and periodicals was 55, having an aggregate circulation of 80,900 and issuing annually 8,901,400 copies. Of these, 5 were daily, with an aggregate circulation of 16,100; 4 tri-weekly, circulation 9,600; 42 weekly, 44,000; 3 monthly, 10,000; and 1 quarterly, 1,200. In 1875 there were reported 7 daily, 3 tri-weekly, 3 semi-weekly, 62 weekly, 1 bi-weekly, 2 semi-monthly, 4 monthly, and 2 quarterly; total, 84. The total number of religious organizations in 1870 was 1,457, having 1,308 edifices, with 491,425 sittings and property valued at $3,276,982. The denominations were represented as follows:

| DENOMINATIONS. | Organizations. | Edifices. | Sittings. | Property. |
|---|---|---|---|---|
| Baptist, regular | 518 | 466 | 190,750 | $688,882 |
| " other | 5 | 5 | 800 | 1,600 |
| Christian | 2 | 2 | 200 | 400 |

—The first attempt to colonize the territory now comprised in South Carolina was made by Jean Ribault, a Frenchman. (See RIBAULT.) The province of Carolina was created by Charles II. in 1663. (See NORTH CAROLINA.) The first permanent settlement in South Carolina was made on the banks of the Ashley river in 1670 by English colonists, who removed in 1680 to the present site of Charleston. Under the name of Carolina, both the present states of North and South Carolina were held as a proprietary government, nominally under the celebrated model constitution prepared by John Locke, till July, 1729, when the king bought out the proprietors, and formed the Carolinas into two royal colonies. In 1685 a large number of French Huguenots settled in South Carolina, and subsequently there were considerable settlements of Swiss, Irish, and German emigrants. The colony at various times suffered severely from Indian depredations, and with Georgia was engaged under Oglethorpe in a contest with the Spanish settlements in Florida. South Carolina was the scene of severe warfare during the revolutionary struggle, hotly contested battles being fought at Fort Moultrie, Charleston, Camden, King's Mountain, Cowpens, Eutaw Springs, &c. The British held the country for the greater part of the years 1780 and 1781. The battle of Eutaw Springs, September, 1781, between Gen. Greene and Col. Stuart, in which both sides claimed the victory, was the last engagement of any importance during the revolution. A state constitution was first adopted on March 26, 1776; the constitution of the United States was ratified by South Carolina on May 23, 1788. Immediately after the presidential election of 1832, a convention of the people of South Carolina was called to meet at Columbia, to take action on the high tariff of 1828 and 1832. The convention met on Nov. 19, unanimously adopted the "nullification ordinance," which pronounced the tariff "null, void, and no law, nor binding on this state, its officers and citizens," and prohibited the payment of duties on imports imposed by that law within the state after Feb. 1 ensuing. The ordinance contemplated an act of the legislature nullifying the tariff, and declared that no appeal should be made to the supreme court of the United States against the validity of such act. It was also declared that should the general government attempt to enforce the law thus nullified, or to interfere with the foreign commerce of the state, the people of South Carolina would "hold themselves absolved from all further obligation to maintain or preserve their political connection with the people of the other states." This action was approved by the governor, Robert Y. Hayne, in his message to the legislature, and measures were adopted by that body to give practical effect to the ordinance. In view of the threatened emergency, President Jackson ordered Gen. Scott to Charles-

ton for the purpose of "superintending the safety of the ports of the United States in that vicinity," and soon after the meeting of congress in December issued a proclamation in which he held that nullification was treason and should be punished as such. During the session of this congress the compromise tariff was passed, which being acceptable to South Carolina, the course threatened by that state was not pursued. In April, 1860, the South Carolina delegates to the national democratic convention in session at Charleston withdrew from that body because the convention did not expressly deny in its platform "the power either of the federal government, or its agent, the territorial government, to abolish or legislate against property in slaves by either direct or indirect legislation." South Carolina was the first of the southern states to institute active measures for withdrawing from the Union on the election of Mr. Lincoln, and the first to pass an ordinance of secession. On Nov. 7, 1860, an act was passed by the legislature calling a state convention. On the same day the United States officials in Charleston resigned, and on the 10th the South Carolina senators withdrew from the United States senate. An election of delegates having been held on Dec. 6, the convention assembled in Charleston on the 18th, and passed the ordinance of secession on the 20th without a dissenting vote. Commissioners were appointed to go to Washington to treat with President Buchanan for the possession of federal property within the limits of South Carolina, while others were sent to the slaveholding states to invite their coöperation in the formation of a southern confederacy. On the 24th the representatives in congress withdrew from that body, and on the same day Gov. Pickens proclaimed the dissolution of the union between South Carolina and the other states. On the 27th Fort Moultrie and Castle Pinckney were seized by the state. The bombardment and capture of Fort Sumter, April 12, 13, by Gen. Beauregard (see SUMTER, FORT), was the beginning of open hostilities, and caused great excitement throughout the country. The ports of the seceded states were declared blockaded by President Lincoln on April 19. Hilton Head and Bay Point were captured on Nov. 7 by an expedition under Admiral Du Pont and Gen. T. W. Sherman. On April 7, 1863, Admiral Du Pont made an unsuccessful attempt to reduce the defences of Charleston harbor, losing one of his vessels in the engagement. A land attack was made in July by Gen. Q. A. Gillmore, who took possession of Morris island, but was repulsed with great loss in an assault upon Fort Wagner. That work was reduced by bombardment, Sept. 7, and shells were thrown into the city itself. In the latter part of January, 1865, Gen. W. T. Sherman's army began its march from Savannah through South Carolina, having Goldsboro, N. C., as an objective point, and threatening Charleston and Augusta at the same time. Columbia was surrendered on Feb. 17, and Charleston and all its defences were evacuated on the same day. (See CHARLESTON, and COLUMBIA.) Gen. Sherman, resuming his march from Columbia, and destroying railroads, bridges, &c., reached Cheraw on the Great Pedee, March 3, whence he moved to Fayetteville, N. C. B. F. Perry was appointed provisional governor of South Carolina, June 30, 1865. On Sept. 4 delegates were chosen to a convention, which assembled in Columbia, Sept. 13, repealed the ordinance of secession, and declared slavery abolished. James L. Orr was chosen governor at a general election held on Oct. 18. At the same time a legislature was elected, which met before the close of the month. Gov. Orr assumed the duties of his office on Nov. 29, but it was not till Dec. 25 that the provisional governor was relieved and the authority in the state restored to the officers elected by the people. This government continued in force until supplanted by the military government provided by congress in March, 1867, when Gen. Sickles was appointed to the command of the second military district, embracing North and South Carolina. He was succeeded in the beginning of September by Gen. Canby. A registration of voters was now held, preliminary to an election to ascertain the will of the people in reference to calling a state convention to frame a constitution and civil government, and 78,982 colored and 46,346 white voters were registered. At the election, held on Nov. 19 and 20, 68,876 colored and 130 white persons voted for a convention, and 2,081 whites against it. Of the delegates chosen, 34 were white and 63 colored. The convention assembled on Jan. 14, 1868, and adopted a constitution, which was ratified by the people, April 14, 15, and 16, by a vote of 70,758 to 27,288. At the same time state officers, members of the legislature (of whom 72 were white and 85 colored), and representatives to congress were chosen. The legislature assembled on July 6, and on the 9th Gov. Scott was inaugurated. The state became entitled to representation in congress by the ratification (108 to 10) of the fourteenth amendment to the federal constitution, and reconstruction was practically completed by the withdrawal of the military authorities on the 13th. The fifteenth amendment to the federal constitution was ratified by the legislature on March 11, 1869, by a vote of 18 to 1 in the senate and 88 to 3 in the house. At the presidential election in 1868, 62,916 votes were cast for Grant (republican) and 45,237 for Seymour (democrat). This was the first time in the history of the state that the people had voted for president and vice president; previously the presidential electors had been chosen by the legislature. During 1868 and subsequently disorders alleged to have been committed by masked outlaws called "Ku-klux" were reported in this state, espe-

cially in the N. W. counties. In the latter part of 1871 and the beginning of 1872 numerous arrests were made under an act of congress for the suppression of these outrages, and many persons were convicted in the United States courts and punished.

**SOUTHCOTT, Joanna**, an English religious enthusiast, born at Gittisham, Devonshire, about 1750, died in London, Dec. 27, 1814. Until nearly 40 years of age she was a domestic servant, and for some years was a member of the established church, but shortly before promulgating her peculiar notions she united with the Wesleyans. In 1792 she began to attract attention by claiming supernatural powers and narrating remarkable revelations made to her in dreams. She published prophecies and warnings in extravagant prose and rude doggerel, challenged the clergy to investigation and discussion, and labored with so much energy and zeal that her sect at the time of her death was estimated at 100,000 persons. When upward of 60 years old she announced that she was pregnant and would give birth to a second Shiloh. Shortly before her death she expressed the conviction that "if she was deceived, she had at all events been misled by some spirit, good or evil." A *post mortem* examination disclosed the fact that dropsy was mistaken by her for pregnancy. Before her death a communication, said to be from her, directed her followers to hold no more meetings until after the birth of Shiloh. Little was heard of the sect till 1825, when a man named Twort professed to be the Shiloh promised. One George Turner made a like claim. In the census of 1851 there were reported in England four congregations of her followers. John Wroe became their leader in 1822, and in 1857 opened a mansion at Wenthorp for a community of Southcottians.

**SOUTHERN, Thomas**, a British dramatist, born at Oxmantown, Ireland, about 1660, died in Westminster, May 26, 1746. After spending two years at Trinity college, Dublin, he entered in 1678 the Middle Temple, London, but soon gave up the law for literature. Of the ten plays which he wrote, the best known are "Isabella, or the Fatal Marriage," in which Mrs. Siddons won her first laurels, and "Oronooko," in which he denounced slavery and the slave trade. A complete edition of his works appeared in 1774 (3 vols. 12mo).

**SOUTHERNWOOD.** See Artemisia.

**SOUTHEY. I. Robert**, an English author, born in Bristol, Aug. 12, 1774, died at Greta hall, near Keswick, March 21, 1843. In his 14th year he was placed at Westminster school, the expenses being borne by a maternal uncle. For publishing in "The Flagellant," a periodical started by him and his associates, a satirical article on corporal punishment, he was expelled in 1792. He entered Balliol college, Oxford, in January, 1793, accepted with enthusiasm the liberal ideas to which the French revolution had given currency, and began his career of unparalleled industry as a man of letters. He wrote in 1793 the dramatic poem of "Wat Tyler," first published surreptitiously in 1817, which was assailed in the house of commons as seditious. With Coleridge and Lovell he formed the abortive plan of a pantisocracy, or perfect society, on the banks of the Susquehanna. He left the university in 1794, published in connection with Lovell a volume of "Poems" (1794), and received from Cottle 50 guineas for his "Joan of Arc" (1795), an epic poem, which was favorably received. In 1795-'6 he spent six months with his uncle in the Peninsula, and published "Letters written during a Short Residence in Spain and Portugal" (1797). In 1797 he went to London to study law, but soon took lodgings for most of the time in the country, and continued his literary pursuits. He was the editor and principal writer of the "Annual Anthology" for 1799 and 1800. His health failing, he again visited Portugal in 1800, and collected materials for a history of that country. For his second epic poem, "Thalaba, the Destroyer" (2 vols. 12mo, 1801), he received 100 guineas. The post of secretary to the chancellor of the exchequer for Ireland was offered to him with a salary of £350, but he soon resigned what he termed "a foolish office and a good salary." In 1804 he settled at Greta, near Keswick, where Coleridge was living, and about 14 m. from Wordsworth at Grasmere. From this time he appears in his writings as an uncompromising monarchist and churchman, and his life was marked by untiring and cheerful labor, and by repeated acts of generosity. He received as permanent inmates of his house the wives of Lovell and Coleridge, sisters of his own wife, assisted in editing the works of Chatterton for the benefit of the sister of that poet, and extended his kindness to several unfortunate poets, among whom was Henry Kirke White, whose "Remains" he edited with a biography. He visited and formed a life-long intimacy with Sir Walter Scott in 1805; became an occasional contributor to the "Quarterly Review;" received in 1807 a pension of £160; undertook in 1809 the historical department of the "Edinburgh Annual Register;" was appointed poet laureate in 1813; received the degree of LL. D. from the university of Oxford in 1821; visited Holland in 1825, and remained three weeks at Leyden in the house of Bilderdijk; declined the offer of a baronetcy in 1835, but accepted an addition of £300 to his pension; and made a tour in Normandy and Brittany in 1837. His intense and protracted activity had now resulted in mental prostration; his memory failed, and his recognition of time and place gave way, and during the last year there was an utter extinction of his faculties. He left at his death one of the most remarkable private libraries in England, which was sold by auction in London.—There is scarcely a department of literature in which Southey did

not engage. His three best poems are "Thalaba, the Destroyer" (1801), an Arabian tale, "The Curse of Kehama" (1810), founded upon fables of the Hindoo mythology; and "Roderick, the Last of the Goths" (1814), the subject of which is the fall of the Gothic dominion in Spain. "Madoc," one of his longer poems, is founded on traditions of Welsh voyages to America. His principal prose works, besides his translations of "Amadis de Gaul" and the "Chronicle of the Cid" from the Spanish, and of "Palmerin of England" from the Portuguese, are: "History of Brazil" (3 vols. 4to, 1810–'19); "Life of Nelson" (2 vols. 8vo, 1813); "Life of John Wesley" (2 vols., 1820); "History of the Peninsular War" (3 vols. 4to, 1822–'32); "Book of the Church" (2 vols. 8vo, 1824); "Sir Thomas More, or Colloquies on the Progress and Prospects of Society" (2 vols., 1829); "Life of John Bunyan" (1830); "Essays, Moral and Political" (2 vols., 1832); and "The Doctor" (7 vols., 1834–'7; best ed., 1 vol., London, 1856). His curious erudition is happily shown in the last, and also in his "Commonplace Book," of which four volumes were edited after his death by his son-in-law, the Rev. J. W. Warter. Southey collected his poetical works (10 vols., 1837–'8), and Mr. Warter has published four volumes of his "Letters" (1856). His life was written by his son, the Rev. C. C. Southey, in which is interwoven his correspondence with many distinguished men of his time (6 vols., 1849–'50). **II. Caroline Anne Bowles,** second wife of the preceding, born at Buckland, Hampshire, Dec. 6, 1787, died July 20, 1854. She was the only child of Capt. Charles Bowles, a retired officer. She published "Ellen Fitz-Arthur," a poem (1820); "The Widow's Tale, and other Poems" (1822); "Solitary Hours, Prose and Verse" (1826); and "Chapters on Churchyards" (2 vols., 1829). In 1839 she married Robert Southey, between whom and herself a long friendship had existed. They had planned to write many works together; but only two or three fragmentary volumes appeared as their joint production.

**SOUTH SEA SCHEME** (often called the South sea bubble), a financial delusion of the early part of the 18th century. In 1711 Robert Harley, earl of Oxford, then lord treasurer, proposed to fund a floating debt of about £10,000,000, the interest, about £600,000, to be secured by rendering permanent the duties upon wines, tobacco, wrought silks, &c. Purchasers of this fund were to become also shareholders in the South sea company, a corporation to have the monopoly of trade with Spanish South America, a part of the capital stock of which was to be the new fund. After the peace of Utrecht, however, Spain refused to open her commerce to England, and the privileges of the South sea company became worthless. As many men of wealth were among its shareholders and directors, the corporation continued to flourish as a monetary institution. The bad success of its trading operations was concealed, and accounts of the riches of Chili and Peru, together with false reports of intended concessions by the king of Spain, were skilfully used to increase its credit. The breaking out of the Spanish war in 1718 did not shake the popular confidence in its promises. The stock of the company was in great request, and the directors determined to enter upon the same career that John Law was then running in France. In April, 1720, parliament by large majorities in both houses accepted their plan for paying the national debt, that of the bank of England being rejected. Walpole was almost the only eminent man who protested against the measure. The South sea company took upon itself the whole debt of the state, £30,981,712, in consideration of 5 per cent. per annum secured to them for four years, after that to be redeemable by the government, and the interest to be 4 per cent. Hereupon a frenzy of speculation seized the whole nation. Shares of the South sea company, which at the passing of the bill sold at £300, soon began to rise rapidly; and an enormous traffic in them sprung up, in which all classes engaged. By May 29 two thirds of the government annuitants had exchanged the securities of the government for those of the company. Not even the collapse of Law's scheme at the end of May checked the popular infatuation; South sea stock kept on rising until early in August, when it reached its maximum, £1,000. Soon afterward it became known that Sir John Blunt, the chairman, and some others had sold out, and the stock began to fall. Toward the close of September, in spite of great efforts both of the government and of the bank of England to save its credit, the company stopped payment, and thousands were beggared. An investigation ordered by parliament disclosed much fraud and corruption, in which many prominent persons were implicated. Some of the directors were imprisoned, and all of them were fined to an aggregate amount of over £2,000,000 for the benefit of the stockholders. A great part of the valid assets of the company was also distributed among them, yielding a dividend of about 33 per cent.—See Coxe's "Memoirs of Walpole" (2 vols., 1798), and "Memoirs of Extraordinary Popular Delusions," by Charles Mackay (London, 1850).

**SOUTHWELL,** or **Sotwell, Nathaniel,** an English scholar, born in the county of Norfolk about 1600, died in Rome, Dec. 2, 1676. He was educated in the English college at Rome, became a Jesuit, and in 1624 was sent as a missionary priest to England. He returned to Rome in 1627, and from 1637 to 1668 was secretary general of his order. He revised, reedited, and completed the *Bibliotheca Scriptorum Societatis Jesu*, begun by Ribadeneira and continued by Alegambe (fol., Rome, 1676; new ed. by the Jesuit Oudin, Rome, 1745; with supplements, Rome, 1814, 1816). He was also the author of "A Journal of Meditations for Every Day in the Year" (London, 1669).

**SOUTHWELL, Robert,** an English author, born at Horsham St. Faith's, Norfolk, in 1560, executed at Tyburn, Feb. 21, 1595. He was educated at Douai, became a Jesuit at Rome in 1578, was appointed rector of the English college there in 1585, and in 1586 was sent as a missionary to England. He ministered secretly to the scattered Roman Catholics, residing principally as chaplain in the household of the countess of Arundel. In 1592 he was imprisoned in the tower, and was ten times subjected to the torture to make him disclose a plot against Queen Elizabeth. He was much revered among Roman Catholics for his gentleness and purity of life, and his cause has been lately introduced for canonization in the Roman ecclesiastical courts. His most important poems are contained in "St. Peter's Complaint and other Poems" (4to, London, 1595; last ed. with sketch of his life by W. J. Walter, 1817), and "Mæoniæ, or Certaine excellent Poems and Spirituall Hymnes" (4to, 1595). His chief prose works are: "The Triumph over Death" (1595); "Epistle of Comfort to those Catholics who lie under Restraint" (8vo, 1605); and "Marie Magdalen's Funeral Teares" (4to, 1609; new ed., 1823). Collective editions of his works were published in 1620, 1630, 1634, 1637, and 1828; and a complete edition of his poetical works in 1856.

**SOUTHWORTH, Emma D. E.** (Nevitt), an American authoress, born in Washington, D. C., Dec. 26, 1818. She was married in 1841, and two years later, being thrown upon her own resources, she resorted to her pen for support. She wrote for the "National Era," a newspaper published in Washington, and in 1849 republished from it her first novel, "Retribution." Her later works are very numerous, including "The Deserted Wife," "Shannondale," "The Curse of Clifton," "The Lost Heiress," "The Discarded Daughter," "Cruel as the Grave," "Tried for her Life," "A Beautiful Fiend" (1873), and "The Spectre Lover" (1875). An edition of her works was published at Philadelphia in 1872, in 35 vols.

**SOUVESTRE, Émile,** a French author, born in Morlaix, April 15, 1806, died in Paris, July 5, 1854. After failing to get his first drama performed in Paris, he became in 1820 a publisher's clerk at Nantes, and finally a journalist and littérateur, settling in Paris about 1836. After the revolution of 1848 he received a professorship in the new school of administrative science, and delivered popular lectures there and subsequently in Switzerland, which were published under the title of *Causeries historiques et littéraires* (2 vols., 1854). He excelled as a writer of didactic novels and tales. His *Philosophe sous les toits* received in 1851 an academical prize. Shortly after his death the Lambert prize for the most beneficent works was given on his behalf to his widow, who also wrote and translated various works. His sketches of life in Brittany include *Les derniers Bretons* (4 vols., 1835–'7). In 1868 an English translation of his "Legends of Brittany" appeared in New York, and one of "Pleasure of Old Age" in London.

**SOWERBY. I. James,** an English naturalist, born in Lambeth, March 21, 1757, died Oct. 25, 1822. In early life he was a painter of portraits and miniatures, and later took up natural history in connection with his art. He published "English Botany, or colored Figures of all the Plants Natives of Great Britain," with descriptions by Sir J. E. Smith, M. D. (36 vols. royal 8vo, 1792–1807; supplement by his son James De Carle Sowerby, 4 vols., 1815–'49; new ed. by J. T. B. Syme, 10 vols., 1863–'70); "Colored Figures of English Fungi or Mushrooms, with Descriptions" (3 vols. fol., 1797–1809); "British Mineralogy" (5 vols. 8vo, 1804–'17); "Exotic Mineralogy" (2 vols. roy. 8vo, 1811–'17); "British Miscellany" (animal subjects, 12 parts, 1804–'6); and "Mineral Conchology of Great Britain" (6 vols., 600 colored plates, 1812–'41; vols. v. and vi. by his son James De Carle). He was a fellow of the Linnæan and geological societies. **II. George Brettingham,** son of the preceding, born in Lambeth, Aug. 12, 1788, died July 26, 1854. He assisted his father in the entomological portion of his works, and published "Genera of Recent and Fossil Shells" (42 parts 8vo, 264 colored plates, 1822–'34; drawings and engravings by his father and his brother James De Carle), and "Species Conchyliorum, or Original Descriptions and Observations of all the Species of Recent Shells with their Varieties" (4to, 1830, unfinished). **III. George Brettingham,** son of the preceding, born March 25, 1812. He has published "Manual of Conchology," with upward of 650 figures of shells on 24 copper plates (8vo, 1839; 4th ed., revised, 1852); "Conchological Illustrations" (6 vols. 8vo, 1841); "Thesaurus Conchyliorum, or Figures and Descriptions of Shells" (30 parts imp. 8vo, 1842–'71); "Popular British Conchology" (16mo, 1854; new ed., 1866); "Popular History of the Aquarium" (16mo, 1857; new ed., 1865); "Illustrated Companion to Kingsley's Glaucus" (1858); "Illustrated Index of British Shells" (royal 8vo, 24 plates, 1859); and "Labels for the recognized Species of British Shells" (1861). He also furnished drawings for Reeve's "Elements of Conchology" and "Land and Fresh-water Mollusks of the British Isles."

**SOY** (Japanese, *sooja*), a sauce prepared in Japan and China from the seeds of a plant formerly called *soja hispida*, but now *glycine hispida*. The plant is erect, much branched, and roughly hairy, has pea-like flowers in axillary racemes, and hairy pods with two to five compressed seeds. In preparing the soy the seeds are boiled with water nearly to dryness, then put in wide-mouthed jars with water and sugar, and exposed to the sun and air. Every day they are well stirred; and when the fermentation is completed the mixture is strained, salted, and boiled, and skimmed until clarified. Soy

is in general use as a condiment throughout Cochin-China, China, and other eastern countries; the Japanese is considered the best. It has a peculiar flavor, neither too salt nor sweet; a thick consistence and clear brown color; and leaves when shaken in a glass a coat of bright yellowish brown upon the sides. It is imported to be used with fish. The Chinese name for the sauce, according to Archer, is *kitjap*, from which our word catsup or ketchup is derived.

**SOYER, Alexis,** a French cook, born about 1800, died in England, Aug. 5, 1858. For several years anterior to 1850 he was chief cook at the Reform club, London. During the Crimean war he introduced among the troops at Constantinople an intelligent system of cooking. He published "Cookery for the People," *Délassements culinaires* (8vo, London, 1845), "Gastronomic Regenerator" (1847), "The Modern Housewife" (1849), &c.

**SPA,** or **Spaa,** a watering place of Belgium, in the province and 16 m. S. E. of the city of Liége, in a beautiful valley of the Ardennes; pop. about 5,000. It is well built, and has several squares and a fine bathing establishment, erected in 1865. The Pouhon or principal spring is under a colonnade built in honor of Peter the Great, who was here restored to health. The waters are chalybeate, and 150,000 bottles are exported yearly. The annual number of visitors exceeds 16,000.

**SPADA, Lionello,** an Italian painter, born in Bologna in 1576, died in Parma in 1622. He received his earliest education in the school of the Carracci, where he was employed while a boy as a color grinder; subsequently he became a pupil of Caravaggio. After executing important works in Reggio, Modena, and Parma, he entered the service of Ranuccio, duke of Parma. His masterpiece is "San Domenico burning the proscribed Books of the Heretics."

**SPAGNOLETTO,** a Spanish painter, whose real name was José Ribera, born in San Felipe de Jativa, Jan. 12, 1588, died in Naples in 1656. He was a pupil of Caravaggio, whose peculiar style he followed with enthusiasm, and settled in Naples about 1612. He excelled in chiaroscuro, and delighted in gloomy subjects. His chief works are in Spain, but Naples possesses his "Martyrdom of St. Januarius," "St. Jerome and St. Bruno," and "Descent from the Cross." Among his pupils was Salvator Rosa.

**SPAIN** (anc. *Iberia;* Lat. *Hispania;* Span. *España*), a kingdom of S. W. Europe, forming with Portugal the Pyrenean or Iberian peninsula. The name Hispania came into use among the Romans after the destruction of the Carthaginian power in the peninsula. It lies between lat. 36° and 43° 48′ N., and lon. 3° 20′ E. and 9° 21′ W. Its greatest extent N. and S., from Cape Peñas in Asturias to Tarifa point and the strait of Gibraltar, is about 540 m.; E. and W., from Cape Creus in Catalonia to near Cape Finisterre in Galicia, about 630 m. It is bounded N. E. by France, with which it is connected by an isthmus about 240 m. wide, and W. partly by Portugal; on all other sides it is surrounded by water, viz.: E., S. E., and S. by the Mediterranean and the strait of Gibraltar, which separates it from Africa, S. W. and W. by the Atlantic ocean, and N. by the bay of Biscay. In extent it holds the sixth rank among European states, being surpassed by Russia, Sweden and Norway, Austria, Germany, and France.—The coast line of Spain, which forms nearly two thirds of its perimeter, is about 1,370 m. in length, of which about 600 m. belongs to the bay of Biscay and the Atlantic, and 770 m. to the Mediterranean. In the north, from the French frontier to Cape Ortegal and thence to the mouth of the Minho, the coast is rocky, the height ranging from 40 to 300 ft. In the southwest, from the mouth of the Guadiana to that of the Guadalquivir, the shore is mostly low, sandy, and swampy; then it rises gradually, and in the bay of Algesiras presents suddenly the magnificent rock of Gibraltar. From Gibraltar to Cape Palos at the southeast it is mostly rocky, but of little elevation. The E. coast, from Cape Palos to the French frontier, is alternately high and low; a part of it is lined with lagoons, along which numerous salt works are established. The indentations of the Spanish coast are not considerable; the greatest are the bay of Rosas and the gulf of Ampolla in the east, and the gulf of Almería, the strait and bay of Gibraltar, and the bay of Cadiz in the south. Among the most important capes are Creus, St. Sebastian, St. Martin, and Palos in the east, Gata and Trafalgar in the south, Finisterre in the west, and Ortegal, Peñas, and Machichaco in the north. There are few islands near the Spanish coast; the most important are the Balearic, a group consisting of two larger (Majorca and Minorca) and a number of smaller islands, and Iviza and Formentera (the Pityusæ of the ancients). Other small islands are the Isla de Leon, on which Cadiz stands, and the Columbretes, off the coast of Valencia. Excellent harbors are found in the northwest and west, of which those of Ferrol and Vigo are conspicuous; the southwest has the almost unassailable harbor of Cadiz, and the northeast the harbors of Barcelona and Rosas.—Spain has 230 rivers, of which only a few are navigable. From the general direction of the mountain ranges, the main streams flow generally either E. or W. The principal rivers which water the basins inclining toward the Mediterranean are the Ebro, Guadalaviar, Jucar, and Segura, each of which receives several affluents. Five large rivers run into the Atlantic, the Minho (Sp. *Miño*), Douro (*Duero*), Tagus (*Tajo*), Guadiana, and Guadalquivir. Two of these rivers, the Douro and the Tagus, have their mouths in the territory of Portugal, and two others, the Minho and Guadiana, on the confines of the two countries. The most important of them in point of navigation is the Guadalquivir, the others being encumbered with rocks, shallows, and falls. The lakes are

not important; the most remarkable is that of Albufera, S. of Valencia.—Spain is eminently a region of mountain ridges and broad elevated plateaus. From near the Mediterranean to the Atlantic the whole peninsula is traversed by successive mountain belts, including between them high lands watered by numerous small streams. As many as five distinct belts are traced across the peninsula, the most prominent of which, ranging along the northern border, has been described under the heads Cantabrian Mountains and Pyrenees. Each belt is marked by bold precipitous fronts facing the south and gentler slopes toward the north. The second belt, the Sierra de Guadarrama (with its continuations the Sierras de Gredos and de Gata), divides Leon and Old Castile from Estremadura and New Castile, and the waters of the Douro from those of the Tagus. Some of its peaks, as the Puerto del Pico in the province of Ávila, and Peñalara on the border of Segovia and Madrid, rise to a height of about 8,000 ft. Toward the east, on the borders of Aragon, this belt is broken up into various irregular ranges which, under the name of the Iberian chain, including in this designation the spur from the Cantabrians before referred to, extend in a S. E. direction and spread over the E. coast. The third range, called the mountains of Toledo, separate the waters of the Tagus from those of the Guadiana. This range is less marked than the others. The next is the Sierra Morena, along the southern slopes of which flow the branches of the Guadalquivir. Under various names this important belt is traced from the province of La Mancha on the east to the S. W. extremity of Portugal at Cape St. Vincent. The name Morena, brown or dark-colored, is said to be given to the mountains from the dingy color of the forests of kermes oak along the southern edge. The southern coast range, of which the Sierra Nevada forms a part, and which is spoken of collectively by that name, runs close to the Mediterranean, through southern Murcia and Andalusia, from Cape Palos to Cadiz by one branch, and to the rock of Gibraltar by another. It contains the Cerro de Mulhacen, the highest point of the peninsula, and of Europe except in the Alps and the Caucasus, being 11,654 ft. high, and the peak of Veleta, 11,375 ft. Besides these there are numerous minor ranges, which may be regarded as offshoots or continuations of the principal chains. —The geological formations of Spain range with the mountains E. and W. across the peninsula, and consist in the mountains themselves of metamorphic granites and crystalline schists, and on their flanks are represented the Silurian, Devonian, and sometimes the carboniferous formations. In Asturias the last named are met with in highly tilted strata. The older palæozoic rocks are frequently covered by groups of the tertiary, some of the most recent of which, as along the southern slopes of the Guadarrama, lie inclined from the uplifting of the mountains, and in Leon along the Cantabrian range they even stand in a vertical position; but back from the mountains over the great plains of Castile the same strata lie horizontally. The uplifting of the Sierra Morena appears to have been previous to the deposition of the miocene, calcareous beds of which, filled with fresh-water shells, are seen on both sides of the mountains lying horizontally upon highly inclined Silurian slates. The Iberian chain is in great part made up of the newer secondary formations. Moncayo on the western borders of Aragon, the highest mountain of this group, is referred to the Jura, and many other mountains in the eastern provinces more than 5,000 ft. high are composed of Jurassic or cretaceous rocks. These formations extend around on the S. coast, and the rock of Gibraltar is Jurassic limestone. The trias also is traced from the Pyrenees to Andalusia, near the Mediterranean, in beds of conglomerates, sandstones, limestones, clays, marl, gypsum, and salt. —The mineral productions of Spain are various and rich, and its mines of lead, mercury, tin, iron, silver, copper, salt, &c., have been worked from the remotest times. Iron ores are very generally diffused, but the production of iron is comparatively small. Linares, in the province of Jaen, and the Sierra de Gador, a spur of the Nevada, possess rich mines of lead. The little copper produced in Spain is chiefly from the mines of Linares and that of Rio Tinto N. W. of Seville, all in Andalusia. Tin ores are found only in Galicia, and are worked to a very moderate extent. Lead and copper are also found here, and in ancient times silver and gold were produced in Galicia. Antimony was formerly extracted from the mines of La Mancha. Near Cardona in Catalonia are famous mines of rock salt associated with beds of gypsum in the trias formation. Silver is now obtained only from the mines of Guadalcanal, in the province of Seville. The quicksilver mines of Almaden, in Ciudad Real, are the richest in Europe. Asturias and Aragon have important coal mines.—The climate of Spain is divided into three greatly differing zones. The northern zone, which extends to the Ebro and the Minho, comprises Galicia, Asturias, the Basque provinces, Navarre, Catalonia and the northern part of Old Castile, and Aragon. The mountains which cover this zone, the almost perpetual snows of the Pyrenees, together with the N. and N. E. winds, lower the temperature, increase the number and supply of the waters, and promote vegetation. Agriculture is therefore the principal occupation, especially of the Basques and Catalonians. The winters in this zone are generally cold, and the springs moist; but the climate is on the whole temperate. The middle zone, which embraces northern Valencia, New Castile, southern Old Castile, southern Aragon, Leon, and Estremadura, is composed of vast and elevated plateaus, the uniform and monotonous surface of which is swept by the winds

and burned by the sun. Although high mountain ridges line and traverse this region, it has few rivers, not sufficient to fertilize it. The temperature is subject to extremes; the winters are cold and the summers burning, but the spring and autumn are pleasant. The southern zone, which comprises Andalusia, Murcia, and southern Valencia, is exposed to the influence of the burning winds from Africa, and to the reflection of the rays of the sun from the naked and rocky mountain walls. The valleys in this zone are deeper and the plateaus less extended and better supplied with water than in the middle zone; the soil is more diversified and better adapted for agriculture. The temperature, delicious in autumn and in spring, is tropical in summer, and more rainy than cold in winter. Two kinds of winds are very troublesome. The *gallego*, a N. and N. W. wind, blowing from Galicia, is cold and piercing, and causes painful affections of the eye. The southern provinces are visited by the *solano*, the sirocco of Italy.—Spain is one of the most fruitful countries of Europe. Wheat, maize, barley, hemp, and flax are extensively cultivated, especially in the eastern and northern provinces. Saffron and other dye plants are chiefly found in the interior. Mulberry trees are largely cultivated for rearing silkworms in Valencia, Murcia, and Granada. In the south there is a great variety of the finer fruits, including the almond, date, fig, orange, citron, pomegranate, pineapple, and banana. Large forests, especially of evergreen oaks, including the cork tree, are still found in Asturias, the Pyrenees, the Sierra Morena, and the Sierra Nevada; but on the whole Spain has less timber than any other of the large countries of Europe, owing to the want of cultivation. The culture of the vine is general; but only the coast districts of Jerez, Rota, and Malaga, in Andalusia, and of Benicarlo and Alicante in Valencia, furnish considerable quantities for exportation. The quadrupeds, birds, reptiles, and insects are mostly of the same kinds as those of S. France. Wolves, lynxes, foxes, and wild boars are still to be found on the high mountains; but the bear, which two centuries ago was common, is only to be met with in the Pyrenees. The Barbary ape, the only monkey naturalized in Europe, inhabits the rock of Gibraltar. Descended from breeds which the Moors introduced, the Spanish horse has preserved the fire, docility, grace, and vigor of the Arabian. Those of Seville, Granada, and Estremadura are most valued. The asses and mules are superior; the former rival those of Egypt, but mules are preferred for transportation. The bulls used for bull fights are found wild in the Sierra Morena. Sheep are everywhere extensively raised, a considerable proportion belonging to the merino breed. Hogs are bred in large numbers; those of Estremadura, Galicia, and Asturias are celebrated for the delicacy of their flesh. There are important fisheries on the coasts; the fish of the Atlantic are preferred to those of the Mediterranean.—The kingdom, inclusive of the less remote islands, is divided into 49 provinces, named after their respective capitals except the last six in the table, viz.: Navarre, capital Pamplona; Biscay, Bilbao; Guipúzcoa, St. Sebastian; Álava, Vitoria; Balearic Islands, Palma; Canary Islands, Santa Cruz de Tenerife. The area and population of the provinces and of the ancient divisions, according to official estimates in 1870, are given in the *Almanach de Gotha* for 1875 as follows:

| PROVINCES. | Area, sq. m. | Population. |

The area and population of the foreign colonies of Spain according to the latest data are as follows:

| COLONIES. | Area, sq. m. | Population. |
|---|---|---|
| AMERICA. | | |
| Cuba | 45,883 | 1,400,000 |
| Porto Rico | 3,596 | 625,000 |
| Total | 49,479 | 2,025,000 |
| ASIA AND OCEANICA. | | |
| Philippines (exclusive of independent parts) | 65,908 | 6,000,000 |
| Carolines and Palaos | 916 | 28,000 |
| Ladrones or Marianas | 417 | 5,610 |
| Total | 67,241 | 6,033,610 |
| AFRICA. | | |
| The Guinea islands | 489 | 35,000 |
| Total Spanish colonies | 117,209 | 8,093,610 |

The Canary islands, which geographically belong to Africa, are included by the Spaniards in their European possessions. Besides them, the town of Ceuta, on the coast of Morocco, is included in the European province of Cadiz, and the Presidios, likewise on the N. coast of Africa, are included in the European province of Granada. In population Spain ranks seventh among the powers of Europe, being surpassed by Russia, Germany, France, Austria, Great Britain, and Italy. The increase since 1700 is shown in the following table:

| YEARS. | Population. | YEARS. | Population. |
|---|---|---|---|
| 1700 | 8,000,000 | 1849 | 14,216,219 |
| 1769 | 9,160,000 | 1857 | 15,454,514 |
| 1797 | 10,541,000 | 1870 | 16,835,506 |
| 1834 | 12,597,719 | | |

The increase since 1834 has been about equally divided; only one province, Ciudad Real, shows a small decrease, from 277,788 to 264,649. The largest ratio of increase is in the eastern provinces, where Lérida has advanced from 151,322 to 330,348, Valencia from 388,759 to 665,141, and Barcelona from 442,273 to 762,555. The thinnest population is found in the interior provinces of Leon, the two Castiles, and Estremadura; and the densest in the north, Galicia, Asturias, the Basque provinces, Navarre, Aragon, and Catalonia. The entire population is distributed among 169 *ciudades* (cities), 4,707 *villas* (towns), 30,386 *lugares* (villages), and 10,788 *aldeas* (hamlets). The principal cities are Madrid, the capital, Barcelona, Malaga, Valencia, Seville, Granada, Cadiz, and Saragossa. Spain is believed to have been in former times much more densely inhabited than during the last two centuries. Under the dominion of the Romans, the population, according to some calculations, was upward of 30,000,000; and in the 14th century it is believed to have amounted to 24,000,000. Most of the inhabitants belong to the Spanish race, a mixture of the descendants of the old Iberians and Celts with the Carthaginians, Romans, Vandals, Suevi, Goths, and Moors, with a general predominance of the Roman element, although the several provinces show in some respects marked differences in the national character. National amusements are music, singing, and dancing, the last named often assuming, especially in the favorite *fandango* and *bolero*, a passionate and sensuous character. From the Romans the Spaniards have inherited a fondness for bull fights, which are still the greatest popular festivities, and equally delight all classes. The men are generally well built, and have a dark but clear complexion, black hair, eyes full of fire, sharp features, and gestures measured and solemn. The women are well formed and distinguished for noble carriage. Besides the Spaniards proper, there are three other races, the Basques, the Modejars, and the gypsies. The Basques, probably the descendants of the ancient Iberians, numbering (besides those in France) about 650,000, and forming the majority of the population in the Basque provinces and in Navarre, have retained their ancient language, manners, and customs. (See BASQUES.) The Modejars, about 60,000 in number, are the descendants of the Moors; they are chiefly found in Granada and Castile, and many of them still preserve the customs of their forefathers. The gypsies or Gitanos, numbering about 50,000, and scattered throughout Spain, speak a peculiar dialect current only among themselves. Spain has a very numerous nobility; according to some they form the 21st, according to others even the 15th part of the population. The higher nobility (*titulados*, *grandes*) own immense possessions, while the lower class (*hidalgos*) are in many instances poor.—Agriculture, although still very imperfect, has made of late considerable progress. Wheat, which at the beginning of the century

was not yet grown in sufficient quantities for home consumption, forms now a considerable article of export. Wine and oil constitute the chief riches of some of the provinces. Agriculture has made especial progress in Biscay, Navarre, and Aragon, and all the arable ground near the roads has been cultivated. But the most careful cultivation is found in the *huertas* or irrigated lands of Granada, Murcia, and Valencia, which are regarded as the gardens of Spain, and produce all kinds of fruits, vegetables, and plants. The farmers are for the most part wretchedly poor, and are obliged to obtain money at exorbitant prices by mortgaging their crops. Certain privileges, very injurious to the interests of agriculture, are enjoyed by the proprietors (called *mestas*) of large migratory flocks of sheep, especially merinos. They are not only allowed to drive their flocks over village pastures and commons, but the proprietors of such cultivated lands as lie in their way are obliged to leave for them a wide path; and no new enclosures can be made in the line of their migrations, nor can any land that has once been in pasture be again cultivated till it has been offered to the *mesta* at a certain rate. Only about 53 per cent. of the soil is under cultivation.—Manufacturing industry in former centuries was very prosperous. In the middle ages, the wool and silk tissues of Seville, Granada, and Baeza, the cloths of Murcia, and the arms of Toledo enjoyed a high reputation. The expulsion of the Moors and Jews, the monopoly given to the royal manufactories, the onerous taxes weighing down private industry and aggravated by the avidity of the fiscal agents, combined to undermine this prosperity. Seville in 1519 counted 16,000 silk workshops, employing 130,000 workmen; in 1673 it had only 405 manufactories. The manufactories of Segovia, in which formerly 25,000 pieces were annually produced, made in 1788 only 400 pieces. In recent times industry has greatly improved again, especially by the influx of foreign capital, as a considerable portion of the former property of the clergy has passed into the hands of French and English capitalists. The cotton industry, which is concentrated chiefly in Barcelona and other places in Catalonia, employs 1,200,000 spindles, and supports about 100,000 men. Metallurgic industry has been developed in Guipúzcoa, Biscay, Aragon, Catalonia, and Granada; silk goods are manufactured at Barcelona, Manresa, Tarragona, Toledo, Seville, and Valencia; woollen stuffs at Segovia, Arevalo, Colmenar (on the Manzanares), and Alcoy; linen in Galicia and Catalonia; leather at Barcelona, Cordova, Burgos, Toledo, Granada, and Madrid; and glassware at Barcelona. There are manufactories of firearms in the Basque provinces, Catalonia, and Segovia, and cannon founderies at Seville, Liergames, Trubia, and Barcelona. The number of stock companies has greatly increased of late years. At the close of 1866 there were 65 credit and other commercial and industrial associations, with a nominal capital of $37,900,000. In 1867 there were 27 railroad and other public works associations, with a nominal capital of $204,480,000. The number of banks was 23, capital $35,600,000. A decree of March 19, 1874, founded a new national bank, with which the old privileged Spanish bank and the provincial banks were to be consolidated.—The first railroad in Spain was opened in 1848, from Barcelona to Mataro, 18½ m. Notwithstanding the mountainous nature of the country, their extension has been pursued with some vigor; but in consequence of the wretched state of Spanish industry, the want of good inland roads, and frequent political disturbances, the financial condition of the railroads is unsatisfactory, and their progress has been less rapid lately than in any other European country. In 1867 only 26 m. of new railroads were opened; in 1868, 72 m.; in 1869, 6 m.; in 1870, 36 m.; in 1871, 20 m.; in 1872 and 1873, 60 m. Some of the main lines were not yet completed in 1875. The aggregate length of the railroads on Jan. 1, 1874, was 3,364 m. In 1867 the number of passengers carried was 10,357,351. The total length of telegraph lines in 1871 was 7,287 m.; number of stations, 193; number of despatches, 996,912. The number of post offices was 2,347; of letters, 78,174,000. There are several canals, some of them on a magnificent scale, but mostly unfinished and unfit for navigation. The chief of these are the Imperial canal, begun by Charles V., and extending along the right bank of the Ebro, and the canals of Castile, Manzanares, Murcia, Albacete, and Guadarrama. The aggregate length of the canals in 1874 was 430 m., of which 131 m. were navigable. The number of the boats on the latter was 332.—The most important articles of export are wines, specie, metals, especially lead, raisins, olive oil, flour, cork, soap, wool, brandies, and salt; and the imports comprise sugar, cotton and cotton goods, woollen, silk, and linen goods, iron in bars, codfish, machines, cacao, guano, and coal. In 1849 a protective tariff was adopted in place of the former prohibitive system. A decree of the regency, dated Aug. 1, 1869, introduced a new tariff, which abolished all prohibitions and reduced considerably the duties on most articles. It provided also for a further reduction to take place on July 1, 1875. The imports and exports from 1867 to 1869 inclusive, according to official reports, were as follows:

| YEARS. | Imports. | Exports. |
|---|---|---|
| 1867 | $76,800,000 | $56,600,000 |
| 1868 | 110,200,000 | 53,300,000 |
| 1869 | 84,900,000 | 51,200,000 |

The trade of Spain is chiefly with France, Great Britain, and Cuba. In 1867 the value of im-

ports from France was $33,648,000, from Great Britain $26,112,000, and from Cuba $7,680,000; of exports to France $15,936,000, to Great Britain $16,224,000, and to Cuba $9,936,000. The merchant navy in 1867 consisted of 4,363 sailing vessels, tonnage 345,186, and 151 steamers, tonnage 45,484; total, 4,514 vessels, of 390,670 aggregate tonnage. In the same year 9,640 vessels, of 1,532,000 aggregate tonnage, entered the ports.—The government of Spain, which has undergone many changes since 1812, is now a constitutional monarchy. The constitution of June 1, 1869, vests the legislative power in a cortes, as representative of the sovereign Spanish nation. The king, who is inviolable and not subject to responsibility, sanctions and promulgates the laws, and exercises the executive power through the state ministry. In January, 1875, the ministry was composed of a president and eight ministers, the departments being foreign affairs, finance, interior, justice, commerce and public works, war, marine, and colonies. The cortes is divided into a senate and the congress. The requirements for a senator are to be a Spaniard, to be 40 years of age, to be possessed of civil rights, and either to have been the occupant of a high political, ecclesiastical, or literary position, or to be one of the large taxpayers. One fourth of the senate is removed each time that general elections for deputies are held. The lower house, the congress, which is wholly renewed every three years, is composed of at least one deputy to each 40,000 of the population. To be eligible as a deputy one must be a Spaniard, of age, and in possession of civil rights. The cortes must meet for at least four months every year. Each house nominates its own officers. The provinces, districts, and communes of Spain are governed by their own special laws, and this principle of provincial and municipal self-government has generally been recognized by all the governments. Every commune of at least 60 members has its own elected *ayuntamiento*, which is presided over by an alcalde. Each province has its own parliament, the *deputacion provincial*, the members of which are elected by the ayuntamientos. The courts of justice comprise the supreme tribunal at Madrid, 15 *audiencias territoriales* (courts of the second resort), and 499 courts of ordinary jurisdiction. The army of Spain, according to the military law of Feb. 17, 1873, is divided into the active army and the reserve. The former, the numerical strength of which is established annually by a law, is recruited wholly by volunteers from 19 to 40 years of age, who enlist for a term of at least two years, after the expiration of which they may reënlist for at least one year. The reserve is formed of all who have reached their 20th year, excepting those who serve in the active army. The time of service is three years, and no substitutes are accepted. The reserve of a province may be mobilized by a decree of the government, but the mobilization of the entire reserve requires a national law. Whenever the number of volunteers is insufficient to fill the active army, the reserve may be mobilized. In 1875 the Spanish army was in process of reorganization on the basis of these provisions. The military force in Spain was to number about 216,000 men. To this number should be added about 60,000 men in Cuba, 9,400 in Porto Rico, and 9,000 in the Philippines; total, 78,400, making the whole strength of the Spanish army 294,400. As it has been common with most of the governments which have followed each other in rapid succession to make military appointments for political reasons, the number of officers of the highest military rank is disproportionately large. There is a school of infantry cadets at Toledo, a school of cavalry cadets (established in 1851) at Alcalá de Henares, a special school of artillerists, an academy of engineers, and a school of the general staff at Madrid, and a general military school at Toledo. Spain has 125 fortified places, among which are 25 of the first order. The navy, which in former times commanded all seas, and afterward greatly declined, has only recently begun to improve again. The fleet in 1874 consisted of 20 vessels of the first class (7 ironclads, 10 screw frigates, and 3 wheel steamers), 21 vessels of the second class (10 wheel steamers, 9 screw steamers, and 2 screw transports), and 161 vessels of the third class (20 screw steamers, 54 gunboats, 10 wheel steamers, 4 screw transports, and 73 brigs); total, 202 vessels with 894 guns. Besides these are the following vessels not classified: 5 steamers with 5 guns, a monitor with 3 guns, 2 despatch boats with 6 guns, 1 floating battery, and 1 sailing transport. The navy was manned in 1874 by 9,700 sailors and 5,000 marines.—The finances of Spain have long been in a wretched condition, and there is no longer any hope among Spanish statesmen for a permanent improvement. The apparent surplus of receipts which appeared in several of the budgets presented to the cortes was generally found to be fictitious, and since 1867 even the budget estimates have invariably left a large deficit unprovided for. Even the extensive sale of national and church property has failed to restore the equilibrium and to arrest the threatening increase of the national debt. In the budget for 1871–'2 the revenue was estimated at about $113,500,000, and the expenditures at $121,000,000; and the minister of finance declared that the state was on the verge of bankruptcy, which could be averted only "by the most strenuous exertions, devoted both to raise the revenue by the imposition of new taxes and otherwise, and to depress the expenditure to the lowest possible point." A report of the minister of finance in May, 1873, estimated the public debt at $1,511,000,000. The payment of interest on the foreign debt was suspended on July 1, 1873. According to the Madrid "Official Ga-

zette" the total revenue for 1874–'5 was $108,-960,000, and the total expenditure $104,105,-000. The revenue was derived chiefly from direct and indirect taxes, stamps, tobacco and other monopolies, sales of national property, and exemptions from military service. The receipts from colonies amounted to only $595,-000. The chief items of expenditure were $55,800,000 for war and marine, and $31,-195,000 for the other ministries. This statement shows a slight surplus of revenue, but if the interest on the public debt had been paid there would have been the usual deficit. —Of the coins of Spain, the *real* is equal in value to about 5 cts., the *peseta* is equal to four *reales*, and the *escudo* to ten *reales*. The French metric system was introduced Jan. 1, 1859, but the old weights and measures are still much used.—Nearly the whole population of Spain belongs to the Roman Catholic church; and before the establishment of the Spanish republic in 1868 no other religious denomination was recognized by law or enjoyed the right of public worship. To teach or to embrace Protestantism, or to circulate, buy, or sell Protestant books, was also punishable by law. Only a few congregations of foreign Protestants and Jews were allowed to worship according to the rites of their respective religions. A few natives were known to profess Protestant opinions, and they gradually came to be tolerated as long as they did not assemble for public worship. After the expulsion of Queen Isabella Protestant congregations were formed in all the large and in some of the small towns; they were soon organized into a Spanish evangelical synod, and a consistory was appointed in Madrid for administrative purposes. Besides the congregations connected with this synod, there are a few Baptist, Scotch Presbyterian, and Anglican churches. The whole number of Protestants in 1874 was variously estimated from 30,000 to 120,000. The Roman Catholic church in Spain is divided into 54 dioceses, 9 of which are archbishoprics, viz.: Burgos, Santiago, Granada, Saragossa, Toledo, Tarragona, Seville, Valencia, and Valladolid. In the Spanish possessions out of Europe, there are in America one archbishopric (Santiago de Cuba) and two bishoprics; in Asia, one archbishopric (Manila) and four bishoprics. The archbishop of Toledo is primate of Spain. In 1830 the clergy and religious orders counted 152,305 members, including 30,900 monks and 24,700 nuns in 1,940 convents. In 1835–'6 nearly all the convents were suppressed; but subsequently various female communities, mostly devoted to teaching and to the care of the sick, and a few male orders, were reëstablished by permission of the government. In 1860 there were 32 male convents with 719 monks, and 866 female convents with 12,990 nuns. The number of priests in 1867 was 43,948. In former times the church owned immense possessions, but in 1835 they were declared national property and confiscated, and the clergy indemnified by fixed salaries. Up to 1839 the ecclesiastical property which had been sold amounted to $78,000,000. A concordat, concluded Aug. 25, 1859, and promulgated Jan. 14, 1860, stipulated that the church should remain in the possession of all the property not yet disposed of, and should have in future the right of acquiring property of any kind.—The organization of public instruction dates from 1845. At the head of educational affairs is a royal council subdivided into six sections, viz.: primary instruction, philosophy, ecclesiastical sciences, jurisprudence, medical science, and administration of public instruction. In 1852 there were fewer than 2,000,000 individuals who were able to read, and scarcely 1,200,000 knew how to write. Since then the government has made efforts to improve public instruction, and the higher institutions of learning have been the object of special solicitude. In 1867 there were 26,332 public schools, with 1,425,339 pupils, of whom 850,762 were boys and 574,577 girls. In 1872 the middle schools consisted of 50 provincial and 13 municipal institutes, besides several private *colegios*, with an aggregate attendance of about 26,000. Spain has 10 universities, in Madrid, Barcelona, Granada, Oviedo, Salamanca, Seville, Santiago, Valencia, Valladolid, and Saragossa. The total number of students in 1868 was 12,269. Three universities (Madrid, Barcelona, and Granada) have each five faculties (philosophy and literature, exact sciences, pharmacy, medicine, and law), two four faculties, one three faculties, and the others but two. The theological faculties have been abolished in all the universities, and theological instruction is imparted at the seminaries connected with the episcopal sees. Normal schools have been established, in accordance with the law of 1857, in the capitals of the several provinces. Special instruction is provided for by a school of engineering, commercial schools, a college for the deaf and dumb, a school for the blind, and a higher veterinary school at Madrid, with branch establishments at Cordova and Saragossa. Spain has many literary societies, yet none of them can compare with similar societies in most other European countries. The best known among them are the royal academy at Madrid, founded in 1714; the academy of sciences at Seville; the academy of plastic arts at Madrid; the academies of arts at Seville, Cadiz, Valencia, Saragossa, and Palma; the royal academy of Spanish history at Madrid; and the academy of geography at Valladolid. Of public libraries there are the royal library and six others at Madrid, one in the Escurial, two at Valencia, two at Saragossa, and one at Toledo, besides those belonging to the different universities. In 1808 only four periodicals were published in Spain; in 1868 there were 468. In 1867 there were 335 theatres, with accommodations for 169,376 people.—The Spanish peninsula was early visited by the Phœnicians, who established flour-

ishing colonies on its coasts, such as Tartessus (probably the Tarshish of Scripture) and Gades (Cadiz). They were followed by the Greeks, among whose colonies were Emporiæ (now Ampurias, on the coast of Catalonia) and Saguntum (Murviedro, in Valencia). Still the interior remained very imperfectly known, and it was not till the second Punic war that the Romans acquired an accurate knowledge of the country. The Greeks at first applied the name Iberia (corresponding to that of the river Iberus, now Ebro) to the eastern coast, calling the western part of the peninsula Tartessis and the centre Celtica; but later they extended the term Iberia to the whole. The Romans exchanged this name for that of Hispania (whence the modern Spain), supposed by many critics to be derived from the Semitic *shaphan*, rabbit, an animal which the Phœnicians found in vast numbers in the country, and by others to be from the Basque *ezpaña*, border. From remote antiquity the elevated regions of the interior were peopled by the Celtiberians, a race formed from the mixture of Celts and Iberians. (See CELTIBERIANS.) A number of Iberian and Celtic tribes, however, retained their distinct nationality. Among the former were the Astures, Cantabri, and Vaccæi, inhabiting the mountainous districts of the north. The unmixed Celts dwelt chiefly near the Guadiana, and in Gallæcia (Galicia). The Turdetani, who lived in the valley of the Guadalquivir, were accounted the most civilized of the Spanish tribes, and even had a literature of their own. The inhabitants were brave and warlike. Even in antiquity the sheep of Spain were highly prized, and the country produced corn, oil, and wine; but its principal riches lay in its mines of gold, silver, and other metals. After the first Punic war the Carthaginians began to establish themselves in Spain, and, under the leadership of Hamilcar and Hasdrubal, subdued several tribes on the S. and E. coasts. Among the cities founded by them was New Carthage (now Cartagena), which soon became a celebrated emporium. Pressed by the Carthaginians, the Greek colonies of Saguntum and Emporiæ applied for aid to the Romans, who obtained from Carthage an agreement not to extend her dominion beyond the Iberus, and to respect the independence of Saguntum. The siege and destruction of Saguntum by Hannibal in 219 B. C. led to the second Punic war, in the course of which Scipio expelled the Carthaginians from Spain (206). The Romans now undertook the subjugation of the entire peninsula, but did not fully succeed until after a war of about 200 years, in which the exploits of the Lusitanian Viriathus, the heroic resistance and final downfall of Numantia (133), and the temporary independence of a part of the country under the gallant Sertorius (84 to 72) form brilliant episodes. In 19 B. C. the subjection of all Spain, with the exception of the Basques, was completed. Augustus divided the peninsula into three provinces: Hispania Tarraconensis, so named from the capital Tarraco (Tarragona), in the north, east, and centre; Hispania Bætica (from the Bætis, now Guadalquivir), in the south, and extending to the Anas (Guadiana), the capital of which was Corduba (Cordova) or Hispalis (Seville); and Lusitania, between Cape St. Vincent and the Durius (Douro), and nearly corresponding to the modern Portugal, the capital of which was Augusta Emerita (Mérida). The country became so thoroughly Romanized that it was one of the principal seats of Roman civilization and literature. Christianity was early introduced, and in the time of Constantine the Christianization of the entire country was completed. The decay of the Roman empire called several German tribes to Spain, who encountered but feeble resistance. The Suevi founded an empire in the N. W. part, in the province of Gallæcia; the Alani occupied Lusitania; and the Vandals settled in the southern province of Bætica, which was called after them Vandalusia (now Andalusia). The Romans called to their aid the Visigoths, who had a powerful empire in S. W. France, already extending across the Pyrenees as far as the Ebro. King Wallia of the Visigoths in A. D. 418 destroyed the empire of the Silingi, a tribe of the Vandals, in S. Spain, and so reduced the power of the Alani that they fused with the Vandals, who in their turn in 429 left under Genseric for N. Africa, where they founded a great empire. The Visigoths soon subdued the whole of Spain with the exception of the northwest, which remained in the possession of the Suevi till 585, when their empire was destroyed by the Visigothic king Leovigild. One of the greatest kings of the Visigoths was Euric, who in 471 put an end to the dominion of the Romans, and gave to Spain the first written laws. Under Reccared I. the Visigoths, who until then had been Arians, adopted the Catholic faith (589), a step which greatly facilitated the thorough coalescence of the Gothic, the Latin, and the native Spanish elements of the population into one Spanish nationality, with a general prevalence of the Latin element. The constitution of the Visigoths was an elective monarchy, which proved to be a prolific source of violence, assassination, and civil war, and finally led to the destruction of their kingdom. The family of Alaric, which had been dissatisfied at a new election, called the Arabs, who had an empire on the N. coast of Africa (in Mauritania, whence they were called Moors), into Spain, and King Roderic fell in the great and protracted battle at Jerez de la Frontera (July, 711). The Arabs, under the leadership of Tarik, Musa, and others, completed within a few years the subjugation of the country, with the exception of the mountainous districts Asturias, Cantabria (E. of the preceding), and Navarre, where a Gothic prince, Pelagius (Spanish, Pelayo), was elected king, and main-

tained himself successfully against the invasion of the Arabs. The conquered part of Spain became at first a province of the eastern caliphs. When the Ommiyade line of caliphs was overthrown by the Abbassides, Abderrahman, who had escaped the massacre of his family, was invited to Spain, and in 756 established an independent Ommiyade dynasty at Cordova, which attained a high degree of prosperity, especially under Abderrahman III. (912–961). Agriculture, commerce, science, and art flourished, and the literary institutions of the Spanish Mohammedans were so celebrated that they were frequented by Christian students from all countries of Europe. The Jews became very prosperous, and it was in Spain that the mediæval Hebrew literature reached its highest development. The language and customs of the Moors became generally predominant; the Christians were deprived of their political rights, yet retained the free exercise of their religion. Early in the 11th century the caliphate of Cordova became the prey of internal revolutions, and in 1031 it disappeared altogether, numerous kingdoms being founded on its ruins. During the three centuries of its existence the Christian power had been steadily extending in the north of the peninsula. The little kingdom which maintained itself under Pelayo in the mountainous districts of N. W. Spain was at first limited to the district of Oviedo, and therefore called the kingdom of Oviedo. The second successor of Pelayo, Alfonso I., the Catholic, conquered Galicia, with a part of Leon and Castile, and assumed the title of king of Asturias. The whole of Leon was conquered by Alfonso III., the Great (abdicated 910), whose son Ordoño II. transferred his residence to the city of Leon, and called his dominion the kingdom of Leon. N. E. Spain was conquered by Charlemagne, and became known as the Marca Hispanica, but the Frank dominion was of short duration. Navarre appears as an independent state in the 9th century, and gradually rose to be a powerful kingdom. Near the sources of the Ebro and the Pisuerga arose the kingdom of Castile, at first a small republic, consisting of some forts and a few towns. If it was ever fully subdued by the Moors, it threw off their yoke very soon, for as early as 759 there appears a count of Castile. Its territory was soon enlarged, but for some time it was subject to Leon, until in 961, under Fernando Gonzales, it recovered its independence. Its rulers soon assumed the title of king, and in 1037 Ferdinand I., the Great, united the kingdom of Leon with Castile, which was henceforth the most powerful Spanish state. Catalonia was ruled by counts, the most prominent being those of Barcelona, who early in the 12th century became the sole rulers. Aragon, which had formed a part of Navarre, became an independent kingdom under Ramiro I. in 1035, and in 1137 it was united with Catalonia. Portugal was made a distinct county by Alfonso VI. of Castile about 1095, and in 1139 was erected into a kingdom. The most important of the Moorish states which arose out of the caliphate of Cordova were Toledo, Valencia, Murcia, Saragossa, and Seville. The last became very powerful under the Abadite princes, and comprised Andalusia, Cordova, Algarve, and other territories. In the latter half of the 11th century the Christians found a brave leader in Alfonso VI. of Castile, whose reign was rendered brilliant by the romantic exploits of the Cid. Alfonso destroyed the kingdom of Toledo (1085), made its capital his residence, and named his conquest New Castile. Toward the close of the 11th century the Moorish sect of the Almoravides, who had established their dynasty in Morocco, invaded Spain, overthrew the kingdom of Seville, and rapidly extended their sway over the other Moorish territories. But before the middle of the 12th century a new revolution in Africa raised the sect of the Almohades to power, and the Almoravides of Spain succumbed. The Christian princes, who like the Mohammedan rulers had constantly warred against each other, resolved to unite their forces in a common effort, and in 1212 Alfonso IX. of Castile, with the kings of Aragon and Navarre, annihilated the power of the Almohades in the great battle of Navas de Tolosa in the Sierra Morena. Their empire fell to pieces, the new states were successively subdued by the Christians, and before the close of the century Moorish dominion had been restricted to the kingdom of Granada, which paid homage to Castile. Granada continued for two centuries a great and populous state. Weakened by continual wars with Castile and by internal dissensions, it finally, after a desperate conflict, succumbed under the famous Boabdil to Ferdinand and Isabella. Among the Christian states of Spain, Aragon and Castile became the most powerful, and in the course of time absorbed all the others. Pedro I. of Aragon conquered the principality of Huesca; Alfonso I. (in 1118) Saragossa, which he made his capital; Alfonso II. and Pedro the Catholic likewise enlarged the empire; James (Jaime) I., the Conqueror, wrested from the Moors the Balearic islands and the kingdom of Valencia; Pedro III. occupied Sicily in 1282; and Alfonso V. united Naples with his kingdom. But, while enlarging its territory, Aragon suffered at home almost continually from civil broils and plots, from contests between the grandees and the kings, and from oppression of the people by taxes. It was, however, the first Christian state in which the third estate obtained a legal position. (See Aragon.) When the Catalonian line of princes became extinct, the cortes of Aragon in 1412 elected Ferdinand, infante of Castile, their king, and his descendants ruled the country until the latter part of the 15th century, when the marriage of Ferdinand V., the Catholic, of Aragon, with Isabella of Castile, consolidated all Christian

Spain into one kingdom. Among the more prominent kings of Castile are Ferdinand III. (1217–'52), who by successful wars against the Moors annexed Jaen, Cordova, and Seville to his dominions; his son Alfonso X., the Wise (1252–'84), a patron of science and art, and himself a great scholar, but a weak ruler, under whom, while he was striving for the imperial crown of Germany, the Moors made new conquests in the southern part of Spain; Alfonso XI. (1324–'50), who broke the power of the Moors; and his son Pedro the Cruel, who, after a distracted reign, perished in 1369. In Castile the towns possessed fewer rights and attained less prosperity than in Aragon, while the privileges and the power of the clergy and the nobility were more extensive. In the 15th century, during the reign of minor princes, the clergy and nobility usurped so much of the royal prerogatives, that when Isabella (1474–1504) ascended the throne, royalty was almost powerless. Ferdinand the Catholic united the dignity of grand master of the three Castilian orders of knights for ever with the Spanish crown, obtained from the pope the right of nominating all bishops, expelled the Jews from the Spanish soil, and reorganized the inquisition. (See Inquisition.) The subjugation of the kingdom of Granada, the last Moorish possession in Spain (1491–'2), completed the political consolidation of the kingdom; while the conquest of Naples (which had been separated from the crown of Aragon) by Gonsalvo de Cordova, and still more the discovery of America by Columbus, and the subsequent occupation of large portions of North, Central, and South America by Spanish generals, soon raised the new kingdom of Spain to the front rank among the powers of the earth. But the expeditions to America led to a neglect of the native soil, and the expulsion of the Jews and of the bulk of the Moors proved a fatal blow to the flourishing industry of Spain. Ferdinand, who had survived his son-in-law Philip I. of Castile, was succeeded in 1516 by his grandson Charles I., who permanently united Castile and Aragon, inherited the Netherlands from his paternal grandfather, the German emperor Maximilian of Hapsburg, was elected emperor of Germany (as Charles V.), and conquered Milan. At the beginning of his reign serious insurrections broke out in Valencia and Castile, where the people demanded a more liberal constitution; but they were soon quelled, and resulted in the abolition of the principal rights of the towns, the restriction of the powers of the cortes, and a stronger attachment of the clergy and nobility to the crown. The constitutional privileges or *fueros* of the Basque provinces were, however, reconfirmed. The conquest of Mexico by Cortes, and of Peru and Chili by Pizarro and Almagro, poured immense riches into the royal treasury; but the wars of Charles against Francis I. of France, against the Protestants of Germany, against the people of Ghent in the Netherlands, against Pope Clement VII. in Italy, and against Tunis and Algiers, exhausted the revenues of the country, burdened the people with enormous taxes, and required the contracting of a heavy debt. Under the reign of his son Philip II. (1556–'98) the vast monarchy began to decay. Philip, under a claim of succession by inheritance, conquered Portugal, which from 1581 to 1640 remained united with Spain; but this conquest, together with the war against the revolted Netherlands, a brilliant naval warfare against the Turks, the unfortunate naval struggle with England, in which the "invincible armada" was destroyed and Cadiz captured by the English, and the extravagance displayed in the building of the Escurial, exhausted the strength of the country. The despotic measures adopted by the inquisition for crushing out Protestantism and the remnants of the Moors (Moriscoes), and by the king for destroying still more thoroughly the ancient privileges of the people, had in great part the desired effect, but also completed the ruin of Spanish commerce, agriculture, and industry. Literature and art, however, continued to flourish, and the Spanish language and fashions controlled the courts of Europe. The imbecile and fanatical Philip III. (1598–1621) left the reins of government to his favorite, Count Lerma, who squandered the revenues of the state, and drove the last of the Moriscoes, 600,000 in number, out of Spain. Under Philip IV. (1621–'65) Portugal recovered its independence; Catalonia was devastated for 10 years by a civil war; the Dutch infested the Spanish possessions in America, especially Peru; three fleets were destroyed by gales, diseases, and the enemy; the Protestant Netherlands were abandoned for ever; insurrections broke out in Naples and Sicily; and the enmity between Olivarez, the Spanish minister, and Richelieu, involved Spain in a war with France, by which the former lost Roussillon. Under Charles II. (1665–1700) another disastrous war was waged against France, and the population of Spain decreased to 8,000,000. The death of Charles, with whom the Spanish house of Hapsburg became extinct, occasioned a war for the succession to the Spanish throne, which both the brothers-in-law of Charles, Louis XIV. of France and Leopold I. of Austria, tried to secure for princes of their respective families. Charles, in a second will, appointed Philip of Anjou, grandson of Louis XIV., sole heir of all the Spanish monarchy; but Germany, England, and Holland contested the validity of the will, and for 13 years resisted the claim of Philip to the Spanish throne. (For the principal events of the war of Spanish succession in the wider sense, see Philip V., Charles VI. of Germany, Louis XIV., Eugene, and Marlborough.) The allies won several signal victories; yet Philip V. finally maintained himself on the throne, although in the peace of Utrecht (1713) he was obliged to cede Naples, the island of Sar-

dinia (a conquest of Aragon), Milan, and the rest of the Netherlands to Austria, Sicily to Savoy, and Gibraltar and Minorca to England. Under his reign Aragon, Valencia, and Catalonia lost the last of their constitutional rights. The great affairs of the state were managed by the queen, Elizabeth Farnese, and her minister, Cardinal Alberoni. In Italy, Naples and Sicily were conquered by the infante Carlos in 1734-'5, and Parma gained for the infante Philip in 1748. Philip's son Ferdinand VI. (1748-'59) was disabled by melancholy from taking active part in the government. He was succeeded by his half brother Charles III. (1759-'88), previously king of Naples, with whose reign a better era began to dawn. Having signed the Bourbonic family compact with France in 1761, he was involved in the French-English war, in which, as well as in an expedition against Morocco and Algiers in 1775, and in the expensive siege of Gibraltar during a second war with England, the Spanish arms were not successful; but the internal prosperity of the country was greatly promoted by the wise administration of the king, who was assisted by a number of enlightened statesmen, as Aranda, Campomanes, Olavidez, and Florida Blanca; agriculture, commerce, and trade began to revive; and the population during his reign showed a considerable increase. The power of the inquisition was greatly restricted, the Jesuits were expelled from all the Spanish dominions (1767), and the boundaries of the empire enlarged by the addition of Minorca and Louisiana. He was followed by his son Charles IV. (1788-1808), who at first continued the reformatory policy of his father, but after 1792 gave himself up to the pernicious influence of Manuel Godoy, duke of Alcudia. At first Spain joined the alliance against the French republic, but was soon compelled to conclude the inglorious peace of Basel (1795), by which Santo Domingo was ceded to France. In 1796 Godoy entered with France into the offensive and defensive league of San Ildefonso, and declared war against England. In 1797 the Spanish fleet was defeated near Cape St. Vincent, Minorca and Trinidad were occupied by the English, and all the ports of Spain blockaded. Spain suffered so much from this war, and the financial embarrassment of the country became so great, that Godoy resigned his position as prime minister, although he retained in fact a controlling influence in state affairs. In 1800 Spain ceded Louisiana to France, and in 1801 commenced, at the instigation of Bonaparte, a war against Portugal, the ally of England, which was terminated by the peace of Badajoz, and resulted in the cession of Olivença by Portugal to Spain. By the treaties of Lunéville and Amiens, Spain ceded Trinidad to England, Parma was annexed to the Cisalpine republic, and the prince of Parma, a descendant of the royal house of Spain, was made king of Etruria. On the reopening of the war between France and England in 1803, France demanded, in accordance with the league of San Ildefonso, the assistance of Spain, which, desirous of preserving a neutral position, agreed to pay to France a monthly subsidy of 4,000,000 piasters. The capture of several Spanish vessels by the English compelled Spain to declare war against England, Dec. 12, 1804. At Trafalgar, Oct. 21, 1805, the combined French and Spanish fleets were totally defeated by Nelson, and Spain alone lost 12 ships of the line. The misery which these unfortunate wars brought upon Spain led to the formation of a powerful opposition to Godoy, who made some feeble and fruitless efforts to extricate his country from the alliance. The success of Napoleon in the war against Prussia thwarted these efforts; he demanded and obtained from Spain two auxiliary armies, one of which, consisting of 16,000 men, was sent to Denmark, the other to Tuscany. Spain had also to submit to the disgraceful treaty of Fontainebleau, in consequence of which French troops were marched into the country. An insurrection compelled Charles IV. to abdicate in favor of the prince of Asturias (March 18, 1808), who ascended the throne as Ferdinand VII. Soon after, however, in a letter to Napoleon, he represented his resignation as compulsory, and revoked it. Both father and son courted the patronage of Napoleon, who, accepting the office of arbiter, invited them to Bayonne, and there extorted from both, as well as from the infantes Don Carlos and Don Antonio, a resignation of their claims to the Spanish throne. Napoleon then called a junta of 150 Spanish and American delegates for the purpose of forming a new constitution, and on June 6, 1808, declared his brother Joseph king of Spain and the Indies. The new constitution was adopted and sworn to by the king and the delegates, July 6. On July 9 Joseph departed for Spain, where insurrections had already broken out in Navarre, Aragon, Estremadura, Castile, Leon, and Galicia. England, on July 4, made peace with "the Spanish people," recognized Ferdinand VII. as king of Spain, and vigorously supported the insurrection of the Spaniards, which was under the direction of a central junta. The junta, at the head of which was the aged ex-minister Florida Blanca, called into the field half a million of combatants, under Palafox, Castaños, Romana, Ballesteros, and other national leaders, who were supported by English armies under Moore, Baird, Wellington, Beresford, and others. A fierce guerilla warfare was waged throughout the country; Saragossa, Gerona, Cadiz, Tarragona, and Valencia were heroically defended. Until 1812 the war was carried on with varying success; yet the greater part of Spain fell into the hands of the French, who were commanded by Suchet, Soult, Masséna, Marmont, Ney, Macdonald, and other generals, and the Spanish patriots and the English maintained themselves only in the western provinces and in Portugal.

But the failure of Napoleon in Russia was soon followed by a retreat of the French from Spain. Soult with 30,000 French troops was recalled; the brilliant victory of Wellington at Vitoria (June 21, 1813) forced the French army to fall back to the other side of the Pyrenees. Only a few strong places remained in their possession, until the bloody victory of Wellington at Toulouse (April 10, 1814) and the capture of that city successfully terminated the Spanish war of independence. The cortes, which in January, 1810, had fled from Seville to Cadiz, completed a new constitution, March 18, 1812. The regency, which was recognized by England and Russia, at once took the oath to acknowledge it. After the termination of the war, the cortes invited Ferdinand VII., who had been set free by Napoleon, to return to Spain and take an oath to support the constitution. Ferdinand returned, but went to Valencia, and declared the constitution null and void. He announced at the same time his intention, not to restore despotism, but to introduce another constitution on a liberal basis. This promise was not fulfilled; the inquisition was revived, despotism was restored, and most of the reforms introduced under Charles III. were annulled. Florida was sold for $5,000,000 to the United States, and the attempts to reconquer the revolted colonies in America proved miserable failures. On Jan. 1, 1820, a military insurrection, under Riego, broke out for the purpose of restoring the constitution of 1812. It spread with great rapidity; several generals, as O'Donnell and Freyre, who were sent out for its suppression, joined the insurrectionists; and in March the king was compelled to proclaim the constitution of 1812, and to convoke the cortes. A new ministry was formed, the press declared free, the inquisition abolished, and within a few days the new order of things was acknowledged throughout Spain. The suppression of a part of the convents and other resolutions passed by the cortes, which met in July, provoked the formation of an "apostolical junta," which demanded the restoration of the absolute power of the king, of the convents, and of feudal institutions. Even a regency was appointed by the apostolical party at Seo de Urgel, in Catalonia; but the troops of the government drove the regency into France in November, 1822, and dispersed all the guerilla bands in the northern provinces in February, 1823. In the mean time France, at the congress of Verona (1822), agreed with the courts of eastern Europe upon an armed intervention in Spain. The Spanish government was called upon to restore the royal sovereignty and to change the constitution; and compliance being refused, a French army of 100,000 men, under the duke of Angoulême, marched into Spain in April, 1823. The Spanish government opposed to them four corps under Ballesteros, Mina, O'Donnell, and Morillo, but most of them were soon overpowered and capitulated; Riego, who maintained himself longer than most of the other generals in the field, was made prisoner and hanged. The king was compelled to follow the cortes to Seville, and from thence to Cadiz; but a new regency at Madrid, in the name of the "imprisoned king," restored political absolutism, together with the convents. When Cadiz was closely invested and bombarded by the French, the cortes restored to the king his absolute power, Sept. 28. Ferdinand VII. at once revoked all the decrees of the constitutional government from March 7, 1820, to Oct. 1, 1823, and confirmed those of the regency. All persons suspected of liberalism were persecuted with great rigor; the municipal rights of the communities were abolished; and a treaty was concluded with France, which provided for a continuance of the French occupation. Still a great part of the absolutist party considered the king as not sufficiently energetic, and formed a coalition for elevating to the throne his brother Don Carlos. Several insurrections broke out in 1825 and 1826, but they were soon quelled. At the same time Spain was compelled to abandon its last position on the mainland of America, Jan. 22, 1826. In 1830 Ferdinand was prevailed upon by his wife, Maria Christina, a Neapolitan princess, to abolish by the pragmatic sanction of March 29 the Salic law of the Bourbon family. In consequence of this change his daughter, the infanta Isabella (born Oct. 10, 1830), became heir to the throne, in place of his brother Don Carlos. In September, 1832, the apostolic party extorted from the king, who was dangerously ill, a revocation of the pragmatic sanction of 1830; but the intrigue was soon discovered, the influence of the party broken, and Maria Christina appointed regent of Spain for the time of the king's illness (October, 1832). She surrounded herself with a ministry of *moderados*, and tried to effect a reconciliation with the liberals in order to break the power of the Carlists. Don Carlos himself entered a protest against his exclusion from the throne, which was sustained by the Bourbonic courts of Italy. The death of Ferdinand VII., Sept. 29, 1833, was the signal for a general civil war. Don Carlos was proclaimed in the Basque provinces as Charles V., and was supported by a majority of the clergy and the country people throughout the kingdom; Maria Christina had the joint support of the moderados and the liberals. At first the Carlists, under the command of Zumalacarreguy, were successful, and the government of Christina implored the aid of England and France, which allowed recruiting within their states for the Spanish army. Soon afterward an army of 10,000 men was enlisted in England to join the royal troops. The cause of the Carlists began to decline with the unexpected death of Zumalacarreguy, June 25, 1835, and still more when Espartero in 1836 assumed command of the royal army in the northern provinces. The government, in the mean while, was compelled to make new con-

cessions to the radical wing of the progressive party (*exaltados*), and to adopt in 1837 the so-called modified constitution of 1812. The Carlists were finally overpowered in 1839, when Don Carlos fled to France. Cabrera maintained himself until July, 1840, when he also fled to France, and the Carlist war was at an end. Yet another revolutionary movement broke out in the same year, when the cortes passed a new *ayuntamiento* law, which abolished the former municipal rights of the Spanish towns. Maria Christina found it necessary to appoint Espartero, the leader of the movement, prime minister; soon afterward (Oct. 12) she resigned, and, with the chiefs of the moderados, embarked for France. The cortes in 1841 appointed Espartero regent during the minority of the queen, and Argüelles, an old constitutionalist of 1812, her tutor. The administration of Espartero did more to promote the prosperity of the country than any other before or after him. New roads and canals were constructed, mining was encouraged, and industry and trade were put on a firmer basis; and the functions of public officers were never discharged with greater integrity. But the sale of the ecclesiastical property had provoked the almost unanimous opposition of the Spanish clergy, who, in union with the *moderados* and the *absolutistas*, were strong enough to harass Espartero by insurrections during the entire period of his administration. In May, 1843, an open rupture between Espartero and the cortes, although a majority of them were *progresistas*, was at once followed by a general insurrection throughout Spain, at the head of which were the leading generals of the moderados, as Narvaez and O'Donnell, who had returned from France. Toward the close of July Espartero embarked at Cadiz for England. In October the cortes declared the queen of age, who in the next year formed a ministry of moderados, under the presidency of Narvaez. Christina was recalled from France, her secret marriage with Muñoz, formerly one of her body guards, publicly announced, and negotiations commenced with the pope, who had denounced the sale of church property as robbery. In the cortes which met in October, 1844, the moderados had a majority, and in the constitution which they adopted (the constitution of 1845) the rights of the cortes were limited, and the trial by jury for offences of the press and the national militia were abolished. The subsequent history of Isabella II., who in 1846 married her cousin, Don Francisco de Asis, is especially noted for the frequent change of her ministers, mostly brought about by palace intrigues. In 1847 the queen yielded for a time to the counsels of her favorite, Gen. Serrano, and appointed a ministry of progresistas, which promulgated a general amnesty and conferred on Espartero, whom they recalled from England, the dignity of a senator. But before the end of the year the moderados regained the control of the state under the energetic leadership of Narvaez, who showed a conciliatory spirit, maintained the amnesty, and made no objection to the return of Espartero. Two illicit expeditions against Cuba, in 1850 and 1851, which were prepared by Cuban refugees in the United States, and met with great encouragement in the southern states of the Union, and subsequently the declarations of the American democratic party in favor of an acquisition of Cuba by the United States, disturbed the relations between the two governments. The relations with the papal court were settled on a friendly footing by the concordat of 1851. Narvaez resigned in 1851, and till 1854 short-lived and weak ministries succeeded each other, most of which had reactionary tendencies. In 1854 the progress of illiberal legislation, the financial operations of Maria Christina, her husband Muñoz, and the banker Salamanca, who had wrongfully obtained the most important railroad concessions, and the imposition upon the country of a compulsory loan of 180,000,000 reals, led to a military insurrection, one of the leaders of which was Gen. O'Donnell, who called on all liberal parties to unite and restore the constitution of 1837. On July 24 the queen saw herself compelled to charge Espartero with the formation of a new government. Constituent cortes were called, in accordance with the law of 1837, which met in a single chamber, and elected Espartero their president, Nov. 28; but two days later he was again appointed prime minister. The cortes restored in the main the liberal constitutions of 1812 and 1837, and declared themselves in favor of religious toleration, and for the sale of the church property. A large minority demanded the one chamber system, and that the decrees of the cortes should not need the sanction of the crown. The ascendancy of liberalism lasted until July, 1856, when, reactionary influences having again prevailed in the palace, Espartero resigned, and O'Donnell was appointed prime minister. An insurrection in Madrid and the other large cities was suppressed, and the entire kingdom declared in a state of siege. On Aug. 15 the national guard was dissolved, and gradually the illiberal legislation of 1845 restored, especially since Narvaez had become prime minister. The sale of church property was inhibited, and the concordat of 1851 restored. The church property question was finally adjusted by a convention with Rome, on Aug. 25, 1859; and the Spanish government became the strongest supporter of the temporal sovereignty of the pope. In 1858 Spain united with France in sending an expedition against the emperor of Anam, which conquered part of the coast of that country. At the close of 1859 war was declared against Morocco on account of Moorish piracies, and an army under O'Donnell was sent into Africa. After several indecisive conflicts the Moors were defeated, Feb. 4, 1860, near Tetuan, which

was captured, and on April 27 a treaty of peace was signed in which the sultan agreed to pay an indemnity of 400,000,000 reals, and to accord to Spanish trade the same rights as were enjoyed by the most favored nations. Diplomatic relations with Mexico had been broken off in 1857 on account of outrages on Spanish subjects and the non-payment of Spanish claims. Negotiations with France and England, which complained of similar grievances, led in 1861 to the conclusion of a tripartite treaty, in accordance with which the three governments toward the close of the year sent an expedition against Mexico, to obtain satisfaction. The castle of San Juan de Ulloa and Vera Cruz surrendered to the Spanish squadron under Gen. Gasset without a struggle (Dec. 14–17); but the project of the establishment of an empire under Maximilian being disapproved of, the Spanish forces were withdrawn in May, 1862. In 1860 a Carlist insurrection was incited by Gen. Ortega, governor of the Balearic islands, who proclaimed as king the count de Montemolin, eldest son of Don Carlos. The attempt failed, Ortega was captured and shot, and the count de Montemolin was forced to renounce his claim to the throne; but soon after he repudiated his abdication at Cologne. He died at Trieste on Jan. 13, 1861, when his brother Don Juan asserted his right to the Spanish crown. In the same year Spain resumed her authority over the republic of Santo Domingo on the invitation of President Santana, who despaired of allaying internal dissensions. Troops were sent thither, but in 1863 an insurrection broke out, which resulted in the relinquishment of the country by Spain in 1865. In 1864 war was declared against Spain by Peru in consequence of the seizure by the former of the Chincha islands. Chili joined Peru in 1865, and the war continued till 1866, when the Spanish forces were withdrawn from the Pacific. (See Chili, and Peru.) The misdeeds of Queen Isabella's administration and her own personal misconduct caused widespread dissatisfaction and led to numerous insurrections in 1865–'8, and resulted in the defeat of the royal army at Alcolea, Sept. 28, 1868, and the flight of the queen to France. A provisional government was established, presided over by Generals Serrano and Prim and Señor Olózaga. These events were immediately followed by an insurrection in Cuba. (See Cuba.) During 1869 several republican insurrections against the provisional government were suppressed with much bloodshed, and the cortes voted by a large majority against a republic and for a regency, which was established on June 15, with Serrano at its head. Violent discussions then took place concerning the choice of a king. After the rejection of the candidacy for the throne by several princes, the provisional government proposed to the cortes in July, 1870, the election of Prince Leopold of Hohenzollern-Sigmaringen; but he declined becoming a candidate in consequence of the strong opposition of France, which resulted in the Franco-German war. Meanwhile republican agitation was renewed in the provinces, but on Nov. 16 the cortes elected for king Amadeus, duke of Aosta, the second son of King Victor Emanuel of Italy, who accepted the crown on Dec. 4. On Dec. 28 Marshal Prim was mortally wounded by assassins in his carriage in the streets of Madrid, and two days after Amadeus landed at Cartagena. He endeavored to rule the country as a constitutional monarch; but the dislike of the Spaniards for a foreign prince, and the demoralized condition of all parties, caused his utter failure. After a stormy reign, during which Sagasta, Topete, Serrano, and Zorrilla were the leading statesmen, he abdicated on Feb. 11, 1873, and the cortes established a government under the presidency of Estanislao Figueras. Meanwhile a Carlist insurrection, which had broken out in the north in 1872, began to develop itself. Don Carlos, son of Don Juan, who had renounced in his favor his hereditary rights in 1868, took command of the insurgents and proclaimed himself king under the title of Charles VII. Among the commanders under him were his brother Don Alfonso, accompanied by his sanguinary wife Doña Blanca, the curate Santa Cruz, Dorregaray, Elio, Saballs, Lozano, Tristany, and Lizárraga; but the old Carlist chief Cabrera finally declared for the Madrid government. The insurrection gradually spread over Navarre, the Basque provinces, Catalonia, Aragon, and even Valencia. On June 8, 1873, the cortes, having previously abolished slavery in Porto Rico, adopted and proclaimed a democratic federal republic by a vote of 210 to 2, and Señor Pi y Margall was chosen president of the executive power. He was succeeded on July 19 by Don Nicolas Salmeron, who was succeeded in turn on Sept. 7 by Don Emilio Castelar. But the republic had scarcely been established when the *intransigentes* and internationals began a series of revolutionary movements in favor of "cantonal sovereignty," and insurrections broke out in various cities, chiefly of the south and southeast, while the Carlists infested the north. Alcoy, where frightful atrocities were committed, Malaga, Seville, Cadiz, Granada, Valencia, and Murcia were easily reoccupied by the government troops under Pavia, Campos, and others (July and August); but Cartagena, in which Gen. Contreras led the insurgents, resisted for six months (July, 1873, to January, 1874). Here a portion of the Spanish fleet had fallen into the hands of the insurgents, with which they made piratical excursions against Almería and other towns of the coast. The blockade was, however, pushed forward with vigor, and a heavy bombardment finally compelled the surrender of the fortress, Contreras and other leaders escaping to the coast of Algeria. Less successful were the government troops under Moriones in the north, who failed to relieve Bilbao. Castelar

resigned on Jan. 2, 1874, when his ministry was found to be in the minority. On the following day Gen. Pavia, captain general of Madrid, dissolved the cortes with an armed force, and a new ministry was formed under the presidency of Gen. Serrano. Cartagena having been reduced shortly after his accession to power, Serrano personally took the command against the Carlists, who had taken Portugalete, and after considerable fighting with varying success around Sommorostro (March–May), Portugalete was retaken and Bilbao relieved. Marshal Concha, however, who succeeded Serrano in command of the army of the north, fell in battle before Estella in June, and in July Don Alfonso advanced with his Carlists as far as Cuenca. Puycerda, which the Carlists besieged, was relieved in August, and Irun in November. Serrano held the executive power until Jan. 9, 1875, when Alfonso, son of Isabella II., who had been proclaimed king by the armies of the centre and north and in Madrid, landed in Spain. The new king took the field against the Carlists in person, but with slight success. Subsequently, however, operations were resumed with greater vigor, and the Carlists were repulsed from St. Sebastian and before Vitoria, and forced back beyond the Ebro. Catalonia was almost entirely freed from them, and the capture of Seo de Urgel with its garrison (October) proved a demoralizing defeat. Many Carlist chiefs submitted, others fled into France, and still others were shot as traitors. At the close of 1875 the Carlist insurrection seemed to be on the point of succumbing to the forces of Alfonso XII.; but an empty treasury, the troubles caused by the *intransigentes* and by the acrimonious disputes of the different political factions in Madrid, and the still unsuppressed rebellion in Cuba, give little hope of a peaceful reign to the new king.—Among the best histories of Spain are those of Mariana (1601; with continuation by Sabau y Blanco, 20 vols., Madrid, 1817–'22), Bossi (8 vols., Milan, 1821), and Lembke and Schäfer (in the collection of Heeren and Ukert, 3 vols., 1831–'67). The most valuable illustrations of Spanish history in English are in the works of Prescott, Irving, Ticknor, Watson, Robertson, Coxe, Dunlop, Southey, Stirling, and Ford. Some of the more recent works on Spain are the following: Coello, *Reseña geográfica, geológica y agrícola de España* (Madrid, 1864); F. Garrido, *La España contemporánea* (Barcelona, 1865); H. M. Willkomm, *Das pyrenäische Halbinselland* (Leipsic, 1866); G. de Lavigne, *L'Espagne et le Portugal* (Paris, 1867); Ch. de Mazade, *Les révolutions de l'Espagne* (Paris, 1869); H. Ségoillot, *Lettres sur l'Espagne* (Paris, 1870); Augustus J. C. Hare, "Wanderings in Spain" (London, 1872); Baron Ch. Davillier, *L'Espagne*, illustrated by Doré (4to, Paris, 1873; English translation by J. Thompson, London and New York, 1875–'6); V. Cherbuliez, *L'Espagne politique*, 1868–1873 (Paris, 1874); N. L. Thieblin, "Spain and the Spaniards" (London, 1873; Boston, 1875); H. W. Baxley, "Spain: Art Remains and Art Realities; Painters, Priests, and Princes" (2 vols. 8vo, London, 1875); and H. J. Rose, "Untrodden Spain and her Black Country, being Sketches of the Life and Character of the Spaniards of the Interior" (2 vols. 8vo, London, 1875).

**SPAIN, Language and Literature of.** The Spanish language sprang from the vulgar Latin, which was introduced into Spain with Roman domination, and became prevalent throughout the peninsula. But vestiges still remained of ancient dialects and of idioms introduced by Phœnicians, Greeks, and Carthaginians, who founded colonies on the coast. The invasion of the Goths soon determined the corruption of the Latin; but as the conquerors had already been in extensive communication with the Romans, the corruption was not so complete as in some other provinces of the empire overrun by northern nations. Even after the Gothic rule was firmly established, the bishops of Rome retained much influence in the government, and through them the distance between the conquerors and the conquered was greatly lessened; and when they finally coalesced, the language of the latter prevailed, though somewhat disfigured. At the time of the Saracen invasion this adulterated Latin was the tongue in common use. After the destruction of the Gothic empire the national language was preserved in the fastnesses of the north, but in so corrupt a state that in the 9th century the Latin of books was no longer intelligible to any but the churchmen. This uncultured idiom was extended gradually by conquest to the parts occupied by the Moors, where it acquired many Arabic words, which contributed materially to its vigor and richness. Such was the process of formation of the Castilian tongue, in earlier times called the *Romance vulgar*. The Latin continued to be the language of the cloisters and the colleges, and in it were written most of the important works down to the 15th century, when it was superseded by the language of the people. The following are some of the more important changes in the formative part of the language. The vowels *e* and *o* of the accented penultima frequently develop into the diphthongs *ie* and *ue*, as in *tiempo*, *bueno*, *fuerte*, *puente*, from *tempus*, *bonum*, *fortem*, *pontem*. Harsh consonants show a tendency to soften, and combinations to change into single consonants, as in *abrir*, *saber*, *digo*, *agua*, *edad*, from *aperire*, *sapere*, *dico*, *aqua*, *ætatem*. Such combinations as *cl*, *fl*, *pl*, &c., are often changed into the liquid *ll*, as in *llave*, *llama*, *llano*, from *clavis*, *flamma*, *planus*; *ct* passes into *ch*, as in *noche*, *dicho*, from *noctem*, *dictum*; initial *f* is changed into mute *h*, as in *hacer*, from *facere*. These mutations occur in the accented penultima, and disappear generally with a transposition of accent, or with the addition of one or more syllables, as in

*tiempo*, *temporal*, *bueno*, *bonísimo*, *llamar*, *exclamar*, &c. The *d* in the middle of a word between two vowels has often been dropped, as in *creer*, *fiel*, from *credere*, *fidelis;* and a *b* or *d* is, as in cognate languages, inserted where *m*, *n*, or *l* would meet with *r*, as *nombre*, from *nomen; tendré*, future of *tener; saldré*, future of *salir*. The introduction of the strong gutturals *g* (before *e* or *i*) and *j* (or *x*) is to be ascribed to Teutonic influence. In words beginning with *s* followed by another consonant, a euphonic *e* is invariably prefixed, as in *estar*, *espiritu*, *escudo*, from *stare*, *spiritus*, *scutum*. *Ni*, *ne*, *nn*, and *gn* have been often changed into the liquid *n* (*ñ*), as in *España*, *entraña*, *año*, *leño*, from *Hispania*, *intranea*, *annus*, *lignum*. The inflections of the noun and the verb show a marked influence of the Gothic. The refined system of declension was too complicated for the northern barbarians; they used only one case ending for each of the singular and plural numbers, and this ending was supplied in the singular, not by the Latin nominative, but by the accusative, with the rejection of the consonantal ending *m*, and sometimes of the syllabic ending *em*. Thus the Latin *nix*, *dux*, and *virtus* pass into *nieve*, *duque*, and *virtud;* but the neuter nouns *corpus*, *tempus*, and *caput* form *cuerpo*, *tiempo*, and *cabo*. The loss of cases was remedied by the use of the article, not unknown to the Goths, and obtained from the vulgar Latin, in the shape of the demonstrative pronoun *ille* and the numeral *unus*. The verb also has lost some terminations, the place of which has been supplied, though imperfectly, by the more frequent use of the auxiliaries. The composition of the future (*amaré* instead of *amar he*, I have to love), and the expression of the passive voice by means of the auxiliary verbs, are the most remarkable instances of the influence of the Gothic. The words of northern origin are calculated to amount to about one tenth of the whole number, many of which refer to war and strife, or to peculiarities of the Teutonic race. From the Arabs, who maintained themselves on Spanish soil for nearly 800 years, the Spanish language received that oriental coloring which distinguishes it among the Romanic languages; but on words and forms the influence of the Arabic was slight. The sound of *z*, and of *c* before *e* and *i* (precisely that of *th* in the English *think*), is of Arabic origin; so are most of the words beginning with *al* (the Arabic article), some of which, as *almanaque*, *alcohol*, &c., have passed through the Spanish into all the modern languages of Europe. Among the numerous dialects simultaneously developed in the peninsula from the amalgamation of the Latin and the Gothic languages, the Castilian gradually gained the ascendancy, and has become established as the language of Spain. All the other dialects have perished in the course of time, with the exception of the Portuguese, which has become a separate language, and the Catalan, still spoken throughout Catalonia. The Basque, which is spoken in some of the northern provinces, is supposed by philologists to be the lineal descendant of the language most in vogue in the peninsula before the Roman invasion. The territory of the Spanish language is one of the most extensive in the world, embracing, besides Spain, all of the Spanish American republics, most of the West Indies, the Philippine islands, and small portions of Africa. The Spanish language has 27 letters or signs of as many distinct sounds. Two of these, the liquids *ll* and *ñ* (pronounced respectively like *li* in *Julia* and *ni* in *union*), are peculiar to it. The language is destitute of the sound of *z* in *zeal*, the Spanish *z* having always the *th* sound, and *s* the sharp sound as in *sun*. All letters are pronounced except *h*, and *u* in the combinations *gue*, *gui*, *que*, *qui*. The six vowels do not change in sound, like the English vowels, but have always the same pronunciation, which agrees with that of the Italian.—The substantives have only two genders, masculine and feminine; but the article has three forms, *el*, *la*, and *lo*, the last of which is used for changing adjectives into substantives, as *bueno*, good, *lo bueno*, that which is good. The plural is formed by adding to the singular either *s*, as *libro*, *libros*, or *es*, as *mes*, *ley*, *rubí*, pl. *meses*, *leyes*, *rubíes*. A declension proper does not occur, the inflections of the Latin having been lost, and being replaced by the use of prepositions, especially *de* and *á*. The Spanish is uncommonly rich in augmentative and diminutive terminations, which have gradually become the regular and very common means of adding to the original meaning of words the expression of great or small size, and feelings of admiration or contempt. The comparative is generally formed by prefixing to the positive the adverb *mas* (Latin *magis*, more), and the relative superlative by adding to the comparative the definite article; as *grande*, large, *mas grande*, larger, *el* or *la mas grande*, the largest. It has also the forms *mayor*, larger, and *la mayor*, the largest. It has retained from the Latin, like the kindred idioms of Italy and Portugal, an absolute superlative, formed by the addition of the ending *ísimo*. In the verb the subjunctive has two more tenses than the Italian and French languages, viz.: second conditional and future conjunctive. The number of conjugations has been reduced to three, as the formation of the infinitive by discarding the final *e* of the Latin infinitive effaced the distinction between the second and third Latin conjugations. The Spanish has also, almost alone among the Romance languages, a double set of auxiliary verbs, *haber* and *tener*, *ser* and *estar*, and uses the reflexive form of the verb more extensively than almost any other language of Europe. The most important of the native grammars are those of Lebrija, the first of all (Salamanca, 1492), the Spanish academy

(new ed., Madrid, 1868), Salvá, Rementería, and Bello; among foreign ones, those of Mallefille (Paris, 1846) and Chantreau (Paris, 1862). The best material for a historical grammar is to be found in *Orígines de la lengua española*, by Mayans y Siscar (Madrid, 1737 and 1873). The best dictionaries are those of the Spanish academy, Salvá, and Dominguez, purely Spanish; while among the bilingual dictionaries, the most valuable are those of Salvá and of Nuñez de Taboada, French-Spanish; of Seckendorf (3 vols., Hamburg, 1823), Spanish-German; and of Neuman and Baretti, revised by Velazquez de la Cadena (New York, 1852), Spanish-English. A comprehensive dictionary purely Spanish, etymological and *raisonné*, is now (1876) in course of preparation by a society of literati in Bogotá.—LITERATURE. The literary life of the Spanish people began under the rule of the Romans, when Spain became a chief seat of Roman civilization, and produced many of the greatest writers of Latin literature. After the Christianization of Spain and S. W. Europe in general, ecclesiastical literature found, next to Italy and Gaul, its most fertile soil in Spain. After the invasion by the Arabs, Arabian literature attained a high degree of prosperity, and the numerous Jews cultivated Hebrew literature with great success. The national literature of Spain begins in the 12th century with epic and didactic poems in Castilian verse, and resting on strong national sentiments as a basis. The first of these poems in age as well as in importance is the one commonly called the "Poem of the Cid," composed probably in the second half of the 12th century. Its subject is taken from the adventures of Ruy Diaz, surnamed *el Cid Campeador*, "the Lord Champion," the popular hero of the chivalrous age of Spain, and the defender of his country against the Moorish invaders. It is a rhymed narrative of events in chronological order, partly historical and partly romantic, told with Homeric simplicity; and, although its verse is rude and unadorned, the poem deserves to be ranked among the finest productions of the middle ages. Before this Spain had many popular songs, both lyric and epic, but we know little of their original form, as they were not committed to writing before the 16th centnry. The single manuscript which has preserved the "Poem of the Cid" contains three other poems, all like that anonymous, viz.: "The Book of Apollonius, Prince of Tyre," "The Life of our Lady, St. Mary of Egypt," and "The Adoration of the Three Holy Kings." These poems, as well as the rhymed "Lives of Saints" by the priest Gonzalo de Berceo (died about 1260), and the anonymous poem of "Count Fernan Gonzales," a hero of the earlier period of the Christian conflict with the Moors, who is to the north of Spain what the Cid became somewhat later to Aragon and Valencia, betray the influence of the ecclesiastical poetry of those times and of the chivalric poetry of France. They are written either in stanzas of Alexandrine verse or in the indigenous rhythm of the *redondillas*. Berceo is the earliest Spanish poet whose name can with certainty be connected with his works, which comprised more than 13,000 lines. A great impulse to the development of literature was given by King Alfonso the Wise of Castile, who substituted the Spanish language for the Latin in the courts, and ordered the laws to be published in it. Alfonso himself was a prolific author. In order to bring uniformity into the different systems of Spanish legislation, he compiled several codes of laws, the most celebrated of which has the title *Las siete partidas*. Several historical works, as a universal history of the world, a history of the crusades (*La gran conquista de ultramar*), and the celebrated *Crónica general*, a general history of Spain until the death of his father, were compiled under his direction. By these works, as well as by a translation of the Bible into Spanish, he became the creator of Spanish prose. Some of his poetical works have also considerable merit, though in general they are most remarkable for the variety of their metres, some of which were first introduced by Alfonso into Spanish poetry. The *Poema de Alejandro* of Juan Lorenzo Segura is a work of more than 10,000 lines on the life of Alexander the Great, filled with the fables and extravagances of the times. A continuation of it, called *Los votos del pavon*, is now lost. Alfonso found many imitators, as author and patron of literature, among the succeeding kings and the princes of the royal family. The most important of these works of royal origin is *El conde Lucanor*, by the prince Don Juan Manuel (died about 1347), a collection of 49 tales, anecdotes, and apologues, in the oriental manner, and partly taken from oriental sources. The most remarkable poet of the 14th century is Juan Ruiz, commonly called the archpriest of Hita (died about 1350). His works, embracing religious, pastoral, and erotic songs, fables, satires, and proverbs, consist of nearly 7,000 verses; and, although generally written in the four-line stanza of Berceo, they contain no fewer than 16 metrical forms, some of which are taken from the Provençal. The didactic tendency of the poetry of this period is apparent in the *Consejos y documentos al rey Don Pedro*, commonly called the book of Rabbi Don Santob, a curious poem, addressed by a Jew of Carrion to Pedro the Cruel on his accession to the throne, for the purpose of giving to him wise moral counsels. Another didactic poem is "The Dance of Death" (*Danza general de la muerte*), a kind of spiritual masquerade, in which the different ranks of society, from the pope to the young child, appear dancing with the skeleton form of death. The formation of a courtly school of lyric poets, after the model of the troubadours, had commenced under Alfonso X., who himself wrote lyric poems in the dialect of Ga-

licia. A flourishing school of Provençal troubadours was formed at the court of the counts of Barcelona, and a courtly school of Castilian poets sprang up at the court of the chivalric king John II. The poetry of this school, which moved within the narrow circle of courtly gallantry, lacked vigor and variety. Their works were collected in *cancioneros*, the oldest of which is that of Juan Alfonso de Baena, a converted Jew and one of the secretaries of John II. The most complete collection of the kind, the *Cancionero general* of Fernando del Castillo (Valencia, 1511), contains (in its 10th ed., 1573) the names of 136 authors, from the beginning of the reign of John II. to the time of the emperor Charles V. Among them were the marquis of Villena, the marquis of Santillana, and Juan de Mena, who in larger didactic poems tried to imitate classical and Italian models; Diego de San Pedro, who also wrote two love novels, *Cárcel de amor* and *Cuestion de amor;* and Guzman, who is also celebrated as a historian. In opposition to the Provençal and courtly schools, a more popular literature began in the second half of the 14th century, growing directly out of the enthusiasm which had so long pervaded the whole mass of the Spanish people; and it asserted for itself a place which in some of its forms it still maintains. This popular literature may be divided into four classes, ballads, chronicles, romances of chivalry, and the drama. Of most of the old ballads, as far as the time when they were thought worthy to be written, both authors and dates are unknown; about 1,000 are extant, unequal in length and still more in merit, which have been collected in the *Romancero general* (13 parts, 1605–'14). The chronicles, or the half genuine, half fabulous histories of the great events and heroes of the national annals, were originally begun by authority of the state, but they were always deeply imbued with the popular feelings and character. Some of them have already been referred to; other works of this class, which evince a steady progress of the historical prose, are the chronicles of Ayala and of Juan Nuñez de Villaizan, the "Chronicle of the Cid," the "Chronicle of the Travels of Ruy Gonzalez de Clavijo," and others. The first and most celebrated of the romances of chivalry is the "Amadis de Gaul," originally the work of a Portuguese gentleman of the 14th century, Vasco de Lobeira, but translated into Spanish by Montalvo between 1492 and 1504. The Portuguese original can no longer be found; but the Spanish version proved one of the most successful books of this branch of literature, establishing a high reputation in every country of Europe, and having, as Don Quixote said, descendants innumerable. The Spanish drama arose out of the representations so extensively connected with the festivals of the church during the middle ages. Among the best productions of this early period of Spanish literature belong the pastoral plays of Juan de la Encina and the celebrated dramatic novel of *Celestina* by Fernando de Rojas.—The second period of the national literature of Spain extends from the accession of the Austrian dynasty at the beginning of the 16th century to Cervantes. Under Charles I. (V. of Germany) Spain rose suddenly from a second class kingdom of Europe to be the most powerful empire of the world; and, as in the history of other countries, the political glory reflected itself in the rapid progress of literature. The union of Aragon and Castile led to the general adoption of the Castilian dialect as the commercial and literary language of the people. In consequence of the conquest of Naples by Gonsalvo de Cordova (1503–'4), and the increased intercourse of Spaniards with Italy, Italian literature, at that time the most advanced of Europe, began to have a marked influence on the poetry of Spain. The great Italian models, especially Dante and Petrarch, were imitated, and Italian measures, as the verses of seven and eleven syllables, and Italian forms, as the sonnets, *ottave rime*, and *canzoni*, were introduced. The first poet of this class was Juan Boscan Almogaver (died 1543), who made an experiment in Castilian of sonnets and the other forms of verse used by Italian authors. In most of these poems, although they are obvious imitations of Petrarch, a Spanish tone and spirit are perceptible, which rescue them from the imputation of being copies; yet there is an absence of the delicate and exact finish of the original. To a still greater perfection the best forms of Italian verse were carried by a friend of Boscan, Garcilaso de la Vega (died 1536), whose pastoral poems, unexcelled in Spanish literature, are remarkable for gentleness, a pleasing neatness of expression, and a rare sweetness of versification. His sonnets, elegies, and epistles are of less poetical value. Among those who aided most in the introduction and establishment of Italian metres was Diego Hurtado de Mendoza (died 1575). His sonnets are rougher than those of his predecessors, but his epistles (*cartas*) are rich in sentences, portraitures, and characteristics of great excellence. Though counted among the Italian school, he often gave himself up to the old *redondillas* and *quintillas*, and to the national tone of feeling and reflection appropriate to these ancient forms of Castilian verse. His satirical rogues' novel, *Lazarillo de Tormes*, a work of genius and a wholly original conception, became in Spain the foundation of a class of fictions essentially national, under the name of the *género picaresco* or rogues' style, which the "Gil Blas" of Le Sage has made famous throughout the world. Mendoza's history of the war against the Moriscoes in Granada is distinguished for manliness, vigor, truth, and picturesqueness of style. The Italian school of poets of this period includes also several Portuguese who wrote in the Castilian dialect, as Sa de Miranda (died 1558), the au-

thor of idyls, and Jorge de Montemayor (died 1562), the author of the celebrated pastoral novel *Diana*. The two greatest lyric poets that Spain has ever produced were Fernando de Herrera (died 1597) and Fray Luis de Leon (died 1591). Herrera wrote some excellent elegies, and the first classic odes in modern literature. The poetry of Luis de Leon is chiefly religious and deeply imbued with mysticism. The best of his poetical compositions are odes in the old Castilian measures, with a classical purity and vigorous finish before unknown in Spanish poetry. He ranks also among the greatest masters of Spanish eloquence for his prose, which is richer and no less idiomatic than his poetry. Less original, and at present less known, are Hernando de Acuña (died 1580), a lyric poet and skilful translator, and Gil Polo (died 1572), who ably continued and completed the *Diana* of Montemayor. Epic poetry was cultivated with but little success, and the attempts to sing the exploits of Charles V. made by Zapata (*Cárlos famoso*), Urrea, the translator of Ariosto (*Cárlos victorioso*), and Samper (*Carolea*), were failures. Cristóval de Castillejo (died about 1556), the most efficient among the early opponents of the Italian school, wrote novels and erotic songs, which are masterpieces; but the satire with which he inveighed against the innovators was generally too exaggerated to have any effect. Attempts made by Villalobos, Perez de Oliva, and others, to give a new impulse to dramatic poetry by the translation of old classics, were failures; but the epic elements of the old national novels led at the beginning of this period to the development of a truly national drama, of which Naharro (about 1517) must be regarded as the father. He was followed by Lope de Rueda, who, being both a dramatic writer and an actor, was the first to establish and regulate the Spanish stage; and by Juan de la Cueva (died about 1608), whose plays, mostly on historical subjects, are divided into four *jornadas* and written in various measures, including *terza rima*, blank verse, and sonnets, but chiefly in *redondillas* and octave stanzas. The two tragic plays of Gerónimo Bermudez, which treat of the sad history of Ines de Castro, are happy imitations of the old classic tragedy. In this period arose also the ecclesiastical plays (*autos sacramentales*) and the burlesque interludes (*entremeses y sainetes*) and preludes (*loas*), though their full development belongs to the following period. Prose literature consisted mostly of chivalric novels, formed after Italian originals, and without any intrinsic value or importance for the history of literature. Foremost among the prose writers were Mendoza and Luis de Leon, both of whom have already been named among the poets. Gerónimo Zurita, the author of a history of Aragon (*Anales de la corona de Aragon*), was the first of the Spanish historians as distinguished from the chroniclers, who in particular emancipated the historical literature of Spain from the monkish credulity of the old chronicles. Among the best specimens of didactic prose belong the dialogue of Oliva on the dignity of man (*Diálogo de la dignidad del hombre*) and the essays (*Discursos*) of Morales on subjects of practical philosophy and literature.—The golden era of Spanish literature begins in the second half of the 16th century with Cervantes (1547–1616), whose name and masterpiece are better known in foreign countries than those of any other Spanish author. His "Don Quixote," an ironical parody of the trashy literature of chivalric novels then in vogue, is the never equalled model of Spanish prose, the oldest classical specimen of romantic fiction, and one of the most remarkable monuments of modern genius. His *Novelas ejemplares* and his *Trabajos de Pérsiles y Sigismunda* inaugurated in Spain the literature of serious romantic fiction, in which he found many imitators, but none who equalled him. His *Galatea* is one of the best pastoral novels of Spain. The Spanish drama was raised to the elevated position which it occupies in the modern literature of Europe by the prolific Lope de Vega (1562–1635). He fixed its several modifications, and from his times we meet with the division into ecclesiastical and secular dramas (*comedias divinas y humanas*). The principal kinds of the secular drama were *comedias heróicas*, historical and mythological plays, and *comedias de capa y espada*, dramas with cloak and sword, the principal personages of which belong to the genteel portion of society, accustomed in Lope's time to the picturesque national dress of cloaks and swords. The ecclesiastical dramas were divided into *vidas de santos*, lives of saints, and *cantos* or *autos sacramentales*, plays at the Corpus Christi festival. In point of composition nearly all the dramas of Lope de Vega are alike; the unity of action, time, and place is little or not at all observed; acts and scenes barely connect the whole; language and representation are sometimes vigorous, sometimes weak, now noble, now common and coarse. The number of his dramas is almost fabulous, and is put by Perez de Montalvan, his intimate friend and executor, at 1,800 plays and 400 *autos*. He wrote also several epic poems, as *Jerusalen conquistada*, *Corona trágica*, &c., which were far inferior to his dramas, and were soon forgotten. His minor poems, among which are some of great merit, are almost innumerable. The number of poets at this time increased amazingly, though but few of them showed any originality. Among the lyric poets, the first, as far as their general influence was concerned, were the two brothers Argensola. Many of this class of writers belonged to the school of the *conceptistas*, who expressed themselves in metaphors and puns, alike in the pulpit and in poetry, or to that of the *cultos*, imitators of Gongora (1561–1627), who claimed for themselves a peculiarly elegant and cultivated style of composition, and who,

while endeavoring to justify their claims, ran into the most ridiculous extravagances, pedantry, and affectations. The essence of epic poetry was singularly misunderstood, as all epic poems were little more than versified history. Even the best work of the class, the *Araucana* of Alonso de Ercilla y Zúñiga (died about 1594), though not destitute of beautiful epic machinery, is condemned as tedious and prosaic by many critics; but a talent for animated description and portraiture, and a natural and correct diction, are conceded to its author. Of all kinds of poetry, the drama was cultivated most and with greatest success. A last attempt to write purely tragical plays was made by Cristóval de Virues, whose *Semíramis* and *Casandra* were, in true expression of tragic pathos and in vigorous dialogue, superior to all former efforts; but as the people had a decided preference for the national drama, in which, as in life, tragic scenes alternate with comic, it did not succeed. Higher than all former and later tragic poets stands Pedro Calderon de la Barca (1600–'81), one of the greatest dramatists that ever lived. To the originality and overflowing imagination of his predecessors he added a greater depth of reflection and a more careful execution in details. Female characters, in particular, were delineated by him more faithfully and more ingeniously than by any other Spanish poet. In elegance of language and versification he is also unequalled. The most prominent among his numerous successors were Francisco de Rojas, Agustin Moreto, Fragoso, Diamante, Antonio Hurtado de Mendoza, Juan de la Hoz, Antonio de Solis (better known as a historian), and Agustin de Salazar y Torres, who inclines toward the "cultivated style." The decline of Spanish literature shows itself in the writings of Francisco de Quevedo y Villegas, the most learned writer of his times, some of whose works, however, as his burlesque sonnets and his prose satires, are among the best of their kind in the Spanish language. Exaggeration and affectation vitiate the otherwise unparalleled erotic songs of Estéban Manuel de Villegas. The corruption of Spanish prose was hastened by the constant stream of bad and shallow novels, in which branch of literature the rogues' novel, *Guzman de Alfarache*, by Mateo Aleman, deserves an honorable mention. The only historians of note were Mariana (*Historia de España*) and Solis (*Conquista de Méjico*).—The fourth period, which begins with the accession of the Bourbon family at the beginning of the 18th century, embraces the collapse of the old national literature, the intrusion of foreign elements, their temporary victory over the old Spanish, and the final attempts to regenerate the old native element, and to fuse it with the best elements of modern European civilization. The first prominent advocate of the French element was Ignacio de Luzan, who in his *Poética* (1737) applied the rules of French critics to native literature, and in his own poems tried to substitute brilliancy for genuine poetry. He was principally opposed by Garcia de la Huerta, whose *Rahel* and *Agamemnon* were written in the old Spanish forms, and were received, in spite of the objections of Gallicizing critics, with immense applause. A middle course was pursued by the school of Salamanca, which endeavored to avoid the excesses of both parties and unite their merits. Its proper founder was Melendez Valdez (1754–1817), a poet of eminent talents, whose works exceed all that had been produced in Spain since the disappearance of the great lights of the 16th and 17th centuries, and were received with general enthusiasm as the dawn of a brighter period. Under the influence of the Salamanca school were also Iglesias, Noroña, Quintana, Cienfuegos, Arriaza, and Gallego, who like Valdez remained thorough patriots in sentiment, though not disdaining to follow great French, Italian, and English models. The liberal and patriotic movements of 1812, 1820, and 1834 exercised a very favorable influence on the invigoration of the Spanish mind and the progress of literature. Their fruit is to be seen in the works of Xérica, Lista, Martinez de la Rosa, José Joaquin de Mora, Ángel de Saavedra, and Breton de los Herreros. The number of recent poets is very large; among the best of them are Tapia, Maury, Juan Bautista Alonso, Jacinto de Salas y Quiroga, Espronceda, Serafin Calderon, Zorrilla, Hartzenbusch, R. de Campoamor, Santos Lopez Pelegrin, the satirist Villergas, and Gertrudis Gomes de Avellaneda, a native of Cuba. The modern age is least successful in epic poetry, the only notable attempt in this class of composition being the unfinished *Diablo mundo* of Espronceda. Better results have been obtained by a recultivation of the old romance and fable, the first impulse to which was given by Saavedra, who has been followed by Mora, Zorrilla, Gregorio Romero y Larrañaga, Manuel de Santa Ana, and others. In dramatic poetry, Leandro Fernandez Moratin, a chief representative of the classic school of France, secured for himself a permanent place on the national stage, and for the school to which he belonged a great influence, which lasted until in France the romantic school became powerful. The works of that school, partly in translations, partly in imitations, controlled for some time the stage of Madrid, but were opposed by Breton de los Herreros, Martinez de la Rosa, Tapia, Saavedra, and more recently by Gil y Zárate, Hartzenbusch, Gutierrez, Escosura, Zorrilla Moral, Trueba, and others. A reformation of prose literature, which had been reduced by the school of the *cultos* to the lowest ebb, was prepared by the Benedictine Feyjoó, who returned to the simplicity of the classic models of Spain, and by the Jesuit Isla, who in his satirical novel *Fray Gerundio* ridiculed the trivial and bombastic pulpit eloquence of his times. Ulloa, Muñoz, Capmany, Ferreras, Quintana, Navarrete, Clemencin, To-

reno, Lafuente y Alcántara, Gayangos, Muñoz Maldonado, and Modesto Lafuente (as a satirist known under the pseudonyme of Fray Gerundio) have in modern times distinguished themselves as historians. Among the best political writers and orators are Jovellanos, Argüelles, the philosopher Balmes, Miñano, Marina, Larra, Alcalá Galiano, Donoso Cortés, Martinez de la Rosa, Figueras, and Castelar. Novel literature began to be cultivated with great activity when the standard works of England and France became known. Among the best works of the kind are those of Humara y Salamanca, Escosura, Martinez de la Rosa, Larra, Villalta, Serafin Calderon, Gertrudis de Avellaneda, and Cecilia Böhl Faber de Aron ("Fernan Caballero"). Among the brilliant Spanish writers of the present century is the orator Emilio Castelar, who has won a wide reputation. Besides novels, he has published *Discursos parlamentarios*, *Recuerdos de Italia* (translated into English as "Old Rome and New Italy"), and *Vida de Lord Byron* (English translation by Mrs. Arthur Arnold, London and New York, 1875–'6).—There are still many writers in the Catalan dialect, which is considered by the Catalans to be a richer language than the Castilian. Catalan literature produced its best authors in the century preceding the reign of Ferdinand and Isabella. The *Cancionero general*, compiled soon after the middle of the 15th century, is a collection of about 300 poems by 30 different Catalan writers. The works of Ausias March (died 1460), the most noted of these, passed through four editions in the 16th century, and were translated into Latin, Italian, and Castilian, the last by Montemayor. Jaume Roig (died 1478), like March a native of Valencia, is also worthy of notice for his "Book of the Ladies," a satire on woman. In 1428 the *Divina commedia* was translated into Catalan by Andres Febrer; and in 1477 Bonifacio Ferrer made a translation into the same dialect of the Bible (folio, Valencia, 1478), but nearly every copy of it was destroyed by the inquisition. In the beginning of the 16th century Catalan writers began to use the Castilian, and by the middle of that century the latter had almost superseded its rival. The contemporary literature of Catalonia consists mainly of poetry, dramatical pieces, and newspaper articles. The leading writers of the present day are Lo Tamburiner d'el Llobregaz, Victor Balaguir, Francisco Camprodon, Serrafi Pitarra, Jaime Cullell, and Bofarull.—Of the Spanish colonies, Cuba alone has produced some writers of enduring fame, as the poets Heredia and Placido, and the female poet and novelist Gertrudis Avellaneda, before mentioned. In all of the Spanish American republics the different branches of literature, but chiefly poetry, have been and are cultivated with considerable success; but only a few of the writers have more than a local reputation. Among those whose names are known abroad, some of the most eminent are Baralt (1810–'60), author of a *Historia de Venezuela;* the popular Ecuadorian poet Olmedo (born 1784); the Venezuelan Bello (1780–1865), the most distinguished of Spanish American poets and grammarians; J. M. Torres Caicedo, a poet and publicist, author of *Ensayos biográficos*, cited below; Mora, who wrote a history of Mexico; Pedro de Angelis, historian of the Argentine Republic; Eyzaguirre, author of a history of Chili from the discovery to the present century; Marmol, an Argentine novelist, who wrote *Amalia;* Toro of Colombia, Lastarria of Chili, and Sarmiento of the Argentine Republic, the last of whom is the author of *Civilizacion y barbarie*, an analysis of South American society, published in French in 1853, and of the *Vida de Abran Lincoln* (New York, 1865).—The best work on the national literature of Spain is the "History of Spanish Literature," by George Ticknor (3 vols. 8vo, New York and London, 1849), a Spanish translation of which, with additions and notes, by Pascual de Gayangos and Enrique de Vedia, was published in Madrid in 1851–'6. See also Eugenio Ochoa, *Coleccion de los mejores autores españoles* (Paris, 1852); Ferdinald Wolf, *Studien zur Geschichte der spanischen und portugiesischen Nationallitteratur* (Berlin, 1859); Manuel Ovilo y Otero, *Manual de biografía y de bibliografía de los escritores españoles del siglo XIX.* (Paris, 1859); Amador de los Rios, *Historia crítica de la literatura española* (Madrid, 1862); Eugène Baret, *Histoire de la littérature espagnole depuis ses origines les plus reculées jusqu'à nos jours* (Paris, 1863); J. M. Torres Caicedo, *Ensayos biográficos y de literatura sobre los principales poetas y literatos latino-americanos* (3 vols. 8vo, Paris, 1863–'8); and J. M. Rojas, *Biblioteca de escritores venezolanos contemporáneos* (Paris, 1875). Among older works, the German of Bouterwek and the French of Sismondi are valuable; they have been translated both into Spanish and English, and the former into French.

**SPAIN, Wines of.** The Spanish peninsula yields to no other part of Europe in natural advantages for wine growing. With a fertile soil, an admirable geological conformation, and a climate which, aided by the proximity of great bodies of water, tends to develop the vine to a high degree of perfection, it ought to produce natural wines of the choicest quality in respect to body and bouquet; but, in consequence of primitive and faulty systems of vinification, these results are seldom attained, and the Spaniards may be said to excel chiefly in the preparation of white, dry, fortified wines, and a few sweet varieties. The culture of the vine in Spain is almost universal, but in the absence of recent trustworthy statistics the annual yield cannot be readily determined. It has been estimated as high as 660,000,000 gallons, and as low as 300,000,000; the latter amount is doubtless more nearly correct. The principal wines of export and those

most intimately associated with Spanish viticulture are the several varieties of sherry, so called from the town of Jerez de la Frontera, in Andalusia, around which lie perhaps the choicest vineyards of Spain. They form part of the wine district of Cadiz, which also includes San Lucar de Barrameda, on the banks of the estuary of the Guadalquivir; Trebujena, N. of San Lucar; and Puerto de Santa Maria, S. of Jerez, on the W. bank of the estuary of the Rio Guadalete, which forms the eastern frontier of the sherry district. The vineyards of all qualities in the district of Cadiz cover about 24,000 acres, and yield not less than 6,000,000 gallons annually, which is very little in excess of the yearly consumption of so-called sherry in England alone. Between natural sherries and the sherries of commerce, which find their principal market in Great Britain and the United States, there is an important difference. The former are generally light-colored and dry, and after the primary fermentation is complete contain an average of 26 per cent. of proof spirit naturally generated. Under this class may be mentioned the so-called *vinos de pasto*. or table wines, which are light, dry, spirituous, and highly flavored. The wines exported under that name exhibit these qualities in a marked degree, although more or less brandied to suit the English and American taste. But the greater part of the sherries leaving Cadiz have previously been subjected to a treatment which renders them as much a factitious product as champagne. The manufacturers generally buy much more must or wine from other growers than they produce themselves. The juice is deposited in butts of 108 gallons each, and after the first fermentation is racked from the lees, each butt receiving from two to ten gallons of spirit, according to the quality of the wine, the inferior sorts requiring most reënforcement. The wine is subsequently flavored with a liqueur called *dulce*, made from the must of over-ripe grapes, the fermentation of which has been checked by the addition of over-proof spirit; and colored by an admixture of *vino de color*, which is simply must boiled until it is reduced to one fifth of its bulk, and has acquired the consistency of treacle. It is deep reddish brown, and has a harsh and bitter flavor. By means of this agent all the popular shades of color are given to the conventional sherries of commerce. Thus pale sherry requires but 7 gallons to the butt, the golden 15, the pale brown 20, and the rich old brown as much as 25 gallons. The choicest wines of the Cadiz district are not customarily sold or drunk, but are reserved for admixture with poorer sorts, whereby the latter, in addition to the flavoring and coloring processes they have undergone, acquire a premature character of age and ripeness. Hence the custom prevalent among manufacturers of sherry, of keeping up the so-called *soleras*, or stock wines. A solera wine is described as "a fine old mother wine, which by care and attention has acquired body and character. Such wines are kept in stock in butts or double butts, and are perpetuated in the following manner: Of say 20 butts of existing ready solera wine the proprietor draws off one half for mixing with the wine about to be exported. He then fills up the voids created in his 20 butts by means of 10 butts of the finest wine of a later vintage which he can obtain. In old established houses solera wine is therefore a mixture of a great number of wines, of which the latest addition forms one half, the last but one a quarter, and the last but two an eighth of the whole bulk, and so forth, in a ratio which terminates only with the first solera produced without any mother wine. The production of this solera wine is a kind of chemical infection whereby good wine is induced to undergo quickly a process of etherification. This process becomes so potent in some soleras that they are absolutely nasty and undrinkable, like most essences, but command prices of from £800 to £1,000 a butt, on account of the large quantity of flavorless wine which a certain small amount of them will infect with the desired sherry flavor." (Thudicum and Dupré's "Treatise on Wines.") Repeated brandyings of the poorer wines take place previous to shipment, until the 26 per cent. of proof spirit contained in the newly fermented natural wine has been increased to an average of about 37 per cent. Some specimens tested by the London custom house officers have exhibited as much as 50 per cent. The finer sherries are free from this extreme alcoholic character. Those from the neighborhood of Jerez often develop a peculiar etherous flavor called the *amontillado*, which is supposed to arise from the presence of aldehyde, and is very noticeable in some white Greek wines. Around San Lucar are produced the well known *manzanillas*, which derive their name from a certain similarity both in flavor and fragrance to the manzanilla or camomile flower. In their highest perfection they are thin and almost colorless, with a bitter aromatic taste. They are said to be the purest wines of their class, from the fact that they will not mingle readily with other growths. The fine wines of Montilla, long famous throughout Spain, are reputed to develop the amontillado flavor in a remarkable degree, but require several years to reach their best condition. Elsewhere in Andalusia are produced wines assimilating in flavor and in general character to those of Jerez, but greatly inferior in quality. The district of Condado de Niebla, between the coast and Seville, yields a wine so perishable that it has to be largely reënforced with alcohol, after which it is taken to Cadiz and made into sherry for shipment to England.—Malaga has long been famous for the production of wines, both sweet and dry, and raisins. The entire country between the port of Malaga and Granada may be said to form one great vineyard, the

mountainous parts of which near Malaga, owing to exceptional climatic advantages, produce not less than three crops of grapes annually. The first is used exclusively for raisins, while the second yields dry wines and the third sweet wines. The most noted of the latter are rich and of a dark amber color, imparted by the addition of boiled must intentionally burned in the boiling. They are said to keep for more than a century, with the aid doubtless of added spirit, but with age lose much of their sweetness. Toledo and La Mancha produce some excellent red wines, those of the latter district being distinguished by ample body and a peculiar subbitter flavor. The muscat of Juencaral near Madrid is one of the brightest colored and most agreeable wines of Spain. Murcia, Valencia, and Catalonia, which border on the Mediterranean, produce immense quantities of deep-colored, full-bodied wines. Those of Murcia are coarse, rough, and inferior, while those of certain districts of Valencia, notably Alicante and Benicarlo, have considerable reputation. The lower grades of Valencia wines are perishable unless reënforced with alcohol, and are largely employed in making imitation port or in mixing with genuine port wine. Many thousands of butts of spirits are also distilled from them. The Alicante wines, produced from the grape of that name, are sweet, strong, luscious, and often of an almost sirupy consistence. Like other wines of their class, they have to be brandied in order to keep any length of time. Those of Benicarlo are sweet and heady, and are in considerable demand for mixing with the red wines of southern France. The Catalan wines are numerous and of many varieties of flavor, the greater part being cheap and of medium quality. The red kinds predominate, and it is asserted that those of the deepest tint, called in England "Spanish reds," derive their color from a liberal admixture of elderberry juice. They require brandying, and are extensively used for building up the poorer growths of Bordeaux. Much of the cheap claret used in England and America is largely impregnated with Spanish Mediterranean wines. In Aragon, Valladolid, Biscay, Navarre, Asturias, and elsewhere are produced red and white wines of fair quality, but mostly of local reputation. Of late years attempts have been made to naturalize the choice wines of Médoc and Burgundy in northern Spain, in the hope of obtaining wine equal to the products of those districts; but the results have, as a rule, been far from satisfactory. The Balearic islands yield considerable quantities of wine, chiefly muscats and malmseys; while the Canaries, where was made the famous *vino secco* or sack of Shakespeare's time, have almost ceased to be a wine-growing country.

**SPALATO,** or **Spalatro** (anc. *Spalatum* or *Spolatum*), a town of Dalmatia, Austria, on a bay of the Adriatic formed by islands, 74 m. S. E. of Zara; pop. in 1870, 15,784. It has been ately much improved and provided with piers and quays. The archbishop of Spalato is primate of Dalmatia and Croatia. It contains a cathedral (anciently a temple of Jupiter) and other churches, an episcopal palace and seminary, a nautical and other schools, and a museum for Roman antiquities, which abound here. The harbor is spacious, and the trade is especially active with Turkey. Spalato belonged for several centuries to Venice, during the Napoleonic era to France, and since 1815 to Austria.—Three miles E. N. E. of Spalato is the village of Salona, which preserves the name of the ancient capital of Dalmatia. Ancient Salona was an extensive city, and a bulwark of the Romans against the Goths and other barbarians. Some of its buildings and many ruins remain. The emperor Diocletian, who was born near it, resided there during his retirement. A portion of Spalato is on the site of his immense palace, built in 303, and occupying about eight acres, in which the people of Salona took refuge on the destruction of their city by the barbarians; and the name Spalatum is a corruption of *Salonæ Palatium.*

**SPALDING,** a W. county of Georgia, bounded W. by Flint river; area, about 190 sq. m.; pop. in 1870, 10,205, of whom 4,878 were colored. The surface is slightly undulating and the soil fertile. It is traversed by the Macon and Western and the Savannah, Griffin, and North Alabama railroads. The chief productions in 1870 were 18,634 bushels of wheat, 125,984 of Indian corn, 17,164 of oats, and 3,630 bales of cotton. There were 460 horses, 728 mules and asses, 1,169 milch cows, 1,554 other cattle, 1,521 sheep, and 4,256 swine. Capital, Griffin.

**SPALDING, Lyman,** an American physician, born in Cornish, N. H., June 5, 1775, died in Portsmouth, N. H., Oct. 31, 1821. He graduated at Harvard college in 1797, assisted Prof. Nathan Smith in establishing the medical school at Dartmouth college, delivered the first course of lectures on chemistry in that institution, and published "A New Nomenclature of Chemistry, proposed by Messrs. De Morveau, Lavoisier, Berthollet, and Fourcroy, with Additions and Improvements" (1799). He entered upon the practice of medicine at Portsmouth in 1799. In 1812 he was elected president and professor of anatomy and surgery in the college of physicians and surgeons at Fairfield, Herkimer co., N. Y., and in 1813 he removed to the city of New York. He originated the plan for the formation of the "Pharmacopœia of the United States," the first edition of which was published in 1820, under the supervision of delegates from all the medical schools and societies. Dr. Spalding published "Reflections on Fever, and particularly on the Inflammatory Character of Fever" (1817); "Reflections on Yellow Fever Periods" (1819); and "A History of the Introduction and Use of Scutellaria Lateriflora as a Remedy for preventing and curing Hydrophobia" (1819).

**SPALDING, Martin John,** an American prelate, born in Marion co., Ky., May 23, 1810, died in Baltimore, Feb. 7, 1872. He graduated at St. Mary's college, Lebanon, in 1826, studied theology, and went to Rome in 1830 to complete his course at the college of the propaganda. He was ordained priest on Aug. 13, 1834, returned to Kentucky, and was appointed pastor of the cathedral of Bardstown. In February, 1835, he founded the "Catholic Advocate," with which he was connected till 1858. He also founded the "Louisville Guardian" in 1854. In 1838 he was elected president of St. Joseph's theological seminary, Bardstown; in 1840 became pastor of St. Peter's church, Lexington, and in 1841 again pastor of the cathedral at Bardstown. He was invited to deliver a series of discourses on the Roman Catholic church in the cathedral of Nashville in 1843; and he afterward lectured in the chief cities of the United States and Canada. His yearly lectures from 1844 to 1847 were published with the title of "Evidences of Catholicity" (1847; 4th ed., Baltimore, 1866). He was appointed coadjutor bishop of Louisville, Aug. 10, 1848, with the title of bishop of Lengone *in partibus infidelium*, and was consecrated on Sept. 10. He established a colony of Trappist monks at Gethsemane near Bardstown, and a house of Magdalens in connection with the convent of the Good Shepherd. In 1850 he became bishop of Louisville as successor of Dr. Flaget, whose life he wrote (Louisville, 1852), and built a magnificent cathedral. In May, 1852, he was present at the first plenary council of Baltimore, obtained the erection of the new see of Covington, and urged the establishment of a system of parochial schools in every diocese. He went to Europe in November, 1852, obtained in Belgium Xaverian brothers for the parochial schools of Louisville, and from Archbishop Zurysen of Utrecht several priests and a colony of sisters to instruct the deaf and dumb. Having taken steps for the foundation of an American college at Louvain, he returned to the United States in April, 1853, and was involved in a controversy with George D. Prentice of the Louisville "Journal" at the beginning of the Know-Nothing movement in 1855. He published his "Miscellania" during this agitation. In the three provincial councils of Cincinnati, in 1855, 1858, and 1861, Bishop Spalding bore a leading part, and drew up the collective address of the bishops at their close. Another controversy with George D. Prentice grew out of a review by Bishop Spalding of Joseph Kay's work on common school education in Europe, the bishop advocating a denominational system of common schools, such as exists in most European states. In his own diocese he introduced a system of church government calculated to secure the rights of the inferior clergy, and preserve them from arbitrary rule. In 1860 he published "A History of the Protestant Reformation in Germany and Switzerland" (2 vols. 8vo, Louisville; 4th ed., Baltimore, 1866), enlarged from a review of D'Aubigné first published in 1844, and delivered a course of lectures at the Smithsonian institution on the history and elements of modern civilization. He succeeded Dr. Kenrick as archbishop of Baltimore, May 12, 1864, and took possession of his see on July 31. One of his first cares was to found an industrial school for boys intrusted to the Xaverian brothers, which was opened Sept. 8, 1866. As apostolic delegate, he convened the second national council of Baltimore, Oct. 7, 1866, and had the principal part in preparing the measures submitted to its deliberations, and in drawing up the acts of the council in so complete a form as to make the work a standard manual of American canon law (*Concilii Plenarii Baltimorensis II. Acta et Decreta*, Baltimore, 1868). To him is mainly due the foundation of the "Catholic Publication Society" of New York, and of the monthly periodical called the "Catholic World." He took a conspicuous part in the council of the Vatican (1869-'70). Together with other bishops of the United States, he wished for an immediate and final doctrinal judgment on the question of pontifical infallibility, but preferred an indirect and implied definition, consisting in the formal condemnation of every sentiment opposed to the inerrancy of the supreme teaching office of the pope. On Archbishop Spalding's arrival in Rome a *postulatum* in this sense was drawn up by him and signed by the American bishops. Subsequently some of the leading reasons on which the *postulatum* was grounded were publicly quoted by Bishop Dupanloup as arguments against the opportuneness of a doctrinal definition. Passages from the late Archbishop Kenrick's theology were also alleged in support of the opposition. This was resisted by Archbishop Spalding in a letter to Bishop Dupanloup (April 4, 1870), in which he vindicated the orthodoxy of his predecessor, and explained the opinions of the American bishops. At the opening of the council he had been appointed a member of the commission of 16 on *postulata*, and the decided stand taken by the majority of the council in favor of an immediate and formal definition finally induced him and his co-signers to make no further opposition. Archbishop Spalding edited with an introduction and notes Abbé Darras's "General History of the Catholic Church" (4 vols., New York, 1866).

**SPALDING, Solomon.** See MORMONS, vol. xi., p. 833.

**SPALLANZANI, Lazaro,** an Italian naturalist, born at Scandiano, in the duchy of Modena, Jan. 12, 1729, died Feb. 12, 1799. He studied at Reggio and Bologna, and was chosen in 1754 to fill the chair of logic, metaphysics, and Greek in the university of Reggio. In 1761 he accepted a professorship at Modena, and began to obtain a wide reputation by his researches in natural science. In 1767 he produced a work

on the phenomena of generation, showing the preëxistence of germs to fecundation; in 1768 he published the result of his investigations on the production and circulation of the blood; and in 1769 translated Bonnet's *Contemplations de la nature.* In 1775 he contested, in opposition to Needham, the spontaneous generation of the infusoria, and maintained by a long series of ingenious experiments the production of these animalcules from atmospheric germs. In 1770 he was appointed professor of natural history in the university of Pavia. In order to add to the museum of Pavia, he travelled at different times through the principal countries of Europe, resided 11 months in Constantinople about 1785, and on his return lectured to more than 500 students. In later publications he announced remarkable discoveries and theories concerning volcanoes, discussed curious problems in regard to swallows, and suspected the existence of a sixth sense in bats, by which they are guided with precision though deprived of sight. His works are numerous, and many of them have been translated into the principal European languages.

**SPANDAU,** a town of Prussia, in the province of Brandenburg, at the junction of the Spree and the Havel, 7 m. W. of Berlin; pop. in 1871, 19,013. It is a fortress of the third class, and the treasury of the German empire is deposited in the citadel, and can be unlocked only by two keys simultaneously, one of which is in the custody of the chancellor and the other in that of the president of the committee for the debts of the empire. Spandau has a large central prison, new barracks and military hospital, an artillery school for infantry, a royal foundery of artillery, and various manufactories. It is one of the oldest towns of the Mittelmark, and was repeatedly the residence of the electors of Brandenburg. It was occupied by the Swedes from 1631 to 1635, surrendered to the French Oct. 25, 1806, and recovered by the Prussians April 26, 1813.

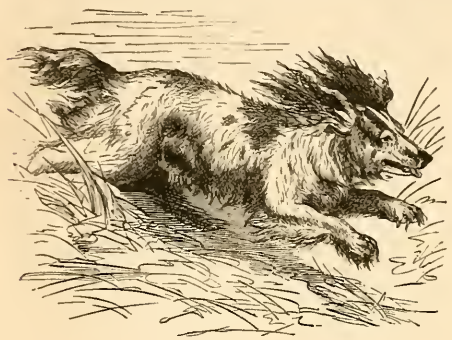
**SPANGENBERG, August Gottlieb,** first bishop of the Moravian church in America, born at Klettenberg, Prussia, July 15, 1704, died at Berthelsdorf, Saxony, Sept. 18, 1792. He graduated at Jena in 1726, began to lecture as a junior professor, and in conjunction with a number of students established free schools in the suburbs of Jena for the children of the poor. In 1731 he was appointed adjunct professor at Halle, and assistant superintendent of Francke's orphan house. His liberal views in respect to such as were not in connection with the established church, and especially his strong love for the Moravians, led to his dismissal from his offices in 1733. He went to Herrnhut, and was appointed assistant to Count Zinzendorf, in which capacity he visited various parts of the continent. Toward the close of 1734 he went to England, where he entered into successful negotiations with the trustees for Georgia relative to a Moravian settlement in that colony. Fifty acres of land were granted him, and 500 acres were made over to Count Zinzendorf. One of these tracts formed a part of the present site of Savannah, and the other lay on the Ogeechee river. Spangenberg arrived at the former tract with nine immigrants in the spring of 1735, and immediately commenced a settlement, which was the first formed by the Moravians in America. Having spent four years partly in Georgia and partly in Pennsylvania, where he preached among his German countrymen, he returned to Europe. His report upon the state of religion in Pennsylvania induced the church to begin an enterprise in that province, and the town of Bethlehem was founded. In 1741 he visited London, where he was made general deacon of the brotherhood, and founded the first organized Moravian society in England. In 1744 he returned to Germany, and, after being consecrated a bishop, went again to America, in order to superintend the entire work of the Moravians in this country, in which he continued for 18 years, interrupted by occasional visits to Europe. He undertook frequent journeys to the Indian country, and was adopted into the Oneida nation. Soon after the conquest of Canada, Spangenberg was appointed a member of the college of bishops and elders elected, subsequently to Count Zinzendorf's death, to govern the three provinces and the missions of the Moravian church. He left America in June, 1762, arrived at Herrnhut in November, and immediately entered upon the duties of his new office, and for 30 years was the leading spirit among his colleagues. In 1764 he was appointed supreme inspector in upper Alsace, and in 1789 president of the general directory. Among his principal works are his *Leben Zinzendorf's* (3 vols., 1772–'5), and *Idea Fidei Fratrum* (1779). The latter is the standard of theology among the Moravians. It was translated into English by Latrobe in 1784, under the title of "An Exposition of Christian Doctrine as taught in the Protestant Church of the United Brethren."

**SPANGENBERG, Friedrich,** a German painter, born in Göttingen in 1843, died while ascending Mt. Vesuvius, June 8, 1874. He studied in Munich, and became known by his picture of Genseric, king of the Vandals, leading the empress Eudoxia and her children into captivity after the sack of Rome. In conjunction with the Belgian painter Pauwel he executed at Weimar "The Triumph of the Union," commemorating the close of the civil war in the United States. While in Rome he painted "A Young Ostrogoth entering into friendly Relations with Citizens of Rome."

**SPANHEIM, Ezechiel,** a Swiss author, born in Geneva, Dec. 7, 1629, died in London, Nov. 7, 1710. He studied at Leyden, was a professor at Geneva, represented the elector palatine in various countries, and subsequently the elector of Brandenburg for many years in Paris, and in the last eight years of his life was Prussian ambassador in London. His works include

*Dissertationes de Præstantia et Usu Numismatum Antiquorum* (4to, Rome, 1664; best ed., 2 vols., London and Amsterdam, 1706–'17), and *Orbis Romanus* (London, 1704; contained also in Grævius's *Thesaurus*, vol. xi.).

**SPANIEL** (*canis extrarius*, Linn.), a well known variety of hunting dog, in form a small setter, with silky hair, long in some parts of the body, and long, soft, pendulous ears. It is figured on some of the later monuments of an-



Spaniel.

cient Italy, and is supposed to be the *C. Tuscus* of the Romans; it probably originated in Spain, whence the name. The colors are various, black, brown, pied, liver-colored and white, and black and white. The English breed is considered the best for sportsmen, being strong, with an excellent nose, and fond of the water. The water spaniel differs from the common breed in the eagerness to hunt and swim in water, whence it is used to drive ducks into the nets in decoy ponds; the hair is also harsher. (See Poodle.) The Alpine or St. Bernard spaniel is the largest and most celebrated of the race, being 2 ft. high at the shoulders, and 5 or 6 ft. from nose to end of tail; it has a peculiar appearance about the inner angle of the eyes, due probably to their being kept partly shut to avoid the high winds and the glare of the snow; this is one of the breeds which search the mountain passes in the vicinity of the *hospice* of St. Bernard in quest of bewildered or weary travellers. The Newfoundland dog resembles the Alpine spaniels; it is large and has great strength, and is probably their indigenous American representative, and useful for many purposes of a beast of burden; it is gentle, very intelligent, and affectionate; it is an excellent swimmer, the toes being partly webbed. The springer is a small spaniel of elegant form, small head, and long ears, usually red and white, the latter predominating, with a black nose and palate; the Marlborough breed is considered the best. The King Charles spaniel is a small and beautiful breed, prized as a lady's pet, generally black and white, or black and tan-colored; the hair is soft and silky, the ears pendulous, the forehead elevated, and the eyes intelligent; the variety prized by Charles I. of England was wholly black; this is the *C. brevipilis* (Linn.). It is supposed to be the parent of the cocker, a sprightly little bird dog, usually black, or white with reddish spots, and comparatively shorter in the back than the spaniel. The Maltese dog is perhaps the most ancient of the small spaniel races, being figured on Roman monuments, and mentioned by Strabo as the *C. melitæus;* the muzzle is round, the hair very long and silky, and the color usually white; it is diminutive, and fit only for a lap dog.

**SPANISH FLY.** See Cantharides.

**SPANISH MAIN,** the appellation formerly given to the southern portion of the Caribbean sea, together with the contiguous coast, embracing the route traversed by Spanish treasure ships from Mexico, Central America, and the northern shores of South America.

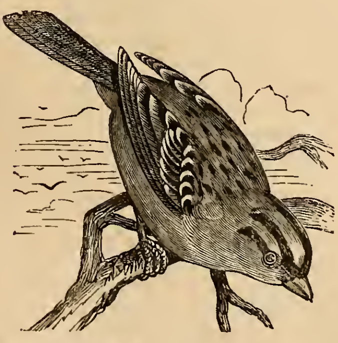
**SPAN WORM.** See Canker Worm, and Caterpillar.

**SPAR.** See Baryta, Calcareous Spar, Feldspar, and Fluor Spar.

**SPARKS, Jared,** an American historian, born at Willington, Conn., May 10, 1789, died in Cambridge, Mass., March 14, 1866. He graduated at Harvard college in 1815, studied theology at Cambridge, and for two years, 1817–'19, was college tutor in mathematics and natural philosophy. He also became one of an association by which the "North American Review" was conducted. In May, 1819, he was ordained as minister of a Unitarian congregation in Baltimore, and the next year published "Letters on the Ministry, Ritual, and Doctrine of the Protestant Episcopal Church" (8vo, Boston). In 1821 he was elected chaplain of the United States house of representatives, and the same year he established "The Unitarian Miscellany and Christian Monitor," which he edited till 1823. In this work he began a series of letters on the "Comparative Moral Tendency of Trinitarian and Unitarian Doctrines" (8vo, 1823). He also edited a "Collection of Essays and Tracts in Theology, from various Authors, with Biographical and Critical Notices" (6 vols. 12mo, 1823–'6). His health becoming impaired, he resigned his pastoral charge in 1823, and removing to Boston purchased the "North American Review," of which he was sole proprietor and editor for seven years. In 1828 he published a "Life of John Ledyard, the American Traveller," chiefly from original materials. After extensive researches in the United States, he made a voyage to Europe in 1828, where he selected and transcribed documents relating to American history in the public offices of London and Paris, and after his return published "The Writings of George Washington, with a Life of the Author, Notes, and Illustrations" (12 vols. 8vo, Boston, 1834–'7). During the preparation of this work he edited and published "The Diplomatic Correspondence of the American Revolution" (12 vols. 8vo, 1829–'30), and "The Life of Gouverneur Morris, with Selections from his Correspon-

dence and Miscellaneous Papers," &c. (3 vols. 8vo, 1832). "The American Almanac and Repository of Useful Knowledge" was founded by Mr. Sparks, who edited the first volume, for 1830. He was also the editor of the "Library of American Biography" (first series, 10 vols. 18mo, 1834–'8; second series, 15 vols., 1844–'8), several of the lives in which were written by him. In 1840 he completed the publication of "The Works of Benjamin Franklin, with Notes and a Life of the Author" (10 vols. 8vo). He then visited Europe a second time, and discovered in the French archives the famous map with the red line drawn upon it, about which so much was afterward said in the debates upon the Ashburton treaty in congress and parliament. In 1852 two pamphlets were printed by him in defence of his mode of editing the writings of Washington, in reply to the strictures of Lord Mahon and others, and a similar pamphlet the next year, occasioned by a reprint of the original letters from Washington to Joseph Reed. In 1854 he published "Correspondence of the American Revolution, being Letters of eminent Men to George Washington, from the time of his taking command of the Army to the end of his Presidency, edited from the Original Manuscripts" (4 vols. 8vo). Mr. Sparks was McLean professor of history at Harvard college from 1839 to 1849, and president of the college from 1849 to 1853. His life, by G. E. Ellis, was published in 1869.

**SPARROW**, the familiar name of many small birds of the finch family, and the old genus *fringilla* (Linn.), which has been numerously subdivided by modern ornithologists; the family characters have been given under FINCH. Among the many American species may be mentioned three distributed under three different genera. The white-crowned sparrow (*zonotrichia leucophrys*, Swains.) is about 7 in. long and 10 in. in alar extent; the body is stout, bill



White-Crowned Sparrow (Zonotrichia leucophrys).

conical, feet robust, the second and third quills longest, and the tail rather long and moderately rounded; the chin, throat, and breast are nearly uniform ashy; the head above black; median and superciliary stripe pure white; a narrow black line through and behind the eyes; back and wing coverts dark reddish brown with paler margins; quills and tail darker; wings with two white bands; whitish below; bill reddish orange tipped with brown; lower lid white. It is found from the Atlantic to the Rocky mountains and from Labrador to Texas, breeding far to the north; the notes are mellow and cheering, six or seven in number, the first loud and clear, and thence becoming fainter and more plaintive; eggs five or six, ⅞ in. long, light sea green with brownish mottlings at the larger end; the nest is on the ground or among moss, and the eggs are laid in Labrador from the 1st to the end of June. The flight is low, but swift and long protracted; the migrations are performed mostly by day; the food consists of seeds, berries, minute shell fish, and insects. The genus *spizella* (Bonap.) differs from the last in its smaller size and longer forked tail. The chipping sparrow (*S. socialis*, Bonap.), commonly called chip bird, is 5½ in. long and 8½ in. in alar extent; the rump, back of neck, and sides of head and neck are ashy; the back has black streaks with pale rufous edgings; the crown is uniform chestnut, the forehead black with a white median line, a white streak over the eyes and a black one from the bill through and behind the eyes; white below, tinged with ashy on the upper breast; tail and primaries with paler edgings, and two narrow white bands across wing coverts; bill black; in the young the crown has narrow blackish lines, and the upper breast and sides are streaked with brown. It inhabits North America from ocean to ocean, very common everywhere, except in woods, in spring, summer, and autumn, going south in winter; it is very social, is found with almost every other species of sparrow, and is so familiar as to enter yards and even piazzas for food. The nest is never made on the ground; the eggs are four or five, ¾ by ⅝ in., greenish blue, with slight brown spots at the larger end, and rather pointed at the smaller. The notes are six or seven rapidly repeated and loud "cheeps;" the flight is short, irregular, and rather low. They are the most numerous of the sparrows in New England, but arrive some weeks later than the song sparrow. The genus *melospiza* (Baird) differs from *zonotrichia* in the shorter and more graduated tail, longer hind toe, shorter and more rounded wings, longer tertiaries, unspotted under parts, and streaked crown. The song sparrow (*M. melodia*, Baird) is 6½ in. long and 8½ in. in alar extent; the general tint above is rufous brown, with dark brown streaks and grayish edgings; crown rufous, with superciliary and median stripe of dull gray; white below, breast and sides streaked with dark rufous; no distinct white on wings or tail. It is found from the eastern coast to the high central plains, and is abundant in the south, where it raises three broods, making a new nest for each. Though not so handsome as some other sparrows, its song is much sweeter, prolonged, and heard at all hours of the

day; it nests both on the ground and in bushes; the eggs are four to six, broad ovate, light greenish white with specks of dark brown; both sexes incubate. The flight is short and much undulated; it goes south in winter, and seldom approaches houses nearer than gardens and orchards; it is very active, feeding on insects, seeds, and berries.—The old world spar-

House Sparrow (Passer domesticus).

rows belong to the genus *passer* (Briss.), in which the wings are moderate, with the second and third quills rather longer than the first, and the moderate tail even or slightly forked. There are about 20 species, residing in cultivated regions, even in the midst of cities; the food consists of buds, seeds, grains, and insects; the nest is in trees or hedges, and the eggs are four or five. The house sparrow (*P. domesticus*, Linn.) is $6\frac{1}{4}$ in. long and $9\frac{1}{2}$ in. in alar extent; in the male the upper part of the head is light brownish gray, the sides of the neck grayish white, throat black, back and wings chestnut and black with a white band across the latter, and lower parts light brownish gray; in the female the head is grayish brown above and the lower parts light brownish gray. They often commit serious depredations in wheat fields; though feeding chiefly on grain, they bring up their young on larvæ, and a pair is said to destroy about 4,000 caterpillars weekly in the breeding season; they are generally distributed over northern and central Europe, and are brighter colored in the country than in the cities; they have no song, except a single note, loud and by no means agreeable. This species has been introduced into the United States, where it thrives well, and does good service in destroying canker worms and other injurious larvæ in and around the large cities and towns; they require feeding and houses during the severe winters. They were first brought to New York about 1862, and there have been several later importations; they drive nearly all other birds from places where they abound.

**SPARROW HAWK,** a small bird of prey of the falcon subfamily, and genus *tinnunculus* (Vieill.), which differs from *falco* (Linn.) in having longer tarsi, covered in front with large transverse hexagonal scales. There are about a dozen species, widely distributed over the globe; their flight is very graceful, irregular, with occasional hoverings; they eat small birds like sparrows, mice and moles, lizards, beetles, and grasshoppers; the nest is made of a few loose sticks on a rock or in a hollow tree, and the eggs are four to six. The American sparrow hawk (*T. sparverius*, Vieill.) is one of the handsomest, most active, and abundant birds in the United States, and is found over the entire continent of America. It is 11 to 12 in. long, with an alar extent of 22 in.; the crown is light red surrounded by blue, the latter color showing itself also on the wings; back light rufous, spotted with black; tail darker, with broad black band near the end, tipped with white, and lateral feathers with broad black bars on the inner webs; quills black, with white spots on inner webs; throat and upper neck on sides white, with two black bands on the latter; three spots on hind neck, and numerous ones on abdomen and sides, black; white below, tinged with yellowish on breast; the young birds have wider bands of black, and the females longitudinal black lines on the crown and stripes on the

American Sparrow Hawk (Tinnunculus sparverius).

tail. The eggs are dark cream or light buff, more or less spotted with brown, nearly spherical, $1\frac{1}{4}$ by $1\frac{1}{8}$ in.; both sexes incubate, two broods being raised in the south; the pairing time is from February to June, according to latitude.—The European sparrow hawk (*T.*

*alaudarius*, Briss.) has been described under KESTREL. The *accipiter nisus* (Pall.) of Europe is also called sparrow hawk; the male is dark bluish gray above, reddish white below with yellowish red transverse bars; the female is grayish brown above, and grayish white below barred with dark gray. The size and habits are about the same in both.

**SPARTA**, or **Lacedæmon**, in antiquity, the capital of Laconia and the chief city of the Peloponnesus. It was on the right bank of the Eurotas, between the tributaries Œnus and Tiasa, about 20 m. from the sea, in a valley of remarkable beauty and fertility, bounded W. and E. by the ranges of Taygetus and Parnon. It was about 6 m. in circumference, and consisted of distinct quarters which were originally separate villages. During its most flourishing period it was unfortified, being protected by the natural ramparts of the valley. Its quarters were Pitane in the north, the favorite place of residence, Cynosura in the southwest, Limnæ in the east along the Eurotas, and Mesoa in the southeast. Ægidæ, in the northwest, adjoining Pitane, is also mentioned by some writers, but it was probably the name of a tribe or family and not of a quarter. One of its steepest hills (the northern hill, according to Leake; the hill of the theatre, according to Curtius) was called the acropolis, on which were the temples of Athena Chalciœcus, the tutelary goddess of the city, of Athena Ergane, the Muses, Zeus Cosmetas, and Aphrodite Areia, and many statues in honor of divinities and heroes. In the agora, near the acropolis, and adorned with temples and statues, were the council house of the senate and the offices of the public magistrates, the Persian *stoa* built of spoils taken in the Persian war, and the place called Chorus where Spartan youths danced in honor of Apollo. Two principal streets, named Aphetaïs and Skias, extended nearly parallel to each other from the agora, the former to the S., the latter to the S. E. extremity of the city. Upon the largest of the Spartan heights was the theatre, a magnificent building of white marble, the two wings of which still remain, 430 ft. apart, built of massive quadrangular blocks, and forming the most important relics of the ancient city. The private houses of Sparta, and even the palace of the kings, were always simple and unadorned, but it was equalled by few other Greek cities in the magnificence of its temples and statues. The modern town of Sparta, built since the war of independence, occupies one of the hills in the S. part of the ancient site. Its streets are laid out on a large scale, and it has a population of about 8,000. The nomarch and other officials of Laconia reside here. The villages of Magula and Psychiko are near it, and 3 m. W. of it is Mistra, which was the chief place of the district in mediæval and Turkish times.—According to tradition, the Leleges were the most ancient inhabitants, and Lelex the first king, in the vale of the middle Eurotas. Lacedæmon, son of Jupiter and Taygete, married Sparta, third in descent from Lelex, and gave the name of his wife to the city which he founded, and his own name to the people and country. During the mythical era of the Achæan monarchies, Menelaus reigned at Sparta, as Agamemnon at Mycenæ and Diomedes at Argos. After the Dorian invasion and conquest of the Peloponnesus, under the Heraclidæ, Sparta fell to Eurysthenes and Procles, the twin sons of the Heraclid Aristodemus; and from that epoch date the long succession of two joint kings, and the distinction between the conquerors, who were called Spartans, and the native Achæans (*Periœci*), who became tributary. At first inferior to Argos, Sparta became the chief of the Dorian powers only after the institutions of Lycurgus had made it a nation of professional soldiers. The introduction of the Lycurgan discipline (not later, according to Grote, than 825 B. C.), the earliest determinable event in its internal history, was followed by aggressions which gradually extended its sway over the greater part of the Peloponnesus. There is no certain personal history of Lycurgus, and his very existence has been doubted by critics. (See A. Trieber, *Forschungen zur spartanischen Verfassungsgeschichte*, Berlin, 1871.) The Lycurgan legislation has been called the codification of the usages of the Doric race. It recognized three classes of persons: 1, the Spartans, of Dorian stock, resident in the city, alone eligible to public offices, all warriors, supported from the lands around the city which belonged to them, and being disfranchised when they failed to pay their quota to the public mess; 2, the Periœci or Laconians, freemen of the neighboring townships, with no political power, devoted to agriculture and industry, paying rent for their land, and forming bodies of heavy-armed soldiers in war; and 3, the helots, or serfs, bound to the soil, which they tilled for the Spartan proprietors, and sometimes employed both in domestic and military service. The equal division of land into 9,000 lots for Spartans and 30,000 lots for Periœci is doubted by Grote; and the number of Spartan citizens diminished from the era of the Persian war, when Herodotus estimated them at 8,000, to the time of Agis IV., when they had dwindled to 700, of whom 100 alone possessed most of the landed property of the state. At the head of the government were two hereditary kings, whose power was gradually restricted till their position was one of nominal honor rather than real authority. The legislative power was exercised by two assemblies, that of the elders and that of the citizens; the former was composed of the two kings and 28 members aged at least 60 years, who were judges in capital cases, and initiated and discussed all measures submitted to the popular assembly; and the latter, composed of all Spartan citizens of 30 years of age and of unblemished character, met once a month, and had the right to ap-

prove or reject measures by acclamation, but not to amend them. The ephors, corresponding to the Roman tribunes of the people, and probably of later origin than the age of Lycurgus, were the representatives of this assembly, and during the Peloponnesian war exerted despotic authority, having completely superseded the kings as directors of affairs. The most important part of the Lycurgan legislation related to the discipline and education of the citizens. The individual was held to exist exclusively for the state, to which he should devote all his time, property, and energies; and every child, therefore, was under public inspection from his birth, and was trained simply with reference to warlike exercises, since mechanical labor, husbandry, and commerce were despised and neglected. If weak or deformed, he was exposed to perish; otherwise, he was taken at seven years of age from his mother's care, and educated in the public classes, where he was subjected to the severest bodily discipline, to habits of subordination, dexterity, and a terseness of speech which became distinguished as "laconic." At the age of 30 he was allowed to engage in public affairs and to marry, but still continued under public discipline, took his meals at the public mess, slept in the public barracks, and was released from military service only in his 60th year. Both sexes were subjected to nearly the same rigorous gymnastic training, the aim being not domestic enjoyment or refinement, but the production of a hardy race of citizens. The great men that arose from this discipline were distinguished exclusively for military genius.—Under the Lycurgan constitution Sparta began its career of conquest. The first and second Messenian wars (743–723 and 685–668, according to the common chronology) doubled its population and territory. Before 600 B. C. it had conquered from the Arcadians the upper parts of the valley of the Eurotas, and after repeated contests compelled Tegea, the capital of Arcadia, to acknowledge its supremacy (about 560). The long struggle between the Spartans and Argives terminated in favor of the former by decisive victories in 547 and 524. Sparta had now acquired the hegemony of Greece, and Crœsus when threatened by the Persians had formed an alliance with it as the most powerful Greek state. It twice invaded Attica, and interfered in the affairs of the growing Athenian democracy. At the outbreak of the second Persian war, it was by unanimous consent intrusted with the chief command. The battles of Thermopylæ and Salamis in 480, and of Platæa in 479, were fought respectively under the Spartan generals Leonidas, Eurybiades, and Pausanias. According to Herodotus, the Lacedæmonians were represented at Platæa by 5,000 citizens, 5,000 Periœci, and 35,000 helots. The allies, excepting Ægina and the Peloponnesian states, were alienated by the arrogance of Pausanias, and therefore in 476 offered the supremacy to Athens. The hegemony thus passed from Sparta to Athens, and the rivalry of these states modified all the history of Greece till the Macedonian era. A destructive earthquake occasioned a revolt of the helots and the third Messenian war (464–455). The Spartans distrusted and rejected an auxiliary force sent by the Athenians under Cimon, which was the cause of hostilities (457–452), the prelude to the long Peloponnesian war (431–404). This war, in which the opposed Doric and Ionic races exhausted their energies, terminated with the conquest of Athens and with the restoration of the hegemony to Sparta. One of its allies was Cyrus the Younger, and in return it aided him in his attempt to dethrone his brother Artaxerxes. The successes of Agesilaus in Asia Minor in 396 had led him to form the project of overthrowing the Persian empire, when he was recalled by a confederacy of Corinth, Argos, Thebes, and Athens, which Persian gold and Greek jealousy had prompted against Sparta. The victories of Corinth and Coronea were counterbalanced by the naval defeat off Cnidus, and the peace of Antalcidas (387), which left it supreme in Greece, deprived it of its cities in Asia Minor. The Spartans exerted unrivalled authority, notwithstanding the alliance of Thebes and Athens against it in 379, until, in the fatal battle of Leuctra in 371, they were defeated by the Thebans under Epaminondas, and, for the first time in their history, by inferior numbers. Invasion followed, Sparta narrowly escaped capture, its army was again defeated at Mantinea in 362, and it was stripped of the dominions which it had acquired from the Messenians, Arcadians, and Argives; and from this time it ceased to be a leading state in Greece. Having incurred the enmity of Philip of Macedon by supporting the Phocians in the sacred war, its losses were confirmed and its power still further reduced by him; but it refused to join the alliance of Athens and Thebes against him before the battle of Chæronea, next to recognize his leadership in the proposed expedition against Persia, and subsequently to join the Achæan league against the Macedonian and Roman supremacy. It prompted an anti-Macedonian movement, which was defeated by the victory of Antipater at Megalopolis in 331. The kings Agis IV. (244–240) and Cleomenes III. (236–220) attempted to revive the ancient virtue by restoring the institutions of Lycurgus, abolishing the ephoralty, cancelling all debts, redistributing the lands, and enlarging the number of citizens by bringing back the exiles and bestowing the franchise on many of the Periœci and on others who were deserving of it; but the defeat of Sellasia (221) by the Achæans and the Macedonians under Antigonus Doson followed, and Sparta for the first time fell into the hands of conquerors. From intestine factions sprang the usurpations of Machanidas and Nabis (210–192), after which it was compelled with the

whole of the Peloponnesus to submit to the Achæan league, until in 146 it fell with the rest of Greece under the dominion of Rome. (See ATHENS, and GREECE.)

**SPARTACUS**, a Roman gladiator, of Thracian birth, leader of a servile insurrection in 73–71 B. C. Originally a shepherd, he became a chief of banditti, and was captured by the Romans. He was sold and trained as a gladiator, and in 73 persuaded 77 of his associates to escape with him from the school of Lentulus at Capua. They took refuge in the crater of Mt. Vesuvius, and chose Spartacus for their leader. C. Claudius Pulcher was sent against them with 3,000 men, but was defeated, and his arms became the trophy of the victors. Spartacus now proclaimed liberty to all slaves that should flee to him, and for two years he held the supremacy in Campania, Lucania, Bruttium, and other parts of Italy. At the head of 70,000 men he triumphed over two consular armies in 72, and forced his Roman captives to fight as gladiators at the funeral games which he celebrated. His army increased to 100,000 men, the consuls were again defeated, and he meditated an attack upon Rome itself. His own desire was to secure the freedom of the slaves by taking them beyond the Alps, but they, eager for plunder, refused to leave Italy. He for a time maintained his superiority in 71, but in consequence of repeated divisions among his troops, he was twice defeated by Crassus, and fled with his followers. Through the treachery of Cilician pirates, who were to carry him over to Sicily, 12,000 of his men fell into the hands of the Romans. He at length effected his escape, but his followers refusing to go to the north, he faced the Romans again, defeated them, and went to Brundusium, where, baffled in his attempt to seize the shipping, he perished in battle with Crassus near the head of the river Silarus. Pompey completed the work of extinguishing the insurrection. Of the rebels 60,000 fell in combat, and 6,000 prisoners were crucified in the Appian way. Roman writers naturally paint the character of Spartacus in the blackest colors, but critical investigations have led modern historians generally to speak in his praise.

**SPARTANBURG**, a N. W. county of South Carolina, bordering on North Carolina, and watered by affluents of Broad river; area, about 900 sq. m.; pop. in 1870, 25,784, of whom 8,408 were colored. The surface is mostly hilly; the soil is productive. It is traversed by the Spartanburg and Union and the Atlanta and Richmond Air-line railroads. The chief productions in 1870 were 73,783 bushels of wheat, 525,698 of Indian corn, 36,106 of oats, 30,247 of sweet potatoes, 2,851 bales of cotton, 15,345 lbs. of wool, and 170,951 of butter. There were 2,465 horses, 1,794 mules and asses, 5,451 milch cows, 6,740 other cattle, 11,380 sheep, and 19,701 swine; 4 manufactories of carriages and wagons, 5 of cotton, 18 flour mills, 8 tanneries, and 8 currying establishments. Capital, Spartanburg Court House.

**SPAULDING, Levi**, an American missionary, born in Jaffrey, N. H., Aug. 22, 1791, died in Ceylon, June 18, 1873. He graduated at Dartmouth college in 1815, and at Andover theological seminary in 1818, was ordained at Salem, Mass., and reached Jaffna, Ceylon, early in 1820. In addition to the usual missionary labor, much of the time he superintended the female boarding school at Oodooville, and performed a large amount of literary labor, superintending the press, preparing tracts and hymns in the Tamil language, and translating or writing books, among which are "Pilgrim's Progress," "Scripture History," a "Tamil Dictionary," "Notes on the Bible," and a revised edition of the Scriptures in Tamil. He revisited the United States in 1844.

**SPEAKER**, a term applied to the presiding officer of each house of the parliament of Great Britain, of the house of representatives of the United States congress, and generally of the lower houses of the state legislatures. The house of commons elects its own speaker, who must be approved by the crown, and who can only speak or vote in committee, except in the case of an equality of votes, when he gives the casting vote. He holds office until the dissolution of the parliament. The office existed as early as the reign of Henry III., when Peter de Montford communicated the answer of parliament to Pope Alexander IV., but the name was not used till the reign of Edward III. The speaker of the house of lords is the lord chancellor for the time being, appointed by the crown. The house of representatives of the United States elects its own speaker at the first session of each congress, who holds office until the meeting of the next congress; and in the state legislatures an analogous practice prevails.

**SPECIES**, in its most general acceptation, a kind or sort of something, which something is the *genus* to which the species belongs. Thus, a black stone is a species of the genus stone; a gray horse is a species of the genus horse; a scalene triangle is a species of the genus triangle; and, generally, it may be said that every adjective denotes a species of the genus indicated by the substantive to which it is applied. In the technology of the physical sciences the term "species" has a more restricted signification. It is used to denote a group of individuals which corresponds with an early stage of that process of abstraction by which the qualities of individual objects are arranged in the subordinated categories of classification. The individual object alone exists in nature; but, when individual objects are compared, it is found that many agree in all those characters which, for the particular purpose of the classifier, are regarded as important, while they differ only in those which are unimportant; and those which thus agree constitute a species, the definition of which is a statement of the com-

mon characters of the individuals which compose the species. Again, when the species thus established are compared, certain of them are found to agree with one another, and to differ from all the rest in some one or more peculiarities. They thus form a group, which in one sense is merely a species of higher order, while technically it is termed a "genus." And, by a continuation of the same process, genera are grouped into families, families into orders, and so on. Each of the groups thus named is in the logical sense a genus, of which the next lower groups constitute the species. The characters on which species are based necessarily depend upon the nature of the bodies classified. Thus, mineral species are founded upon purely morphological characters; that is to say, they are defined by peculiarities either of form, color, and the like, or of structure; which last term may be used to include both the physical and the chemical characteristics of a mineral. The distinction between a species and a variety is wholly arbitrary, except so far as it is commonly agreed that individuals which differ from others only as terms of a gradual series of modifications belong to the same species, and are to be considered merely as varieties of that species. It is conceivable that animals and plants should have been known to us only by their remains preserved in museums or in the fossil state. If this had been the case, biological like mineralogical species could have been defined only by morphological characters; that is to say, by the peculiarities of their outward form and inward structure; and, as a matter of fact, this is the state of our knowledge in respect of a large proportion of the existing fauna and flora of the world, and of all extinct animals and plants. A botanist or a conchologist, who sets to work to arrange a newly received collection, sorts out his plants or his shells according to their likenesses and unlikenesses of form and structure, until he has arranged them into groups of individuals which agree in certain constant characters, and differ only by insignificant features, or by such peculiarities as vary in different individuals in such a manner that an insensible gradation can be traced between those forms which have the peculiarity strongly marked and those in which it is absent. Thus far the considerations which guide the biologist in the establishment of species differ in no respect from those which influence the mineralogist. But although naturalists have no more direct knowledge of any but the morphological characters of the great majority of the species of animals and plants than they would have of so many mineral specimens, they are familiar with many animals and plants in the living state, when they exhibit phenomena to which the mineral world presents no parallel; and the study of these phenomena of active life has complicated the conception of species in biology, by adding physiological to morphological considerations. The fact that living beings originate by generation from other living beings is one of the circumstances in their history which most completely differentiate them from minerals; and ideas derived from the study of the phenomena of generation enter in various ways into the conception of biological species. For example, it is a generally assumed axiom in biology that whatever proceeds from a living being by way of generation is of the same species as that from which it proceeds, whether the morphological differences between parent and offspring be great or small. The two sexes are often extraordinarily different, and in cases of the so-called "alternation of generations" the successive zoöids may differ very widely; but, inasmuch as the differing forms in these cases proceed from one parentage, no one doubts that they belong to the same species. The breeds of domesticated animals and plants often differ morphologically as widely as admitted species do; but, apart from other considerations, historical evidence that they have the same parentage suffices to cause them to be regarded as of one species. It is not quite clear that the converse of the axiom which has just been referred to would now be admitted, and that living beings which arise from totally distinct parents must be held to be of different species, even though morphologically identical. The well-nigh exploded hypothesis of the multiplicity of centres of origin for species of wide distribution, indeed, implies the belief that groups of individuals which have proceeded from distinctly created parents may nevertheless be of the same species; while the supporters of the no less nearly extinct hypothesis of the independent creation of the faunas and floras of successive formations used to affirm that, although indistinguishable, two animals or plants from separate formations must be of distinct species, because they have been created separately. However, these subtleties have ceased to have any practical importance. In the next place, it is observed that, while individuals of the same morphological species breed freely with one another and give rise to perfectly fertile offspring, the unions of individuals of different morphological species are, as a rule, either infertile or imperfectly fertile. Thus fertility, like parentage, has become a physiological character of species; and though in the case of some domesticated animals, as pigeons, the extreme forms are more different from one another than are many morphological species, yet, apart from the historical evidence of their parentage, they are held to be members of the same species because they are all perfectly fertile one with another, and their offspring are also perfectly fertile. Thirdly, it is a matter of experience that, as a general rule, and taking the whole cycle of forms through which a living being runs into account, offspring and parent are so similar that they belong to one and the same morphological species; and it is further in evidence that many species have endured for extremely long periods

without any notable difference being discernible between ancestor and descendant. Moreover, in some cases, varieties are found to revert to the characters of the species from which they have proceeded. The conclusion has been drawn that species are physiologically fixed; that is to say, that, however long the process of generation may be continued, the individuals either retain the identical morphological peculiarities of the oldest ancestor, or, if they vary, the varieties remain fertile with one another. Assuming that species have the physiological fixity thus indicated, certain conclusions respecting the origin of species are inevitable. It is clear that no existing species can have arisen by the intercrossing of preëxisting species, or by the variation of preëxisting species; but that every species must either have existed from all eternity, or have come into existence suddenly in its present form, which is the objective fact denoted by what is termed "creation."—At the dawn of modern biology, a century ago, no scientific evidence respecting the real history of life on the globe was extant, and, for any proof that existed to the contrary, species might have been of eternal duration. But philosophical speculation combined with theological dogma not only to favor the contrary opinion, but to lead the most philosophic naturalist of his day to embody the hypothesis of creation in a definition of species. *Totidem numeramus species quot in principio formæ sunt creatæ* ("We reckon as many species as there were forms created in the beginning"), is the well known formula of Linnæus. In practice, Linnæus regarded species from a purely morphological point of view; in theory, he assumed the ancestral creation and the limited variability of species, though he was disposed to allow more freedom in this direction than most of his successors. On the other hand, he seems to have attached comparatively little weight to the assumed sterility of hybrids, and to have held a sort of modified doctrine of evolution, supposing that existing species may have been produced by the interbreeding of comparatively few primordial forms. It is mainly to the influence of Cuvier's authority that we owe the general acceptance of the views respecting the physiological characters of species which till within the last few years have been almost universally prevalent. In the introduction to the *Règne animal* (1817), Cuvier writes: "There is no proof that all the differences which now distinguish organized beings are such as may have been produced by circumstances. All that has been advanced upon this subject is hypothetical; experience seems to show, on the contrary, that in the actual state of things varieties are confined within rather narrow limits, and, so far as we can retrace antiquity, we perceive that these limits were the same as at present. We are thus obliged to admit of certain forms which since the origin of things have been perpetuated, without exceeding these limits; and all the beings appertaining to one of these forms constitute what is termed a *species*. Varieties are accidental subdivisions of species. Generation being the only means of ascertaining the limits to which varieties may extend, species should be defined, the reunion of individuals descended from one another, or from common parents, or from such as resemble them as closely as they resemble each other; but, although this definition is rigorous, it will be seen that its application to particular individuals may be very different when the necessary experiments have been made." It need hardly be said, however, that in practice Cuvier founded his species upon purely and exclusively morphological characters, just as his predecessors and successors have done. The combination of Cuvier's views on the fixity of species with the discovery of the succession of life on the globe, which was so largely the result of his labors, led his followers into curious difficulties. Developing the fundamental idea of the *Discours sur les révolutions de la surface du globe*, naturalists were necessarily led to conclude, not only that existing species are the result of creation, but that the creative act which brought them into being was only the last repetition of a series of such acts, by which the often depopulated world has been as frequently repeopled. Lamarck, Cuvier's contemporary and countryman, must be regarded as the chief founder of the reaction against the doctrines which Cuvier advocated; a reaction which, overpowered and disregarded for many years, has acquired such force since and through the publication of Darwin's "Origin of Species," that it has already almost swept opposition away. Lamarck's vast acquaintance with the details of invertebrate zoölogy rendered him familiar with the great variability of many species, and led him to see that variation is in some way related to change of conditions. The frequent occurrence of transitional forms between apparently distinct species, when large suites of specimens (especially when they are obtained from different parts of a wide geographical area) are examined, tended to bring into strong light the tenuity of the distinction between species and varieties. The facts of embryology, the occurrence of rudimentary organs, and the fundamental unity of structure which obtains in vast groups, such as the vertebrata and arthropoda, further tended to suggest the existence of a genetic connection between the members of these groups; so that Lamarck was induced to renounce the doctrine of the fixity of species, and to define a species as "a collection of individuals which resemble each other and produce their like by generation, so long as the surrounding conditions do not alter to such an extent as to cause their habits, characters, and forms to vary." According to this definition, the distinction between species and variety once more becomes conventional. A variety is, in fact, a nascent species; and

the notion of the creation of species vanishes, inasmuch as every species is the result of the modification of a predecessor. Lamarck's views of the nature of geological change were in harmony with his biological speculations, and wholesale catastrophic revolutions were as completely excluded from the one as from the other. It is impossible to read the *Discours sur les révolutions* of Cuvier and the *Principes* of Lamarck without being struck with the superiority of the former in sobriety of thought, precision of statement, and coolness of judgment. But it is no less impossible to consider the present state of biological science without being impressed by the circumstance that it is the conception of Lamarck which has triumphed, and that of Cuvier which has been vanquished. Catastrophic geology has vanished, and is everywhere replaced by the conception of slow and gradual change. With it has disappeared the once prevalent notion that the whole living population of the earth has been swept away and replaced in successive epochs. On the contrary, it is now certain that the changes which have taken place in that population have been effected by the slow and gradual substitution of species for species. Moreover, it is well established that, in some cases, the succession of forms in time is just such as that which should have occurred if the hypothesis of evolution is well founded. The rapid advance of comparative anatomy has diminished or removed the wide intervals which formerly appeared to separate the different divisions of the animal and vegetable kingdoms from one another. Even the hiatus between the vertebrata and the invertebrata is bridged over by recent discovery. The establishment of the cell theory, however much the views originally propounded by Schwann have been modified, leaves no doubt that there is a fundamental similarity in minute structure not only between all animals, but between them and plants; while the discoveries of embryologists have proved that even the most complex forms of living beings do, in the course of their development, run through a series of changes of the same order as those which are postulated by the evolution theory for life in time. Again, the facts of geographical distribution, as now known, are absolutely incompatible with the hypothesis that existing animals and plants have migrated from a common centre, and, by demonstrating the similarity of the existing fauna and flora of any locality to those which inhabited the same area in the immediately precedent epoch, have furnished a strong argument in favor of the modifiability of species. Thus, it is not too much to say that the facts of biology known at the present day are all consistent with and in favor of the view of species entertained by Lamarck, while they are unfavorable to, if not incompatible with, that advocated by Cuvier; and that, even if no suggestion had been offered, or could be offered, as to the causes which have led to the gradual evolution of species, the hypothesis that they have arisen by such a process of evolution would be the only one which would have any scientific foundation.—The great service which has been rendered to science by Mr. Darwin, in the "Origin of Species," is that, in the first place, he has marshalled the ascertained facts of biology in such a manner as to render this conclusion irresistible; and secondly, that he has proved the following proposition: Given the existence of living matter endowed with variability, the interaction of variation with the conditions of existence must tend to give rise to a differentiation of that living matter into forms having such morphological relations as are exhibited by the varieties and species which actually exist in nature. What is needed for the completion of the theory of the origin of species is, first, definite proof that selective breeding is competent to convert permanent races into physiologically distinct species; and secondly, the elucidation of the nature of variability. It is conceivable that both the tendency to vary and the directions in which that tendency takes effect are determined by the molecular constitution of a living body; in which case, the operation of changes of external conditions will be indirect, and, so to speak, permissive. It is conceivable, on the other hand, that the tendency to vary is both originated and directed by the influence of external conditions; or that both variation and the direction which variation takes are partly determined by intrinsic and partly by extrinsic conditions. In this case, surrounding circumstances must be regarded as, to a greater or less extent, the true causes of variation.

**SPECIFIC GRAVITY.** See Gravity, Specific.

**SPECTACLES,** contrivances worn to assist sight or to protect the eyes from injury. 1. *Spectacles to assist Sight.* These may operate in two general ways: first, by correction of some optical defects to which the eyes are liable; and secondly, by compensation for functional insufficiency on the part of certain muscles concerned in the exercise of sight. The eye is a camera, where a system of lenses throws an image upon a screen, represented by the retina. For perfect sharpness of this image, the curves of the lenses must be symmetrical, and the refractive power of the system exactly adjusted to the distance of the retina. In the normal or "emmetropic" eye these conditions obtain, the adjustment being such that when the eye is at rest the rays from distant objects come to an exact focus upon the retina. But every possible deviation from these conditions is found. First, there may be a disproportion between the refractive power of the eye and the distance of the retina. If the refractive power is proportionately too great, the rays from distant objects will come to a focus a certain distance in front of the retina. This constitutes the condition called

*myopia* or near-sightedness, and may arise either from excessive convexity of the lens system of the eye, or from an undue depth of the organ from before backward. The latter origin is by far the more common, and is generally the result of a disease of the tunics of the eye at their back part, whereby being weakened, they bulge out backward. However produced, the correction of myopia is the same. The difficulty being that the refractive power of the eye is too great for the distance of the retina, the obvious remedy is to weaken the former, and this is done by wearing a concave glass. (See Optics.) But there are many physiological reasons why full correction of the defect is often improper or useless, which cannot be discussed here. In any but very moderate degrees of myopia glasses should be worn only under competent advice; and in any case great injury may be produced by the use of too strong glasses. The opposite condition to myopia is also very common, that is, where the refractive power of the eye lenses is disproportionately weak, so that the rays from distant objects come to a focus behind the retina, in which case vision of objects both far and near is indistinct. This constitutes the condition known as *hypermetropia*, and, as in myopia, the deviation from the normal condition may be either in the refractive power or in the depth of the eye. Thus a tolerably common congenital malformation is an undue shallowness of the eyeball. Such an eye is necessarily hypermetropic. A normal eye may also become hypermetropic in old age, and in all cases where the crystalline lens of the eye is wanting, as after removal for cataract (see Cataract, and Eye), a high degree of hypermetropia necessarily results. The fault being that the refractive power of the eye is disproportionately weak to suit the distance off of the retina, the necessary additional power can be supplied by a convex glass worn before the eye. But in the case of the more common congenital hypermetropia from deficient depth of the eyeball, so many other considerations than the mere optical one affect the matter of correcting the defect by glasses, that perfect neutralization is often unadvisable or unnecessary. For the eye has itself the power of increasing the refraction of its lens within a certain range, to provide for the focalizing upon near objects. (See Vision, section on accommodation of the eye.) Hence the organ can itself compensate for a certain amount of hypermetropia, and may thus be able to do without glasses, or with weaker ones than those required to neutralize the defect completely. The third optical error remediable by glasses is a certain want of symmetry in the curve of the cornea, where there are two opposite meridians of unequal curvature. This condition is called astigmatism, and is generally a congenital malformation. The consequence of it is that the retinal image, whether of far or near objects, is never sharp. For the correction of this defect a glass is worn having a cylindrical curve equal to the difference in curvature between the two dissimilar meridians, the axis of the cylindrical surface being carefully adjusted so as to be at right angles to the direction of the meridian to be corrected. The nature of the curve, *i. e.*, whether convex or concave, will depend on whether the refractive power of the meridian to be corrected requires to be strengthened or lessened. As it is obvious that this irregularity of corneal curvature may coexist with a general myopia or hypermetropia, compound glasses are often required, having on one face a cylindrical curve to neutralize the astigmatism, and on the other the proper spherical curve required for the other defect.—The second general way in which glasses operate to assist sight is, as already said, by compensating for failure of certain muscles concerned in the use of the eyes to fulfil their function. The most common of these troubles is want of power to focalize the eye upon near objects. This faculty resides in a little muscle within the eye, by the action of which the convexity, and thus the refractive power, of the crystalline lens is temporarily increased. But the substance of the crystalline lens steadily grows harder, and thus less and less compressible, so that the same amount of muscular action comes to produce less and less effect. The consequence is that during adult life the focalizing power upon near objects steadily diminishes, and hence the nearest point of distinct vision gets further and further from the eye, until at about the age of 47 it has receded beyond the distance for convenient use of the hands. Reading, writing, sewing, or any manual work requiring sharp vision of small objects at the customary distance, then become impossible without artificial compensation for the failure of focalizing power. This condition, which is natural to all eyes, is called *presbyopia* or old-sightedness, and the compensation is very simple. The difficulty being an inability on the part of the eye itself to increase temporarily its refractive power, the needed addition is artificially supplied by a convex glass, which is worn of course only when near objects are to be viewed. As the focalizing power keeps on diminishing until in old age it is wholly lost, the strength of the glasses must be steadily increased. As soon as presbyopia begins to show itself, the proper weak glass should be promptly assumed, as only injury to the eyes, or at least useless inconvenience, can result from a fruitless struggle to do without this aid. In all cases the weakest glass with which ordinary type can be clearly and comfortably seen at the usual distance is the proper one to wear. With normal eyes, individuals of the same age take very nearly the same strength of glass; but, for obvious reasons, in myopes the glass will be weaker in proportion to the degree of the optical defect, while in hypermetropes it will be correspondingly stronger. This same inability to focalize upon near objects may also

occur at any age from inherent weakness or paralysis through disease of the muscle concerned, and in such case, as in true presbyopia, a convex glass will be needed for near work. It was probably to compensate for presbyopia by convex glasses that spectacles were first invented. Roger Bacon first pointed out the benefit to old men and "to those that have weak eyes" of viewing letters through a plano-convex lens. Alessandro di Spina, a monk of Pisa who died in 1313, is generally accredited with having made public the use of spectacles, which were apparently invented some time between 1280 and 1311.—Another form of muscular insufficiency that can be compensated by optical means is where some of the muscles moving the eyeball in its socket are unduly weak. In such case the holding of the two eyes fixed upon the same point is attended by a feeling of straining or actual pain, and upon prolonged effort the overtaxed muscle may suddenly relax, producing immediately a temporary confusion of sight. Here, if the insufficiency be but slight, the wearing of a weak plain prism, properly adjusted, compensates for the defect; for even while the eyes are allowed to keep the faulty relative position enforced by the muscular weakness, the rays coming from the object desired to be seen can, by means of refraction through a prism, be made to enter both eyes in the same direction, the only condition necessary for binocular single vision. But this mode of compensation will only do in slight degrees of muscular insufficiency; in the higher grades a radical cure by a surgical operation is necessary. The strength and position of the prisms will of course be determined by the degree and seat of the muscular weakness; and if, as is often the case, the affection in question is associated with myopia, hypermetropia, or astigmatism, a compound glass may be needed, where one or both faces of the prism bear the necessary curves to correct the optical defect.—The designation of the strength of glasses is nowadays by the fraction expressing the refractive power of the lens in terms of inches, the words "positive" and "negative" or the signs + and — indicating respectively a convex or a concave glass; thus "$-\frac{1}{10}$" means a concave lens of 10 in. focal length. Glasses are commonly ground with an equal curve on both faces, but a meniscus for a positive and a concavo-convex for a negative lens may also be used (see OPTICS), in which case the spectacles are called periscopic. The advantage of this form is, that there is less distortion of objects seen through the edges of the lens; but the disadvantages are, that the glasses are heavier than those of the ordinary style, and give more reflection from their back surface. The material for spectacles is commonly glass, but a variety of rock crystal called "Brazilian pebble" is also used. The latter substance is less apt to scratch or to become dimmed by deposit of moisture on being brought from a cold to a warm temperature, but it is heavier and far more expensive than glass. The claims for its "preserving the sight" are fanciful, and many of the spectacles sold as pebbles are not such at all. It is always important that the lenses should be of first class, the substance without flaw, and the grinding accurate. A convenient test is to hold the glass some distance from the eye, and then, moving it from side to side and to and fro, note if there be any apparent flickering or distortion of objects seen through it. If there be, the glass is worthless. In style of frames, as is well known, there is great variety. In general the word "spectacles" is now used to designate a frame held in place by bows reaching behind the ears, and "eye glasses" one held in the hand or made to clasp the nose. The spectacle frame is the best where the glass has to be continuously worn, as in myopia, as the lenses can be more accurately centred and made to set perpendicular to the line of sight. For temporary use, as for reading glasses in presbyopia, good eye glasses, selected so as to be well centred to suit the distance of the eyes apart, are convenient and unobjectionable. The material for the frames is various; silver was formerly in general use, but has been superseded by steel and gold. Tortoise shell is light, but easily broken; it is only used in eye-glass frames. The frame, whether spectacle or eye glass, should be selected to suit the individual conformation of face and the purpose for which the glass is wanted, so that the line of sight shall be through the centre of the glass and perpendicular to its surface. Hence glasses for distant vision, as in myopia, should be set high and vertical, while for near work only, as in presbyopia, they should be lower and inclined. A style of spectacles was invented by Franklin for special cases where a different glass is needed for far and near vision respectively, in which the glass is bisected horizontally, the two segments being of the different curvatures required, the upper for the far and the lower for the near. 2. *Spectacles for Protection.* To shield sensitive eyes from excess of light, colored glasses, either with plane surfaces or of a watch-glass form, are used. The latter give most protection, as they cut off the side light more perfectly. Still better are goggles with wings at the sides. Shades of blue and "London smoke" neutral tint are the best colors. For protection against the glare of snow or white sand, an opaque disk pierced with a narrow horizontal slit is very efficient. A spectacle frame set with wire gauze or plain glass is sometimes worn by workmen as a protection against bits of flying stone or steel.

**SPECTRUM** (Lat., an image), the name given to the image or colored band formed by the decomposition of a beam of light into its elementary colors. Thus, when a beam of sunlight enters a dark room through a narrow slit, passes through a triangular glass prism, and then falls upon a screen, we may observe

that the beam of light has been spread out by the prism into a wedge-shaped beam of various colors, which falling on the screen forms a *spectrum.* This spectrum of the sun's light may be divided into seven colors, red, orange, yellow, green, blue, indigo, and violet, named in the order of their increasing angular deflection from the direction of the beam of light before it encountered the prism. If the light from the flame of a lamp burning alcohol which contains common salt should enter the slit in place of the sun's light, the spectrum formed on the screen will be found on minute examination to consist only of two closely approximate yellow bands, the remainder of the spectrum which had been obtained with the sun's light being entirely absent. With the light from a flame tinged with the vapor of lithium we obtain a spectrum formed only of two bands, one in the red, the other in the orange. It has thus been found that spectra differ widely, according to the nature of the incandescent substances from which they emanate. Some, as in the case of incandescent solids, like platinum, are continuous and formed of all of the seven colors; others, as in the cases of the spectra of sodium, lithium, and potassium, are formed of colored bands separated from each other by spaces devoid of all light; while again other spectra, like those of the sun and of the fixed stars, are continuous, like those of incandescent solids, but crossed transversely by a multitude of very narrow spaces devoid of light, or nearly so. (See SPECTRUM ANALYSIS.) In the present article we shall consider the spectrum of the sun, and will give in order an account of the manner of its production, of the methods of measuring the lengths of the waves of the various rays composing it, and of the actions of light, heat, chemical decomposition, and fluorescence produced by the different spectral rays when they impinge upon bodies peculiarly constituted to develop and make manifest the above named actions.—Spectra are usually obtained either by the dispersive action of a prism, or by the diffraction of a "grating" formed by cutting with a diamond point on glass or on speculum metal several thousand equidistant and parallel straight lines in the space of an inch. The prismatic spectrum is formed with purity when the sun's light enters a fine slit formed between parallel edges about $\frac{1}{50}$ of an inch apart, and, after progressing into a dark room for 15 or 20 ft., passes through a prism of clear homogeneous glass and then traverses an achromatic lens of about 6 ft. focus. This lens is placed so far from a screen that it forms on it the image of the slit through which the sunlight enters the room, when the prism is replaced by a plane mirror which reflects the rays on to the screen. The prism in the above experiment must be placed at "the angle of minimum deviation;" that is, it must be so adjusted that the incident beam receives the minimum deviation from the refractive action of the prism. Fraunhofer substituted a telescope for the lens and screen, and viewed the spectrum formed at the focus of its object glass, as shown in fig. 1. This instrument is called a spectroscope. A spectrum, formed as just described, is crossed transversely by dark lines of various breadths and degrees of blackness. These lines are unevenly distributed throughout the length of the spectrum; but the same line always occupies the same position when referred to the tint in which it exists. Fig. 2 gives the spectral lines as mapped by Fraunhofer in vol. iv. of the "Memoirs" of the academy of Munich for 1814–'15. To distinguish these lines Fraunhofer designated them by the letters of the alphabet, in proceeding from the red to the violet end of the spectrum. Thus A exists in the extreme red, while H is in the violet near the boundary of the visible spectrum. Fraunhofer mapped in the spectrum 576 lines, and ever since the publication of his drawing these

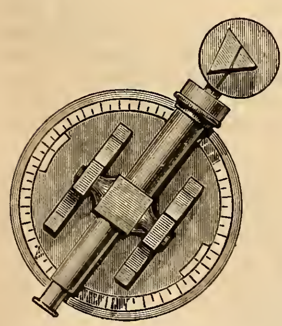


FIG. 1.—Fraunhofer's Spectroscope.

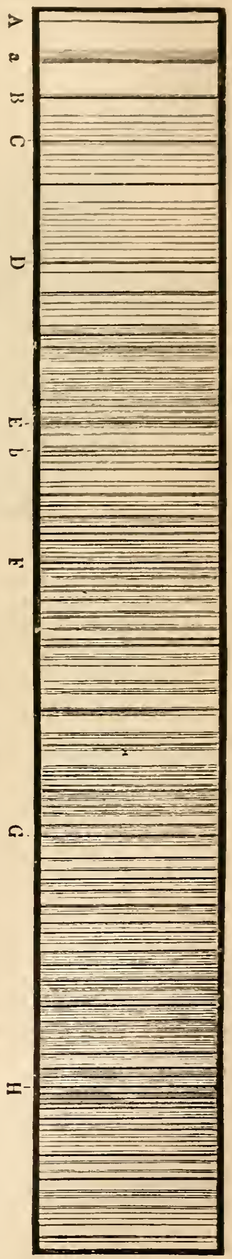

FIG. 2.—Fraunhofer's Solar Spectrum.

lines, and also the invisible lines subsequently discovered beyond the violet and red ends of the spectrum, have been called "the Fraunhofer lines." Subsequent observers modified Fraunhofer's instrument by substituting for the distant slit a collimating telescope (A, fig. 3); this consists of an achromatic lens with the slit at its principal focus. Kirchhoff with the spectroscope shown in fig. 3 has made an exquisite map of the spectrum, containing more than 3,000 lines.—The relative positions of the lines in the spectra obtained from prisms formed of different refracting materials, or even from the same material at different temperatures, differ so much that maps made by different observers are not comparable; hence recourse has been had to spectra formed by transmitting light through gratings. From measurements on these spectra, known as diffraction or interference spectra, can be deduced the lengths of the waves of light corresponding to any tint in the spectrum. The wave lengths are really given corresponding to the fixed lines in the spectrum; and as these lines hold fixed positions in reference to the colors in which they exist, we have unchangeable wave lengths to which to refer any color that may be used in such practical purposes as the determination of indices of refraction or in observations in spectrum analysis. If we look at a distant slit with a telescope before which we have placed a grating, we see a white central image of the slit, just as if the grating were not in front of the telescope; but we observe besides this central white line a series of spectra to its right and to its left. These spectra have their violet ends placed toward the central image of the slit, and they are named in the order of their removal from the slit; as spectrum of the first order on the right or left, spectra of the second, third, fourth, &c., order on the right or left. These spectra are often of great purity, so that hundreds of Fraunhofer lines can be seen with remarkable clearness. If the telescope, T E, be mounted on a divided circle, D, and the grating, G, placed in front of a collimating telescope, C, furnished with the slit at S, as in fig. 4, we can measure in the different spectra the angular distances of these lines from the centre of the image of the slit, and the angular distances from the centre of the image of the slit to the same line in spectra of different orders will be nearly as the number of the orders. Thus, if we call $a$ this angle in the spectrum of the first order, it will be $2a$, $3a$, $4a$, &c., in the spectra of the succeeding orders. It necessarily follows from this fact that the length of the spectrum in any order

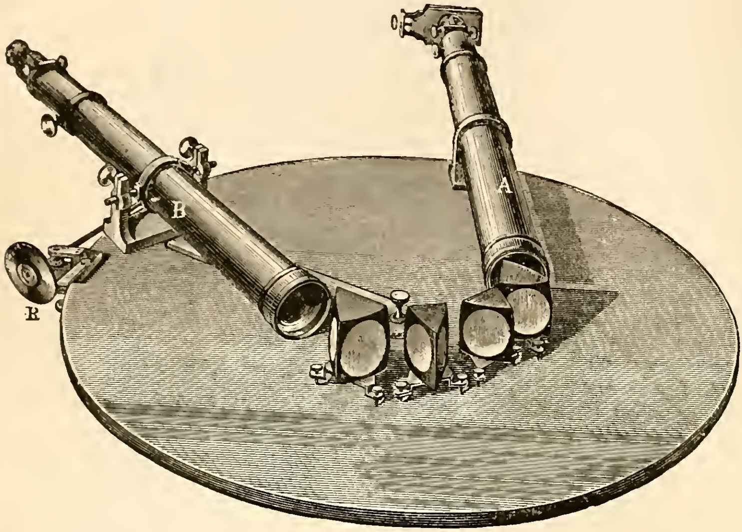

FIG. 3.—Kirchhoff's Spectroscope, by Steinheil.

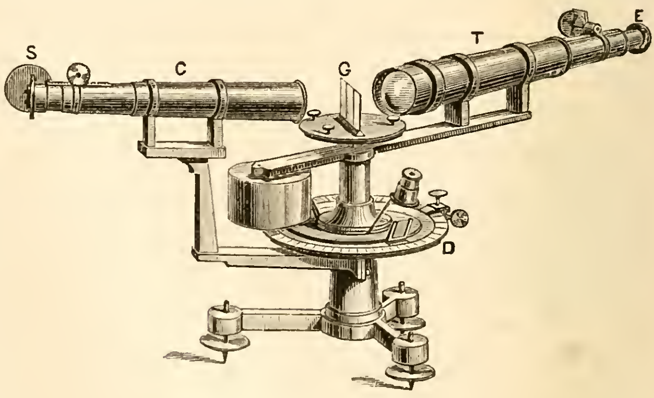

FIG. 4.—Spectrometer.

will be as the number of the order; thus, the spectrum of the third order will be three times as long as that of the first order. It has also been found that the length of the spectrum of any order will be inversely as the distance separating the lines of the grating producing the spectra; thus, the spectrum of the second order produced by a grating of 5,000 lines in an inch will be half as long as that of the second order given by a grating having 10,000 lines in an inch. Let parallel rays of light from a distant point or from the slit of a collimating telescope fall perpendicularly on the plane of the grating G G, fig. 5. The plane of the wave front of the light will be parallel to the plane of the grating, and the vibrations of the ether at each point in the openings of the grating will have the same phase. But whenever light falls upon such constructed apertures as those of the grating, the points in these apertures, situated in the plane of the grating, become centres of origin of vibrations, and the rays which have passed through the apertures diverge in planes at right angles to the lines of the grating. The consideration of the mutual action of these rays will lead at once to remarkable results. All those rays which have traversed the grating in the same direction as that in which they struck it will have the same phase of vibration, and therefore when brought together in the focus of a lens will form there a white image of the distant point or of the slit of the collimating telescope. But it is not so with the parallel rays, which diverge laterally, say in the direction *a e*, *b f*, *c g*, *d h*, &c. If these rays be brought to a focus by means of a lens L, we shall observe at F not a white image of the slit, but a colored one; and it is found that this color will depend on the inclination of the diffracted rays to R N, the perpendicular to the plane of the grating. Suppose that the diffracted rays *a e*, *b f*, *c g*, &c., are so inclined to the plane of the grating that a perpendicular, *b*1, let fall from the centre of one opening in the grating to the parallel ray *a e* emanating from the centre of the contiguous opening, cuts off on the ray *a e* a distance *a*1, equal to the length of a wave of violet light of a definite tint. Also imagine other perpendiculars *c*2, *d*3, &c., let fall in like manner upon the ray *a e*. Then if all of these rays *a e*, *b f*, *c g*, *d h*, &c., be brought to a focus at F, the vibrations of the ether at this point will all have the same phase, and hence will give at F a line which will be formed of violet light; and the intensity of this light will be equal to the sum of the intensities of all the rays *a e*, *b f*, *c g*, &c. The same reasoning will hold good for any other set of rays parallel to those just described, and all symmetrically placed in the openings. Hence all rays emanating from the openings and parallel to the rays *a e*, *b f*, *c g*, &c., and having wave lengths equal to *a*1, will conspire in their vibratory actions when brought to a focus at F. But it is not so with other rays, which, although parallel to the rays *a e*, *b f*, &c., have not the same length of waves as *a*1; for they will not conspire when brought together at F, but will interfere, or in other words will be exactly opposed to each other in vibratory action, and hence will disappear as light when brought to the focus at F. For example, suppose we consider a series of rays of red light which proceed parallel to *a e*, *b f*, &c., and come to focus at F. These rays are formed of waves which are about twice as long as those of violet light, or in other words as *a*1; hence red rays which have emanated from symmetrically placed points in two contiguous openings of the grating and proceed in direction parallel to *a e*, will, on coming to the focus F, all differ by half of an undulation, and hence red light cannot exist at F with an inclination of diffracted ray equal to N *c* F, but can only exist at a point at such an angular distance from R N that the perpendiculars let fall from *a*, *b*, *c*, and *d* on to *a e* cut off on this latter line distances respectively equal to double the lengths *a*1, *a*2, *a*3, *a*4. Again, suppose that the wave lengths of two rays, emanating from symmetrically placed points in two contiguous openings and proceeding parallel to *a e*, differ by only $\frac{1}{1000}$ of the wave length of one of these rays, then these rays will also interfere when brought to focus at F; because the phases of the rays emanating from points symmetrically placed in the 1st and 2d openings of the grating will differ by $\frac{1}{1000}$ of an undulation; those from the 1st and 501st openings will differ by $\frac{500}{1000}$ or half a wave length, and therefore will interfere. The same interference will take place between the rays from the 2d opening and those from the 502d, and those from the 4th and the 504th openings, and so on. Hence rays of light having any other wave length than *a*1 will almost completely disappear as light by their interference, and the light collected at F will be that which is produced by ethereal vibrations of wave lengths equal to *a*1. The same reasoning holds good for any bundle of parallel rays having diffracted angles different from N *c* F, and hence we have a pure spectrum formed at the focus F. It thus appears that there is a connection between the angle N *c* F of the diffracted rays, the length *a*1, and the color observed at F. The color at F varies with the angle N *c* F, or, what is the same, with the length *a*1. For the extreme red rays the angle N *c* F is at its maximum, and *a*1 is

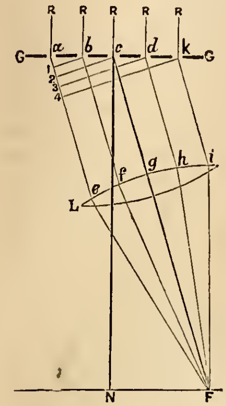

Fig. 5.

equal in length to about ·00077 mm.; for the extreme violet rays the angle N *c* F is at its minimum, and *a*1 is equal to about ·00039 mm.; therefore the violet ends of the spectra will always be toward the image of the slit. The determination of a wave length consists in the measurement of the length *a*1. To measure this length, we first determine the distance between the centres of two contiguous openings in the grating, and then the angle N *c* F corresponding to any given tint or fixed line in the spectrum; and as the angle *a b*1 is equal to the angle N *c* F, *a*1 is equal to *a b* multiplied by the sine of N *c* F. Let *s* stand for *a b*, *d* for the angle N *c* F, and *l* for *a*1, or the wave length; then $l = s \times \sin.\ d$. If the ray *a e*, and symmetrically placed rays, be inclined to the plane of the grating so that the perpendicular *b*1 cuts off on *a e* a distance *a*1 equal to two wave lengths, we shall have the same actions over again, only the spectra produced by them will be more deflected to the side of the image of the slit; and thus are produced the spectra of the 2d, 3d, 4th, &c., orders. The length of any one of these spectra will necessarily be nearly as the number of the order of the spectrum. The wave length of the same tint, or of the same fixed line, can be determined from angular measures made on this tint or line, in the spectra of all orders. From such measures we obtain multiples of the wave length, and the formula for measures on the *n*th order of spectrum becomes $l = \frac{s \times \sin. d}{n}$. In the actual measures which have been made, to form what is called a map of "the normal solar spectrum," the plane of the grating is placed in the axis of a divided circle, and is generally adjusted so that this plane is at right angles to the line of collimation of the collimating telescope carrying the slit. The observing telescope is placed on the other side of the grating, and has attached to it verniers, or reading microscopes, which it carries over the divided circle as it rotates around its axis, as is shown in fig. 4. Measures of the wave lengths of the rays forming the solar spectrum have been made by Fraunhofer (*Denkschriften der münchener Akademie*, vol. viii.; Gilbert's *Annalen*, vol. lxxiv.), Ditscheiner (*Berichte der wiener Akademie*, vols. l. and lii.), Van der Willigen (*Mémoires d'optique physique*, Haarlem, 1868), Mascart (*Comptes rendus*, lviii., p. 111; *Annales scientifiques de l'école normale supérieure*, vol. iv.), Angström (*Recherches sur le spectre solaire*, Berlin, 1869), Eisenlohr (Poggendorff's *Annalen*, vol. xcviii.), and Stefan (*Berichte der wiener Akademie*, liii.). Mascart made an important modification in the process, as above described. In his measures he placed the plane of the grating at such angles to the axis of the collimator that the observed line was seen with its minimum angle of deviation, and thereby obtained greater simplicity of adjustment with superior accuracy in his measures. In his method the formula becomes $l = \frac{2s}{n} \times \sin. \frac{d}{2}$. He came to the conclusion that the upper or more refrangible of the two D lines of Fraunhofer has a wave length of ·0005888 of a millimetre. This result agrees with the determination made by Fraunhofer, and physicists now generally adopt this determination as exact. If the wave length of any one ray is known to the last degree of precision, the position of this ray may afterward serve as a point of departure in the determination of other rays merely by observing their angular departure from this standard ray; and if we knew with certainty the wave length of a definite ray, we might adopt this dimension as a standard of length; for from observations on this ray's angular position in the spectrum, we could determine the distance separating the centres of two contiguous openings in the grating, and hence determine the length occupied by any known number of lines in a uniformly cut grating. The following table gives the wave lengths, in ten millionths of a metre, of the principal Fraunhofer lines, as determined by the observers named:

| FRAUNHOFER LINES. | Fraunhofer. | V. d. Willigen. | Ditscheiner. | Angström. | Stefan. | Mascart. |
|---|---|---|---|---|---|---|
| A | ........ | ·0007609 | ........ | ·0007604 | ........ | ........ |

—The considerable differences observed in the determinations of the wave length of the same ray by different observers are not alone owing to the variations always existing in honest measures of precision, but chiefly to the difficulty of obtaining regularly ruled gratings, and to the resulting uncertainty in the knowledge of the distance separating the centres of two contiguous openings in the grating. All physicists have until recently obtained their gratings from Nobert. Lewis M. Rutherfurd of New York has for several years past given

much labor to the production of perfect gratings, and an engine (fig. 6) which he has recently made produces gratings more uniformly ruled than any known to us. On a hollow cast-iron block are cut, at right angles to each other, two V-shaped guides. On one of these guides slides the iron plate D, moved by means of a screw acting in a nut attached to its under surface. On this plate is fastened the plane of glass or speculum metal which is to be ruled. On the other guide slides the plate L J, having a reciprocating motion given to it by a lever, the action of which will be described further on. To this plate is attached the tool holder carrying the diamond-pointed cutter. The motive power of the machine is a small turbine from which passes a cord around the driving wheel. On this driving wheel is a pin to which

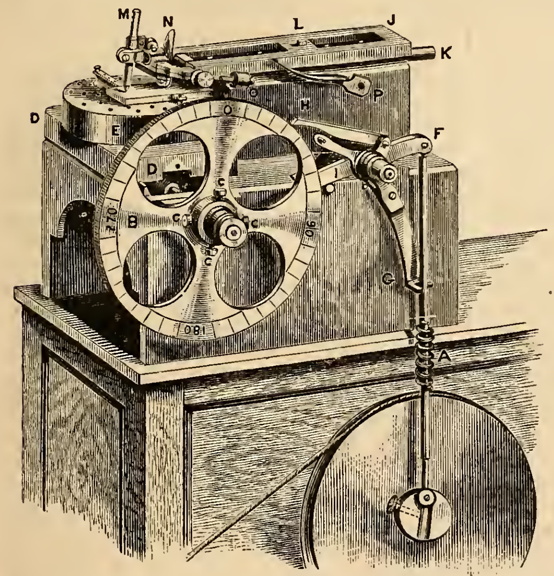

Fig. 6.—Rutherford's Ruling Engine.

is jointed the connecting rod A F. This connecting rod is hollow, and in it moves a rod which is constantly pressed toward the pin on the driving wheel by the spring shown at A. When the rod A F moves upward, the arm F I oscillates on its rocking shaft (the end of which is seen in the figure, projecting horizontally), until the end I of this arm comes against the fixed pin placed under it, and in contact with which it is shown in the drawing. Just before this upward movement of the rod A F begins, the pawl H falls into a notch on the wheel B, which is attached to the screw of the engine, and during the upward motion of the rod A F the pawl H presses against the notched wheel and rotates it a definite fraction of an entire revolution. The pawl H having completed its "throw," the crank pin on the driving wheel passes its upper centre, and then the slotted lever G lifts the pawl out of the teeth of the wheel B, so that no jarrings or tremors are given to the machine while the pawl is retreating to take a fresh hold on the feed wheel B. A pin attached to the connecting rod passes through a slot in the tube A F, and serves to hold the two together when the rod is making its downward motion. The amount of rotation to be given to the feed wheel B is regulated by rotating to the right or to the left the collar on the rock shaft, to which the pawl H is jointed. Directing attention to the plate L J, to which is attached the cradle N carrying the diamond-pointed rod M, we observe at K the right-hand end of a rod the extremities of which pass through holes in the iron frame of the engine. This rod is moved parallel to the V guide of the plate L J by means of an oscillating lever which works in a vertical slot attached to the rod K, and is fixed on the same rock shaft which carries the lever F I. Projecting upward from the rod K is a short rod whose end is shown at L. This rod moves in a short slot cut in the direction of the length of the plate L J, as shown in the figure. The action of the cutting point of the tool M can now be explained. While the pawl H is rotating the feed wheel B, the rod L presses against the left-hand end of its slot and moves the slide J from right to left. The plate J cannot move, as above indicated, until the rod L touches the left-hand end of its slot; and when it reaches this position the left-hand end of the rod K has moved to the left sufficiently to press against the lower point of the cradle N, and hold the diamond-pointed tool M elevated above the plate of glass or speculum metal during the entire left-hand motion of the plate J. When the end F of the lever F I descends, the rod K moves from left to right, and the projecting pin has to move up to the right-hand end of its slot before it can push the plate J to the right. During this motion of L in its slot, the left end of the rod K has allowed the diamond point on M to rest on the glass plate, so that before the plate J begins its right-hand motion the diamond point is at rest on the plate to be ruled. The plate J now moves to the right, and the diamond point cuts a line. But the diamond point is lifted, before the right-hand motion of the plate J ceases, by the side arm O of the cradle N coming against the inclined surface of the side piece P. The diamond is thus raised, and is held in this position by the depression of O against P until the left-hand end of K has moved up to the cradle and holds the tool elevated during the motion of the plate J to the left. After this motion has ceased, the diamond is lowered to the glass plate, and another cut

is made; and so on, the machine working automatically until the plate is ruled. The pitch of the screw is $\frac{1}{48}$ of an inch; hence, by knowing the fraction of the revolution of the screw made between two contiguous cuts, we know the distance, in fraction of $\frac{1}{48}$ of an inch, separating the centres of two contiguous lines on the grating. The diameter of the feed wheel B is 6 in., and from this dimension the reader may estimate the size of the other parts of the engine. The excellence of the work done by this engine depends on certain peculiarities of construction: 1. The errors in the throw of the screw, caused by its eccentricity, or want of coincidence of the axis of figure of the screw and its axis of motion, are corrected by giving to the feed wheel B an eccentricity opposed to that existing in the screw. The screws at C, C, C, C serve to alter the position of the centre of the feed wheel B, and thus to obtain the required eccentricity. This balance of opposing eccentricities is obtained by a delicate and precise method devised by Mr. Rutherfurd. A grating ruled by the engine on speculum metal or silvered glass is examined at such an angle of reflection that the light reflected from the plate appears of one color; for example, red. If we could cause the lines on this grating gradually to approach each other and narrow the spaces separating them, we should observe the red tint becoming gradually lighter in hue, and then gradually changing into orange, yellow, green, &c. Hence uniformity of tint is an indication of uniformity of ruling; therefore, if we tilt a grating placed in front of a flame and examine it by means of a lens and find it of a uniform color, we are sure that the screw is doing accurate work; but if the screw have a periodic error like eccentricity, then we shall observe a columnar appearance on the plate, owing to periodic variations in depth of color. By a careful comparison of the positions of these colors with the known positions of the screw when the corresponding portions of the grating were cut, we ascertain the direction in which to move the centre of the feed wheel B in order to correct the eccentricity of the screw. 2. The nut in which the screw of this engine works is 3 in. long, the threaded portion of the screw being 3½ in. long. This long nut tends to preserve the accuracy of the engine's work. 3. The original method devised by Mr. Rutherfurd to obtain rectilinear V guides is a new and important feature of this engine. A collimating telescope with a vertical slit, or cross threads, at the focus of its object glass, is placed in a firm position in a line with the guide to be tested. On the slide which moves on the V guide is fastened a telescope with cross threads at the focus. The slit of the collimating telescope is viewed in the other telescope as the slide carrying the latter is moved to and from the collimator. If the slit is constantly bisected during this motion, the guide is accurate; but if the image of the slit moves when referred to the cross threads, then the guide has to be corrected until by trial the image of the slit remains stationary during the telescope's motion. 4. The pawl H during its retraction does not fall over the teeth of the feed wheel, and by jarring the machine cause the diamond to cut an irregular or waving line. 5. The method of lifting the diamond point while it is obtaining its position for a new cut is the simplest we know of. 6. The screw of this engine, on which the results mainly depend, is constructed as follows: A screw is first cut in a lathe with a single pointed tool, then scored; it is then hardened, and thus a tap is obtained. This tap is now centred by its threads, and cylinders are ground on its ends so that they are concentric with the threads of the screw. Blocks of metal are now firmly screwed on to the bed plate of a planer, and Vs are cut in these blocks to support the cylindrical ends of the screw tap. A stock holding blank dies is placed in the tool holder of the planer, and these dies are screwed against the screw tap. The stock is then firmly screwed to the tool holder. The threads of the dies are now cut by rotating the screw tap two or three times through the dies; then, relieving the die stock in the tool holder, the dies are again tightened on the screw tap; the stock is now screwed tightly on the tool holder, and the screw tap is again traversed through the dies. This operation is repeated until the dies are finished, when they are hardened. A screw which is to serve for the ruling engine is now cut on the lathe with the same single-pointed tool which cut the thread of the master tap. This screw is nearly finished on the lathe. It is then placed in the same Vs which previously held the master tap, and the dies, just described, are placed in the tool holder of the planer, and with them the thread of the screw is finished. The screw is now rotated on its threads in a long cast-iron V, and shoulders are turned down on the ends of the shaft of the screw. The nut for this screw is cut with a single-pointed tool. The screw is now run into its nut, and they are ground together with finely powdered pumice stone. The screw of this engine has only one collar, on which it turns near the feed wheel B. The other support of the screw is the long nut. Without this arrangement Mr. Rutherfurd found it impossible to cut regular gratings.—*Actions of the Spectral Rays.* A large mass of evidence shows that all of the known emanations from the sun consist of rapid vibrations caused by that luminary in a highly elastic medium, known as ether. We must suppose that this ether fills all known space, for we can only be cognizant of celestial bodies from their vibratory actions on the ether through which they constantly move. The nature of the manifestations of these ethereal vibrations will depend on the nature of the bodies on which they

fall. Thus, what in its essential nature is a mere vibratory motion, we may interpret as light if these vibrations fall on the retina, or as heat if they fall on our skin, or as chemical action if they fall upon a photographer's plate. This preliminary conception established, we can readily interpret the various actions of the spectrum on different bodies, if we also take into consideration the manner in which the spectrum is formed, that is, whether by the diffractive action of a grating, or by the dispersive action of a prism. We should also take into account the nature of the body forming the grating or the prism. The upper portion of fig. 7 shows a prismatic spectrum crossed by the principal Fraunhofer lines, from A to the line O. A photometric examination of this spectrum shows that the distribution of light in it is represented by the curve B, whose heights above points on the base line are in the ratio of the intensities of the light at corresponding points in the spectrum. The maximum of light is found to exist in the yellow at a point distant from the upper D line one third of the distance of this line from the line E. A thermometric examination of this spectrum will give a distribution of heat throughout its length represented by the curve A, and the maximum of heat is shown at a point beyond the extreme red, at a distance equal to that of the line A from the line C. The curve C gives the distribution of chemical action in this spectrum, as found when it falls upon a surface of bromide of silver. The maximum of action is about midway between G and H. It is important to remark that the curves here given only apply to a spectrum which has been formed by this particular kind of glass and has been received on the surfaces indicated. Thus a prism of different glass would change the place of the maximum heat, and the substitution of another chemical surface on which the spectrum falls will cause a shifting of the place of maximum chemical action and a contraction or expansion of the area chemically affected. —*Heat Actions of the Spectrum.* Sir William Herschel in 1800 first discovered that the heat in the spectrum increased from the violet to the red, and reached its maximum intensity at a distance beyond the red "in the invisible rays of the spectrum." He projected the results of his experiments in a curve which bears a close resemblance to the one given in fig. 7. He experimented on these "invisible rays," which he was the first to discover, and showed that they were reflected and refracted according to the same laws that rule in the reflection and refraction of light. He says that "if we may infer the quantity of the efficient from the effect produced, the invisible rays of the sun probably far exceed the visible ones in number." He then condensed these rays by means of concave reflectors and lenses, and made a "trial to render the invisible rays of the sun visible by condensation." He showed "that by condensation their heating power is proportionally increased; for, under the circumstances of the experiment, we find that it extended so far as to be able to raise the thermometer in two minutes no less than 24°." In the same series of researches ("Philosophical Transactions," 1800) he says: "If we call light those rays which illuminate objects, and radiant heat those which heat bodies, it may be inquired whether light be essentially different from radiant heat. In answer to which I would suggest, that we are not allowed by the rules of philosophizing to admit of two different causes to explain certain effects, if they may be accounted for by one. . . . It remains for us only to admit that such of the rays of the sun as have the refrangibility of those which are contained in the prismatic spectrum, by the construction of the organs of sight, are admitted, under the appearance of light and colors; and the rest, being stopped in the coats and humors of the eye, act on them, as they are known to do on all the other parts of our body, by occasioning a sensation of heat." In 1865 Tyndall repeated the researches which had previously been clearly marked out by Herschel. In his first series of experiments he employed the electric lamp as the source of light and heat, and used a linear thermo-battery (see HEAT) as a thermometer. He used prisms of rock salt instead of glass, and in certain of his experiments he passed the beam from the electric lamp through a tank containing a solution of iodine in carbon disulphide. This solution has the property of absorbing all of the radiations producing light, and allowing the invisible rays of heat alone to traverse it. Herschel had already found that the "invisible rays of the sun far exceed the visible in number." Tyndall by similar experiments found that "the thermal energy of the invisible radiation of a very pow-

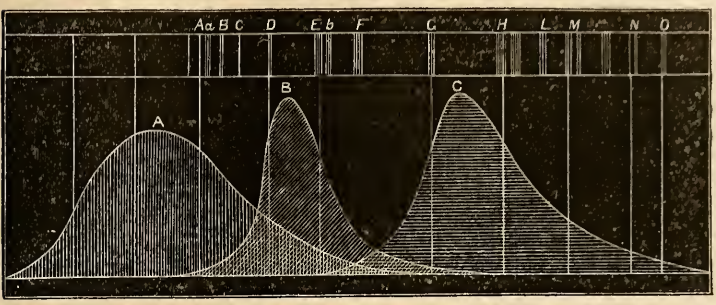

FIG. 7.

erful electric light is eight times that of the visible." Tyndall, with the more efficient means at his command, repeated Herschel's experiments on the condensation of the invisible rays, and caused them to ignite to whiteness solids like platinum. This property of these condensed rays he called "calorescence." Seebeck (*Mémoires de l'académie*, Berlin, 1819) first showed that the position of maximum heat in the spectrum changes with the nature of the prism, and sometimes occurs in the red. Melloni (*Journal de l'institut*, vol. i., p. 212) proved that the effects observed by Seebeck were owing to the absorptive action of the materials of the prisms, and with prisms filled with water and alcohol he observed the maximum temperature in the yellow. In a spectrum which Melloni obtained by passing the sun's rays through a prism of rock salt (the most diathermanous of all substances), he found the maximum of heat beyond the red rays at a distance from the line B nearly equal to the distance of this same line B from the line F. Melloni used the thermo-battery of Nobili for a thermometer. Sir John Herschel ("Philosophical Magazine," April, 1840) examined the distribution of heat in a spectrum by using paper covered on one side with lampblack and then moistened with ether or alcohol. On allowing the spectrum to fall on the uncoated side of the paper, he observed the rate of evaporation of the ether, and thus saw the superior heating effect of the rays beyond the red; and by this method he also detected the existence in the invisible spectrum of athermic bands, which corresponded to the Fraunhofer lines seen in the visible spectrum. In 1843 Dr. J. W. Draper of New York obtained photographs of these bands by projecting a spectrum on a daguerreotype plate, while the latter was at the same time exposed to a diffused light of feeble intensity. In 1847 Fizeau and Foucault, by means of minute mercurial thermometers, detected in the spectrum of a flint glass prism a large athermic band beyond the red, at a distance from the line A equal to the distance of this line from D. In 1871 Lamansky, with a linear thermo battery ("Philosophical Magazine"), confirmed the observations of Herschel. The most recent research on the distribution of heat in the spectrum is by Dr. J. W. Draper ("American Journal of Science," 1872). He maintains that the observed increase of heat in the spectrum, as we proceed to its red end and advance beyond this point, is owing to the fact that any prism by its unequal refractive action on the spectral rays must give a spectrum which is abnormally condensed at its red end and dilated at its violet. He calls attention to the fact that the middle of the normal or diffraction spectrum is at the point where falls the ray whose wave length is ·0005768 of a millimetre. This is a point a little above the line D. The distribution of the rays in the prismatic spectrum of a flint glass prism compared with the normal spectrum is shown in fig. 8, where the two spectra have the same length, and their optical centres, as given by wave length, are in the same line. From a long series of experiments on the spectra obtained by prisms of flint glass, rock salt, carbon disulphide, and quartz, Dr. Draper infers that the amount of heat contained in the visible normal spectrum from its optical centre to the line $H_2$ is equal to the heat contained in the same spectrum from its optical centre to the line A. "Assuming this as true," he says, "it necessarily follows that in the spectrum any two series of undulations will have the same heating power, no matter what their wave lengths may be." It appears that this conclusion is too extended a deduction from such a restricted result as Draper reached; for if the variations of heat in the spectrum were symmetrically divided by a line drawn through its optical centre, the same result would be attained by Draper's method of experimenting. In other words, if the maximum or minimum of heat existed at the optical centre, and the heat declined uniformly above and below this point, or if a series of maxima and minima were symmetrically distributed above and below the optical centre, then each half of the spectrum, divided at its optical centre, would give the same heating power. Recently E. Lundquist (Poggendorff's *Annalen*, vol. clv.) has shown how Cauchy's formula, which serves to connect the index of refraction of a ray with its wave length, may lead to an expression which serves to reduce the distribution of heat observed in a prismatic spectrum to what it would be in a normal spectrum. He finds that the observations of Lamansky, made with flint glass and rock salt prisms, when thus reduced place the maximum of heat about the middle of the normal spectrum, and the heat diminishes uniformly on both sides of this point. In the spectrum of the electric light, however, the maximum of heat is near the line A; hence in this case the optical centre of the spectrum does not divide it into two portions having equal heat-giving powers.—*Chemical Actions of the Spectrum.* Conclusions as to the distribution of chemical action in the spectrum have generally

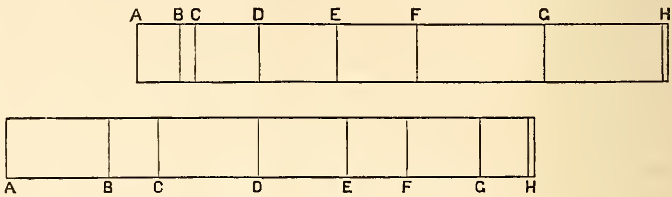

Fig. 8.

been reached solely from the observed actions on compounds of silver; and what is often styled "the curve of chemical force" in the spectrum we have given in fig. 7. This curve is generally referred to as giving the distribution of chemical action in all cases. This is erroneous; as long ago as 1842 Dr. J. W. Draper showed: 1, that so far from chemical influences being restricted to the more refrangible rays, every part of the spectrum, visible and invisible, can give rise to chemical changes, or modify the molecular arrangement of bodies; 2, that the ray effective in producing chemical or molecular changes in any special substance is determined by the absorptive property of that substance. He found that if a spectrum be received on iodide of silver formed on the silver plate of the daguerreotype, and the impression of the light be then developed, after it has acted for a moderate time we shall observe a stain which corresponds in character and position to the blackening effect that under like circumstances would be found on any common sensitive silver paper. If, however, the action of the light be long continued, a white stain makes its appearance over all the less refrangible regions of the spectrum. But if the daguerreotype plate during its exposure to the spectrum be also receiving diffused light of little intensity, it will be found on developing that the impression obtained differs strikingly from the preceding. Every ray that the prism can transmit, from below the extreme red to beyond the extreme violet, has been active. The ultra red athermic lines are present. The impression of these lines is a proof of proper spectrum action, and distinguishes it from that of diffused light, arising either from the atmosphere or from the imperfect transparency of the prism. In a series of photographic prints accompanying a paper by Dr. Schultz Sellak "On the Sensitiveness to Light of Haloid Salts of Silver, and on the Connection between Optical and Chemical Absorption," may be observed the varying extent of the chemical action of the spectrum and the shifting of the place of maximum action depending on the nature of the chemical preparation on which the spectrum is formed. Thus, chloride of silver collodion is acted on by the portion of the spectrum from about half way between the lines G and H up to the line N, fig. 7. Iodide of silver collodion is affected from below G nearly to the line M; bromide of silver collodion from F to M. A mixture of silver salts formed of the iodide and bromide of collodion is sensitive to the action of the spectrum in the space from the line E to the line M. Mixed iodide and chloride of silver collodion are acted on throughout nearly the same area. The remarkable increase of sensitive area when the spectrum falls on the above named mixtures has long been turned to good account in practical photography. (See PHOTOGRAPHY.) The most remarkable confirmation of Draper's first proposition, as given above, is in the case of the spectral action on a surface of West India bitumen. A glass plate is coated with this substance as follows: The bitumen is dissolved in benzine, and the solution poured on a glass plate in a dark room and drained off, leaving a film of bitumen sufficiently thin to be iridescent. This is exposed to the spectrum for five minutes, and then developed by pouring over it a mixture of benzine and alcohol, which will now only dissolve those portions of the film that have not been acted on by the light. The beginning of the impression is below the line A, its termination beyond H. Every ray in the spectrum acts. The proof is continuous except where the Fraunhofer lines fall. Dr. Draper found that the decomposition of carbonic acid gas by plants is accomplished by rays between the lines B and F, which is another instance of the chemical action of the less refrangible rays. In 1842 Sir John Herschel discovered that the yellow stain imparted by the *corchorus Japonica* to paper is whitened by the green, blue, indigo, and violet rays. The rose red of the ten weeks stock is in like manner changed by the yellow, orange, and red. The rich blue tint of the *viola odorata*, turned green by sodium carbonate, is bleached by the same group of rays, that is, by those less refrangible than the yellow. The green chlorophyl of the elder leaf is changed by the extreme red. To a former experimenter, Grotthus, we owe the discovery of the law under which these decompositions of the colors of flowers take place. This law in repeated instances was verified by Herschel, and more recently by Draper. It may be thus expressed: The rays which are effective in the destruction of any given vegetable color are those which by their union produce a tint complementary to the color destroyed. Even the partial establishment of this law, already accomplished, is sufficient to prove that chemical effects are not limited to the more refrangible portions of the spectrum, but can be occasioned by any ray. The second proposition of Draper, that the rays which act chemically on a substance are those which are optically absorbed by it, has received ample independent confirmation by the recent experiments of Sellak in his paper cited above. Sellak found that optical and chemical absorption of light exactly coincide. All colors which are sensibly absorbed (optically) by the haloid salts of silver, of a thickness of a few millimetres, produce chemical decomposition. The optical absorption of transparent plates of these substances is shown by spectral observation to be confined exactly within the limits of chemical action. This is especially the case with mixtures of iodide and bromide of silver. Chloride of silver is colorless, iodide of silver is transparent light yellow, bromide of silver is somewhat deeper yellow, and the mixture of the last two orange yellow.—E. Becquerel in 1842 (*Bibliothèque Universelle de Genève*) was the first to photograph the Fraunhofer lines, and in doing so

he discovered that similar lines existed in the invisible portion of the spectrum, formed of rays more refrangible than the violet. In 1843 Dr. Draper obtained independently the same results. Müller, in the sixth edition of his *Lehrbuch der Physik*, gives a photographic print of the spectral lines extending from a short distance below G to above R. He made this photograph with a prism and lens of quartz. Subsequently Mr. Rutherfurd obtained, with two prisms of carbon disulphide, a superb photograph embracing lines extending from near *b* to a considerable distance above the upper of the H lines. This photograph has excited universal admiration. It is crowded with lines which are not drawn on the maps of Kirchhoff or of Angström. Mascart of Paris obtained the Bordin prize of the academy of sciences for his determinations of the wave lengths of the visible and ultra violet rays of the spectrum. He used a grating of Nobert to obtain his spectra, and measured the wave lengths of the more refrangible invisible rays by obtaining photographs on small glass plates placed in the ocular E of the spectrometer shown in fig. 4. By this means Mascart measured the wave lengths of these invisible rays with a precision little inferior to that obtained in his measures on the visible rays. He also measured the wave lengths of the light lines given in the spectra of volatilized metals, and found that cadmium gave the most extended spectrum of invisible rays. Mascart observed rays whose wave length was only ·00022 of a millimetre. The period of vibration of these shortest waves, compared with the period of the longest visible rays of ·00076 of a millimetre, gives about two octaves of the musical scale; that is, the numbers of their vibrations in the same time will be as 1 : 4. But the ratio of the wave length ·0019 of a millimetre of the least refrangible invisible ray of the spectrum to the shortest invisible ultra violet wave of the spectrum will be as 1 : 8, or as any note is to its upper third octave. The papers of Mascart can be found in the *Annales de l'École normale*. In 1873 Dr. Henry Draper of New York published in the "American Journal of Science" a carbon print of a remarkably perfect photograph of a spectrum produced by one of Rutherfurd's diffraction gratings of 6,481 lines to the inch. The negative was photographed on collodion, and the published carbon print has attached to it a scale giving the wave lengths of the rays. This print was obtained by transferring the original negative to a thick plate of glass by a process known as the albertype, and using the glass in a printing press in the same manner as a lithographic stone. This print therefore represents the work of the sun itself, and is not a drawing either made or corrected by hand. The print consists of two portions. The upper gives all the lines of the spectrum from near G to O, or from wave length ·0004350 mm. to ·0003440 mm. Above this is placed a scale, which is a copy of Angström's from just below G to $H_2$, with the same sized divisions carried out from $H_2$ to O. The lower part is a magnified portion of the same negative, having $H_1$ and $H_2$ about its middle, and extending from wave length ·0004205 to ·0003736 mm. Between wave lengths ·0003925 and ·0004205 mm., Angström's map has 118 lines, while Draper's has 293. We here give a table of the wave lengths of ultra violet rays according to the measurements of Mascart and of H. Draper:

| FIXED LINES. | Mascart. | Draper. |
|---|---|---|
| $H_1$........................ | ·0003967 mm. | ........ |
| $H_2$........................ | ........ | ·0003930 mm. |
| L........................ | ·0003819 | ·0003821 |
| M........................ | ·0003729 | ·0003728 |

| R........................ | ·0003177 | ........ |

—*Fluorescent Action on the Spectral Rays.* Fluorescence is a property possessed by certain substances of absorbing light composed of rays of a certain wave length, and then emitting this light changed into rays of a longer wave length; or, what is the same, changed into light of a lower refrangibility. This phenomenon was first observed by Robert Boyle; an account of his experiments may be found in vol. i. of his works (London, 1772). The

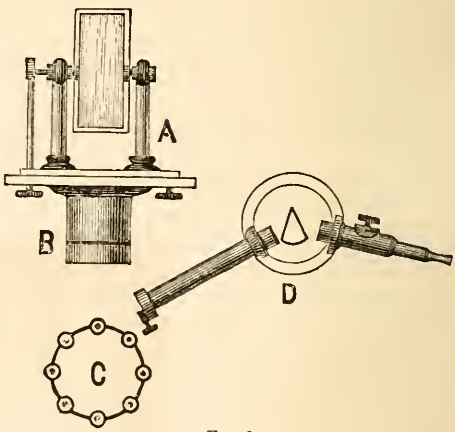

FIG. 9.

method of examining the spectra of fluorescent bodies is as follows: A porte-lumière, A, fig. 9, reflects the sun's rays on to a lens at B. which concentrates the light on the fluorescent substances contained in bottles at C. By the revolution of the stand on which these bottles are placed, they can be brought successively before the slit in the collimating telescope of the spectroscope D. Before the solar rays fall on the fluorescent substance they pass through a tank, placed between B and the spectroscope,

and containing a solution of cupric sulphate in ammonia. The general phenomena of fluorescence are described under FLUORESCENCE; we here add several discoveries made since the writing of that article by Prof. Morton of Hoboken. In a portion of his researches Prof. Morton had the coöperation of Dr. H. C. Bolton of New York, who undertook the chemical work in the investigations. Their attention was particularly directed to the fluorescent properties of the uranium salts. The total number of distinct salts produced and examined so far by these investigators is 75, not including numerous specimens treated in various ways to establish the existence and conditions of their several hydrates. This multiplication of facts has given great value to this research as compared with previous work in the same direction. Thus, where Becquerel has examined one double acetate, these investigators have examined 16; in place of his three double sulphates, they have 16; in place of one fluoride, six; and so on. The methods pursued in the examination of these uranium salts were the same as those of Stokes and Becquerel. The discoveries made by Morton were mainly due to the wider range of substances examined, which made it possible to form inductions and generalizations, and to the scrupulous attention paid to the purity of these substances. We note only the most important results, and refer the reader to the following original papers for additional information: "American Chemist," vols. iii. and iv.; "Chemical News," vol. xxviii. 1. By a comparison of the spectra of 17 acetates and double acetates of uranium in the solid state and in aqueous solutions, the remarkable fact was demonstrated that in the case of these bodies no double salt could exist in solution in water. By further experiments of the same kind this law was extended to all the known salts of uranium. 2. It was proved that by the study of the fluorescent spectra the existence of a new and before unknown salt could be recognized. Thus, on heating the ammonio-uranic sulphate to 100° C. for a short time, it was noticed that its fluorescent spectrum assumed a duplicate character (see spectrum 2 of fig. 10), a new set of bands being added to those of the normal salt (see spectrum 1 of fig. 10). By continuing the heating until the salt ceased to lose weight, a substance was obtained giving spectrum No. 3 of fig. 10. These results naturally suggested that the two spectra 1 and 3 belonged to the hydrated and anhydrous salts, and that spectrum 2 indicated

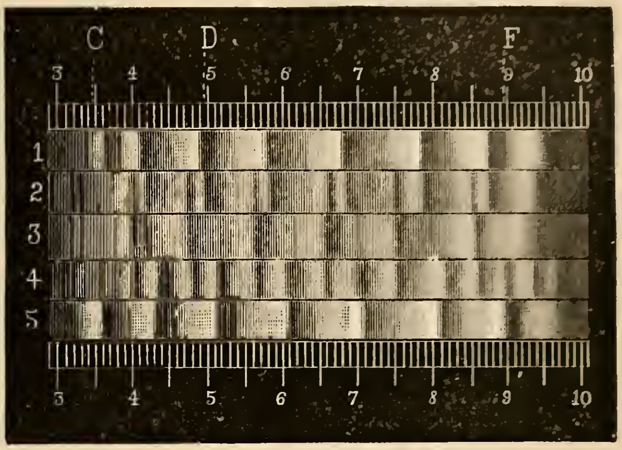

FIG. 10.

a mixture of the two. On heating the dried salt to low redness for a short time, another double spectrum, No. 4, was developed, which by a continuance of the same treatment was reduced to a new simple one, No. 5. Analysis of the product so obtained showed that it was an ammonio-diuranic sulphate, a salt before unknown and not likely to have been discovered by any other means, as contact with water at once reduces it to a mixture of the normal salt and uranic sulphate. 3. It was discovered that certain uranic salts were capable of combining with definite proportions of water to form certain hydrates not heretofore recognized, and that each of these hydrates yielded a perfectly distinct and characteristic spectrum. Thus, the double sulphate of sodium and uranium seems to form no less than five hydrates with from one to five atoms of water respectively. These salts have not all been isolated,

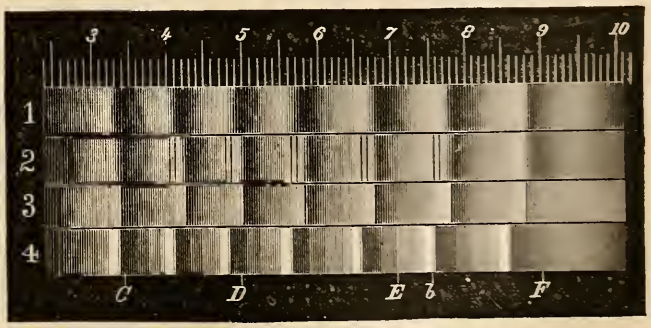

FIG. 11.

but fig. 11 shows the spectra of some of them. Thus No. 1 of the figure is the spectrum of the pentahydrate; No. 2, that of a mixture of three hydrates; No. 3, that of the monohydrate; and No. 4, that of the anhydrous salt. 4. In the case of the double acetates it appears that the position of their bands both of fluorescence and of absorption has a close relation to the atomic weights of the salts. Thus, a list of these salts in the order in which their bands occur, beginning with those which are highest in the spectrum, will be essentially a list of the salts in the order of their atomic weights. 5. It was found that heat had invariably the effect of sending toward the red end of the spectrum all spectral bands of solids and of solutions in all cases where any effect could be observed. In a later memoir Prof. Morton, having investigated the fluorescent relations of the basic salts of uranic oxide, has shown many new ways by which these bodies may be produced, and has found that they yield by fluorescence a light which gives a continuous spectrum. The latter property affords a ready means of distinguishing them, when either alone or in mixture, from hydrates and uranates, which they otherwise often resemble. The same methods of investigation have been applied by Prof. Morton to the following solid hydrocarbons found in the latter products of the destructive distillation of coal tar: anthracene, chrysogen, pyrene, and chrysene. He has also discovered a new hydrocarbon of very remarkable fluorescent properties occurring in the products of the destructive distillation of the heavier petroleum oils; to this he has given the name of thallene, from the vivid green color of its fluorescent light. When a continuous spectrum is thrown on a screen of white paper, half of which is coated with thallene, the effect indicated in fig. 12 is seen. The portion R V, on the paper, shows the usual solar spectrum from red to violet, but the part S T, on the thallene, does not appear, from 8 of the scale upward, blue, indigo, and violet, but appears green of varying intensity. The energy

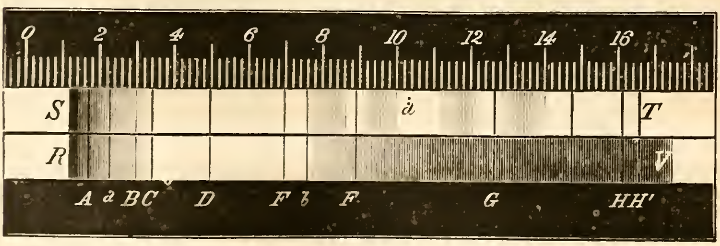

Fig. 12.

of the fluorescent action of this body makes it available for some very striking illustrations. Thus designs painted in it on muslin may be invisible in yellow light, but flash out with a self-luminous light when violet light falls upon them. When a pure spectrum is thrown on the side of a tank containing a solution of thallene in benzole, the appearance indicated in fig. 13 is seen. The trails of light are of the following colors: olive green, bright emerald green, sky blue, and indigo running into violet. The value of the applications of spectrum anal-

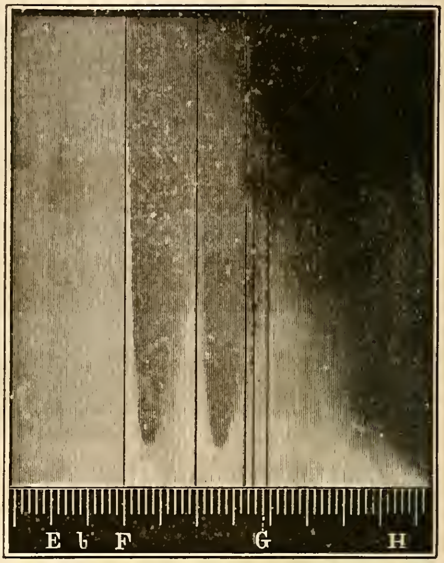

Fig. 13.

ysis to fluorescent phenomena, as developed by Prof. Morton, consists in its opening a new method for investigating chemical and physical changes in bodies while these changes are in progress, and under conditions which would seem to exclude all other means of examination.

**SPECTRUM ANALYSIS,** the name given to a recent method of chemical analysis, conceived and proposed in general form by Prof. G. Kirchhoff of Germany, in which the presence of certain chemical elements is determined by corresponding and peculiar sets of colored bands, imparted by those elements or compounds containing them to the spectra obtained from flames in which such substances are sublimed or volatilized. In reference to the solar spectrum and the transverse dark bands or lines of Fraunhofer marking it, see SPECTRUM; see also SUN. In 1802 Wollaston prepared the way for the discoveries of Fraunhofer, Kirchhoff, and others, by the invention of a new method of observing the solar spectrum. He admitted the solar rays into a dark room through a narrow slit, and placing him-

self at a distance of 12 ft. or more he viewed this slit through a prism of homogeneous glass held close to the eye. This method of observation shows the spectrum crossed transversely to its length by dark lines and bands; and hence the spectrum from a prism of given material and angle becomes a sort of scale or map, to a fixed position in which every gradation of hue and every dark band can be exactly referred. Among the observations upon the spectrum, partially anticipating Kirchhoff's principle, were those of Fraunhofer (1815), of Talbot (1826), of Brewster (1832), of Wheatstone (1835), and of Foucault (1849). In 1855

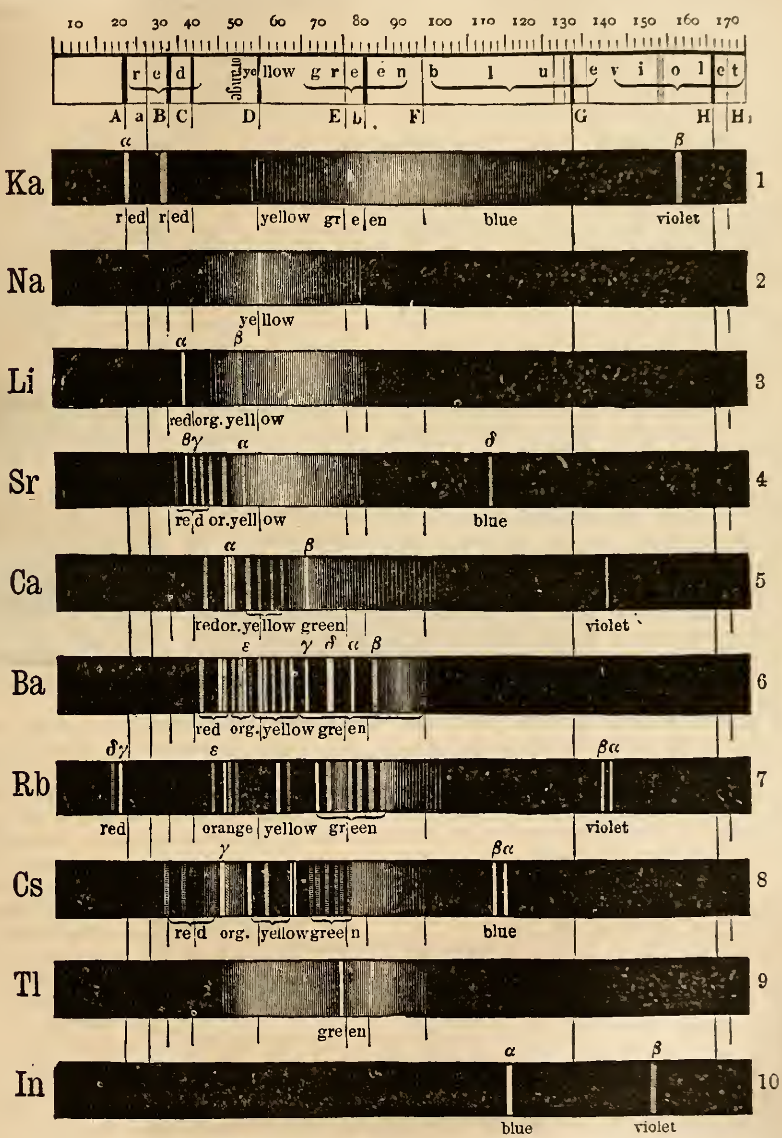

Fig. 1.—Table of Spectra according to Kirchhoff and Bunsen.

Prof. A. J. Angström of Sweden, applying Euler's principle of the reciprocation and absorption by bodies of the same sorts of undulations which they are capable of emitting when themselves originally excited, was led to the view that any body at a glowing heat emits the same rays (refrangibilities) of light and heat as, in the like condition, it will absorb if they impinge upon it. The first decisive and general proof in reference to light of the principle assumed by Euler and Angström was furnished by Kirchhoff's experiments in 1859, with flames

charged with lithium and sodium. A volatilizable compound of any such element being burned in or otherwise diffused through a flame, the incandescent particles of each communicate to the general light of the flame an excess of certain rays, these appearing in the spectrum as brighter bands crossing it in certain parts and having the exact colors proper to such parts, being generally different in situation and hue for the different elements introduced into the flame, and always or generally the same for each element. Fig. 1 shows the spectra of various chemical elements, the symbols of which are given on the left of the spectra. The upper spectrum is that of the sun, and on it are drawn the dark lines of Fraunhofer. (See SPECTRUM.) These lines are extended downward and through the lower spectra, and they thus serve as a kind of scale to which to refer the luminous bands of these spectra. The colored spectral bands are designated by the letters of the Greek alphabet, and are named in order of their importance as characteristic of their respective spectra. When, however, a flame is thus colored, or charged with excess of certain rays, if through this the light of another and more brilliant flame colored with the same element is passed to be analyzed, it is seen that while the general illumination of the spectrum is increased, the previous bright lines characterizing the element are now replaced by dark lines or lines relatively very faint; in a word, the spectrum characteristic of the given element is exactly reversed. The lower dark portion of fig. 2 shows the two bright lines of the spectrum of incandescent sodium vapor; the upper portion of the figure shows these lines reversed by the passage of the light from an incandescent solid through the vapor of sodium. (For an engraving and description of the spectroscope, the instrument with which spectrum analysis is effected, see SPECTRUM.) In the prosecution of the new field of research opened by these experiments, Prof. R. Bunsen soon became associated. When several elements which show systems of bright bands are at the same time in the flame, it is at least generally true that their several spectra coexist; and the instances in which certain lines proper to different elements coincide are as yet few. The spectrum of sodium consists of two approximate bands in the yellow of the spectrum near the orange, and seven relatively very faint lines; and Bunsen has determined that by it the presence in a flame of less than the $\frac{1}{180,000,000}$ part of a grain is detected. Of calcium, barium, strontium, potassium, and lithium, the least quantities detectible vary from $\frac{1}{60,000}$ to $\frac{1}{100,000,000}$ grain; so that no other chemical test approaches this in delicacy. Among results of the new analysis are, the finding that lithium is in fact an element widely diffused in nature, and the discovery of several new metals. (See CÆSIUM, INDIUM, RUBIDIUM, and THALLIUM.)—This method of analysis has proved of great service in metallurgical operations. The application of the method to researches in solar physics will be briefly noticed under SUN. Kirchhoff, having satisfied himself that the bright lines characteristic of several of the metals correspond exactly in place with as many dark lines of the solar spectrum, as shown in fig. 3, infers that these dark lines are produced by a reversal similar to that above shown, and hence indicate the existence of corresponding chemical elements, both volatile in the luminous atmosphere of the sun, and also incandescent in its nucleus. The following table by Angström shows the number of lines belonging to the elements named which correspond with dark lines of the solar spectrum:

—Spectroscopic analysis applied to the stars has shown that they resemble the sun in general constitution and condition. But characteristic differences exist, insomuch that the stars have been divided into four orders distinguished by their spectra, types of which are given in fig. 4. These are thus presented by Secchi, who examined more than 500 star spectra: The first type is represented by $\alpha$ Lyræ, Sirius, &c., and includes most of the stars shining with a white light, as Altair, Regulus, Rigel, the stars $\beta$, $\gamma$, $\epsilon$, $\zeta$, and $\eta$ of Ursa Major, &c. These give a spectrum showing all the seven colors, and crossed usually by many lines, but always by the four lines of hydrogen, very dark and strong. The breadth of these four lines indicates a very deep, absorptive stratum at a high temperature and at great pressure. Nearly half the stars observed by Secchi showed this spectrum. The second type includes most of the yellow stars, as Capella, Pollux, Arcturus, Aldebaran, $\alpha$ Ursæ Majoris, Procyon, &c. The Fraunhofer lines are well seen in the red and blue, but not so well in the yellow. The resemblance of this spectrum to the sun suggests that stars of this type resemble the sun closely in physical constitution and condition. About one third of the stars observed by Secchi showed this spectrum. The third type includes Antares, $\alpha$ Orionis and $\alpha$ Herculis, $\beta$ Pegasi, Mira, and most of the stars shining with a red light. The spectra show bands of lines; according to Secchi there are shaded bands, but a more powerful spectroscope shows multitudes of fine lines. The spectra resemble somewhat the spectrum of a sun spot, and Secchi has advanced the theory that these stars are covered in great part by spots like those of the sun. About 100 of the observed stars belong to this type. The fourth type differs from the preceding in the arrangement and appearance of the bands. It includes only faint stars. A few stars, as $\gamma$ Cassiopeiæ,

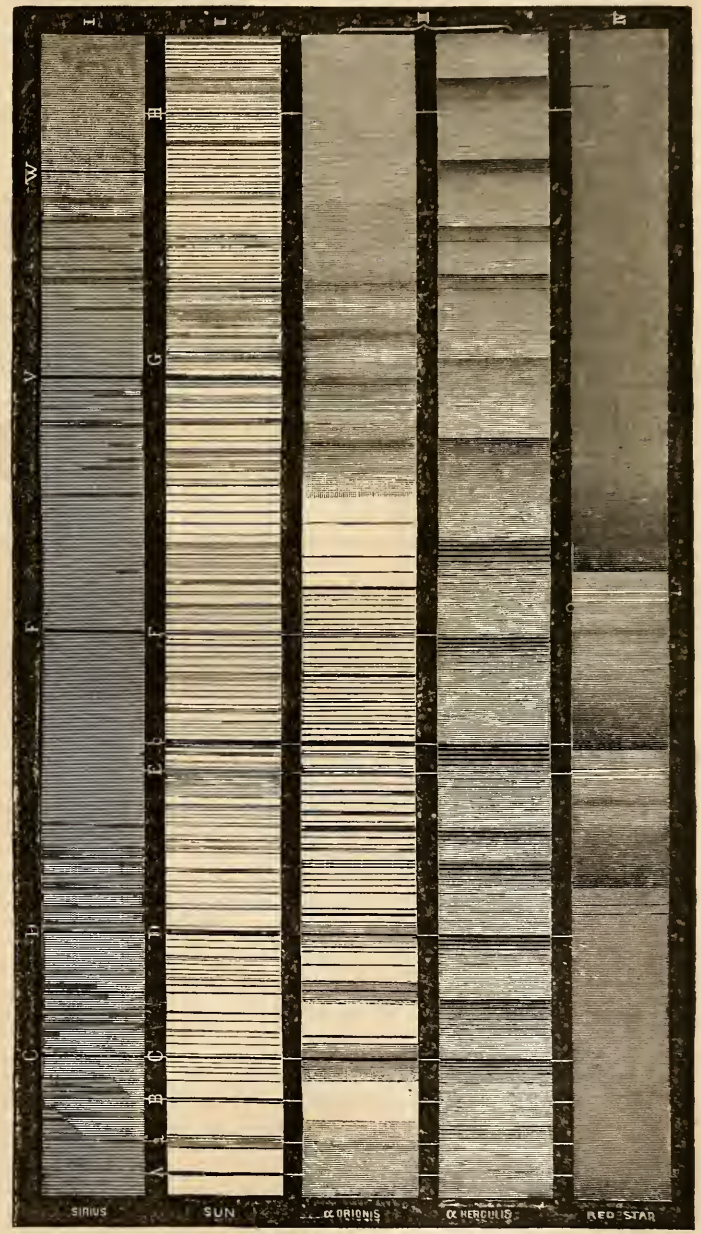

Fig. 4.—Secchi's Types of the Fixed Stars.

η Argûs, β Lyræ, &c., show the lines of hydrogen bright instead of dark, as though surrounded by hydrogen glowing with a heat more intense than that of the central orb itself around which the hydrogen exists. Secchi's observations were comparatively rough, and the inference that particular lines, as those of hydrogen for example, are really present depended in his case simply on the general correspondence of a set of lines with the set belonging to the element. But Huggins and Miller, in England, showed, by the direct comparison of stellar with terrestrial spectra, that certain elements exist in particular stars. Thus they found in the spectrum of Aldebaran lines corresponding with those of hydrogen, sodium, magnesium, iron, tellurium, calcium, bismuth, antimony, and mercury. In the spectrum of Betelgeuse they recognized the lines of sodium, magnesium, iron, bismuth, and calcium, but found those of hydrogen wanting. They discovered that (at least in the instances examined by them) the colors of the double stars are due to the existence of stellar atmospheres exercising an elective absorption. For example, the spectrum of the orange component of the well known double star Albirco shows dark bands in the blue and violet; while the spectrum of the blue component shows many strong lines in the orange and red.—The nebulæ show two orders of spectra. One class, including the clusters, resolvable and suspected resolvable nebulæ, besides other nebulæ which probably are resolvable into stars though no signs of the fact can be detected with the telescope, show a spectrum resembling the stellar spectrum in general characteristics, though usually too faint to be assigned to any given order of stellar spectra. The other class, which includes all the irregular and planetary nebulæ, besides most of the elliptic irresolvable nebulæ, the ring nebula in Lyra, the dumb-bell nebula, and others, presents the remarkable phenomenon of a spectrum of three bright lines (in a few cases four lines are seen). Fig. 5 is the spectrum of the nebula known as H 4,374. This is a small but bright object, and it is the nebula to which Huggins in 1864 first directed his telespectroscope. One line agrees in position with a hydrogen line, another with a nitrogen line, but the third line has not yet been shown to coincide with a line of any known element.—Comets show a mixed spectrum, the nucleus, coma, and tail each giving a combination (though in varying proportions) of a discontinuous or band spectrum, and a continuous spectrum due probably to reflected sunlight. Tempel's comet (1866) was the first analyzed with the spectroscope, by Huggins in England. Winnecke's (1868) was the first to which careful analysis was applied, with the curious result of observing that the bands agree in position with those obtained as the spectrum of carbon, by passing the electric spark through olefiant gas. Huggins obtained the same result (which was confirmed by Professors Harkness and Young in America) from the study of Encke's comet in 1872. The first large and long-tailed comet studied with the spectroscope was Coggia's comet of 1874. Huggins gives the following account of the spectroscopic analysis of this comet: "When the slit of the spectroscope was placed across the nucleus and coma, there was seen in the instrument a broad spectrum, consisting of the same three bright bands exhibited by comet II., 1868, crossed by a linear continuous spectrum from the light of the nucleus. On the continuous spectrum of the nucleus I was not able to distinguish with certainty any dark lines of absorption, or any bright lines, other than the three bright bands. Besides these spectra, there was also present a faint broad continuous spectrum between and beyond the bright bands. When the slit was moved on to different parts of the coma, the bright bands and the faint continuous spectrum were found to vary in relative intensity. When the slit was brought past the nucleus on to the commencement of the tail, the gaseous spectrum became rapidly fainter, until, at a short distance from the nucleus, the continuous spectrum predominated so strongly that the middle band only, which is the brightest, could be detected on it."—The planets, shining by reflected light, can only reveal under the spectroscope the possible presence of absorptive vapors in their atmosphere. (See MARS.)

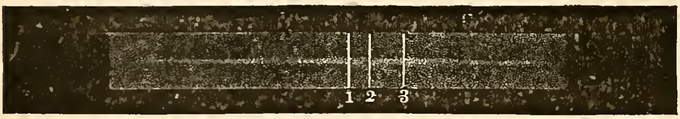

FIG. 5.—Spectrum of Nebula (H 4,374).

**SPECULUM** (Lat., mirror), a term commonly applied to concave metallic reflectors, such as are used in reflecting telescopes for concentrating the rays of light from distant luminous bodies, and presenting the image of these in their focus. Their perfection consists in large surface, whereby they collect the greatest quantity of light; in the highest possible polish, whereby it is reflected with least loss; and in the most exact parabolic curvature, rendering the image distinct and precise. In a speculum of 6 ft. diameter, a variation even at its edge from the true parabolic curvature, so minute as to escape detection with any except the most refined means of measurement, may render the whole useless. The metallic alloy best adapted for the requirements of specula was first employed for this purpose by Sir Isaac Newton, and is similar to that used by the ancient Egyptians for mirrors. It con-

sists of copper and tin, to which Newton added a little arsenic, and sometimes silver or zinc; but Lord Rosse found that the two metals first named are better without the addition of any other. The volatile metals are objectionable. Silver makes the alloy too soft; nickel, though it whitens the yellow alloy of copper, makes the speculum alloy yellowish. Rosse was particular that the copper and tin should be combined in their atomic proportions (4 atoms of copper =126·8, to 1 of tin =59), and the purest metals should be selected; for the smaller specula it is even recommended that the copper be obtained by the electrotype process; this is hardly practicable for the large ones. The alloy is remarkable for its extreme brittleness and hardness. Large masses of it sometimes break from a slight blow or sudden change of temperature; and it is so hard that it cannot be wrought with tools of steel. It takes a most brilliant polish, which it has been known to retain with little tarnish, though exposed to the air for more than 16 years. A large speculum, however, ought always to be covered when not in use, and the air about it should be kept dry by means of an open box of quicklime. Great difficulties have been encountered in preventing the large specula from changing their form by their own weight, and those of 6 ft. diameter are made so thick, to give them the necessary stiffness (though supported when finished by the most ingenious appliances), that they are among the heaviest of bronze castings; and the preparation of the rough mass is among the most difficult of foundery operations. Rosse's six-foot speculum weighs 4 tons; one of 3 ft. 3¾ in. thick, weighs 13 cwt.; and one of 2 ft., 3¼ cwt. The alloy is prepared by melting the metals separately, and pouring the tin into the copper, stirring rapidly, and then, before the tin oxidizes, casting the alloy into ingots. It is tested when cold to ascertain its brilliancy, and more tin is added if necessary. The best mode of preparing the moulds has been arrived at from long experimental trials in the casting of the smaller specula. It was found that sand moulding would not answer for the surface of the disks, as the texture of the alloy near the outside was rendered somewhat spongy and crystalline; and though this was so slight as to be detected only by the microscope, it still seriously impaired the polished surface. The face of the disk at least must then be "chilled," as cast iron is chilled, by pouring it into metallic moulds to increase the density of its surface. But the ordinary temperature of the atmosphere was found to be too low for the moulds to receive this alloy, and they were consequently heated to about 212° to prevent too sudden cooling and consequent irregular contraction. For moderate-sized specula cast-iron moulds were used, necessarily open, or the casting would inevitably fly in pieces. They were made a little deeper than the speculum, with the bottom of the same convexity with this, and so supported that they could be instantly filled from the lowest point, and turned into a horizontal position when charged with the proper weight of the metal. The air and any foreign substance present are thus carried up to the surface, and separated from the alloy. But this was not sufficiently perfect for the largest castings, and Lord Rosse adopted for these the following method. An iron frame of sufficient diameter was filled with pieces of hoop iron set on edge and tightly wedged together, and the upper surface was turned off to the curvature of the face of the speculum. This was to serve for the bottom of the mould, being tight enough to hold the melted metal, while it allowed the escape of the gases through the interstices uniformly over the whole face. Upon this bottom was laid the wooden pattern, made twice as deep as the intended speculum, and with an allowance of $\frac{1}{65}$ in the diameter for shrinkage. The sides of the mould were then formed by ramming sand around the pattern. By this arrangement the first cooling is on the under face, next on the sides, and the final congealing is on the top or back, where the contraction and resulting irregularities will be concentrated in the least important part. The metal while red-hot is removed to a furnace specially prepared for it, the bottom having the curvature of the disk (unless in case of using an iron mould, when this too is taken along). By fires already kept up several days, the inner walls of the furnace should be at a full red heat. The vacant spaces around the casting are then filled with ignited fuel, and every aperture is carefully luted. A large speculum should thus be left to cool for a month to six weeks; and the result may still be unsatisfactory if the walls of the furnace are less than 2 ft. thick.—The production of the true parabolic figure, combined with a brilliant polish, is attained by grinding succeeded by polishing. Machines applicable to this object have been invented by Sir W. and Sir J. Herschel, Lord Rosse, Mr. Lassell, an amateur optician and astronomer, Mr. De la Rue, Mr. Grubb of Dublin, and others, which are too complicated to be particularly described in this place. The object sought for is to restrict the operation of the rubbing tools to the production of the particular curvature required, and insure a uniform action upon every part of the surface of the disk. The speculum, placed upon a slowly revolving platform, presents its face to the action of the rubber above it, which by Lord Rosse's arrangement was caused to vibrate regularly in one and the other direction, while at the same time it revolved at a different rate from that of the speculum. Mr. Lassell caused the rubber to revolve in small circles, while the speculum, turning on its axis, which was not in line with that of the rubber, presented successively all portions of its surface to this circling action of the rubber, thus imitating the movements of the hands by which the

small specula had previously been successfully polished. The principles of the arrangement of Mr. Lassell were so mathematically exact, that, as stated by Mr. Nasmyth, "a speculum having a decidedly hyperbolic figure may be corrected and brought to a perfect parabola, or to a spherical curve, or the same may be done in the reverse order at pleasure." The test of the polishing consists in observing through an eye piece the reflection of the dial of a watch set directly over the speculum, in the case of Lord Rosse's operations at the height of 90 ft. The success of the polishing was dependent on the state of the atmosphere as regards temperature and moisture, both of which required at times to be artificially regulated. The tools for first smoothing the face of the speculum are made up of pieces of gritstone, cemented together in a frame and dressed on the face to the proper degree of convexity. The next are disks of cast iron, their face also of the exact curvature, and grooved by two lines of furrows a quarter of an inch wide and the same deep, crossing each other at right angles. These are fed with sharp quartz sand, and afterward with emery and water. When the work has proceeded to the use of very fine emery the scratches disappear, and the rubber is in perfect and uniform contact with the speculum. For polishing, the cast-iron rubber was used by Lord Rosse, counterpoised and provided with circular grooves in addition to the rectilinear ones. Its face was coated with a thin layer of pitch, with another upon this of rosin and flour, which serves as the bed for the polishing powder or rouge to imbed itself. Mr. Lassell's polisher was of pine wood in two layers, the grain crossing, and the face coated with pitch above. The preparation of these polishers involves nice operations, which may not be neglected without great risk of failure. The largest specula when polished ought never to be removed from their supports; for however carefully lifted, the figure would be almost certain to lose its accuracy by change of pressure in the mass. Even one of 9 in. diameter, when supported by the pressure of springs against three stops bearing on its edges, loses its defining power. Sir John Herschel laid the speculum upon folds of woollen cloth, packing others closely all around it, filling the space between its edges and the box that contained it; but this is not sufficient to preserve the form of the specula of 6 ft. diameter and as many inches thick, and the contrivances for this are a most complicated system of bearings, springs, and levers.—Specula exhibit some peculiarities in their forms and applications to use, according to the kind of reflecting telescope for which they are designed. It is evident that as they reflect images as mirrors, the observer cannot be placed directly in front, and it is not obvious how he can take his position at the opposite end of the telescope, as in using those of the refractory kind. This is accomplished in the reflecting telescope of Dr. James Gregory, known as the Gregorian telescope, by an aperture through the centre of the speculum, and the introduction of a small concave speculum in the centre of the great tube, facing the large speculum, and a little in advance of its focus. Back of the great speculum the tube is extended of reduced diameter, and in its extremity is a magnifying eye piece, by which the image reflected from the small speculum through the aperture of the large one reaches the eye. In Sir William Herschel's great telescope, with its 4-ft. speculum and 40-ft. focal length, the disk was entire, and the image was reflected direct to an eye piece at the mouth of the tube and near one side of it, so as not to intercept too much light. This was effected by a slight inclination of the plane of the speculum. In Sir Isaac Newton's telescope the disk was also entire, and a small plain speculum reflected the cone of rays sent from it, before meeting in the focus, to the eye piece placed in the upper side of the tube. Cassegrain's telescope differs from Gregory's in the small reflector being convex instead of concave.—Specula have recently been made of polished silver surface, which has the advantage over that of the speculum metal of reflecting 91 per cent. of the incident light, instead of 67 per cent. The silver, after the method of M. Léon Foucault, is laid in a very thin uniform coating upon a speculum of glass, figured and polished to a true parabola. This is done by Drayton's process of precipitating the metal from the solution in nitric acid by oil of cassia. The precipitated silver is polished by gentle rubbing with a skin lightly tinged with oxide of iron, and soon acquires a very brilliant lustre without material change of figure. This, however, was questioned by Mr. Grubb, when the subject was under consideration before the British association at Dublin, who asserted from his own experience that the removal of a thickness of $\frac{1}{40,000}$ or $\frac{1}{50,000}$ of an inch might seriously impair the accuracy of the defining power of the speculum. M. Foucault had preserved the silver mirrors for eight months without their being injured by tarnishing; but whenever this might occur they were easily polished again, and the silver itself could be at any time renewed. Mr. Browning of London has carried to a high degree of perfection the construction of silvered-glass reflectors; and the experience of those acquainted with instruments constructed on his plan is strongly in favor of the method. In America the reflecting telescope has not hitherto met with much favor; though the success with which Dr. H. Draper of New York has constructed large reflecting telescopes, and employed them even in the delicate work of lunar photography, promises before long to enlist American ingenuity in the improvement of a class of telescopes which must probably always have the preference over refractors for observations requiring very great space-penetrating power.—The subject of the speculum, in its

mathematical and mechanical details, is treated in various memoirs in the English scientific journals, from the time of Newton's paper in the "Philosophical Transactions" of 1672 to the present day. Lord Rosse's papers are contained in the "Edinburgh Journal," vol. ix., 1828, and vol. ii. (new series), 1829, and in the "Philosophical Transactions," 1840 and 1850. The mechanical details are fully described in Holtzapffel's "Mechanical Manipulations." For Lassell's process, see "Transactions of the Royal Astronomical Society," 1849.

**SPEKE, John Hanning,** an English traveller, born in Somersetshire, May 4, 1827, died near Bath, Sept. 15, 1864. He served as a captain in the British army in the Punjaub under Lord Gough (1849), and subsequently made scientific explorations in the Himalaya. In 1854 he set out with Burton for the Somauli country, where they were attacked and Speke was wounded. He next enlisted in the Turkish army in the Crimea shortly before the close of the war. He gained a wide celebrity by his joint expedition with Burton (1856) to Africa, and the discovery of Lake Tanganyika. (See BURTON, RICHARD FRANCIS.) On July 30, 1858, he discovered alone the Victoria N'yanza lake, and in 1862 he explored its western and northern margin together with Capt. J. A. Grant. (See NILE, and N'YANZA.) Capt. Speke was killed by the accidental discharge of a gun while hunting. His principal work is his "Journal of the Discovery of the Source of the Nile" (2 vols., London, 1863).

**SPELMAN, Sir Henry,** an English antiquary, born at Congham, near Lynn, Norfolkshire, in 1562, died in London in 1641. He was educated at Cambridge, and devoted himself to historical and antiquarian studies. He served as sheriff of his county, and was knighted by James I. and appointed commissioner to determine disputed claims to lands and manors in Ireland. In 1612 he settled in London. He wrote *Glossarium Archaiologicum* (A to L, 1626; completed from his manuscripts, 1664; best ed., 1687); *Concilia, Decreta, Leges, Constitutiones, in Re Ecclesiastica Orbis Britannici* (2 vols., 1639-'64); and *Villare Anglicanum* (1656). The *Reliquiæ Spelmannianæ* (fol., Oxford, 1698) is a collection of his papers relating to the laws and antiquities of England.

**SPENCE, Joseph,** an English author, born at Kingsclerc, Hampshire, April 25, 1699, drowned at Byfleet, Surrey, Aug. 20, 1768. He was educated at Oxford, entered holy orders, and was elected professor of poetry. He published in 1726 "An Essay on Pope's Odyssey," and made a tour through France and Italy in 1730-'33. In 1731 he published a biography of Stephen Duck, afterward prefixed to an edition of Duck's poems, and in 1736 reproduced with a preface at Pope's request Sackville's tragedy of "Gorboduc." In 1742 he was presented by his college to the rectory of Great Horwood, and appointed professor of modern history at Oxford. His most interesting production is "Anecdotes, Observations, and Characters of Books and Men," collected from the conversation of Pope and others, and valuable with reference to the literary history of his time. It was published, with notes and a biography, by S. W. Singer (London, 1820; new ed., 1858).

**SPENCE, William,** an English entomologist, born in 1783, died in London, Jan. 6, 1860. In 1805, while engaged in business at Hull, he presented a few specimens of insects to the Rev. William Kirby, with whom he afterward wrote "Introduction to Entomology, or Elements of the Natural History of Insects" (4 vols., 1815-'26; 7th ed., 1 vol., 1858). It consists of 51 letters, of which 9 were written by Mr. Spence, 20 by Mr. Kirby, and 22 by them conjointly. He was for a time a member of parliament. He removed in 1826 to the continent, and visited the principal European capitals during the next eight years, returned to England and settled in London.

**SPENCER. I.** A N. county of Kentucky, intersected by Salt river; area, 280 sq. m.; pop. in 1870, 5,956, of whom 1,479 were colored. The surface is hilly and the soil fertile. The chief productions in 1870 were 105,211 bushels of wheat, 16,470 of rye, 436,875 of Indian corn, 35,885 of oats, 1,852 tons of hay, 5,500 lbs. of tobacco, 15,385 of wool, 119,748 of butter, and 8,488 gallons of sorghum molasses. There were 3,018 horses, 538 mules and asses, 1,935 milch cows, 3,252 other cattle, 4,530 sheep, and 17,724 swine; 6 flour mills, and 4 distilleries. Capital, Taylorsville. **II.** A S. W. county of Indiana, bordering on the Ohio river, bounded E. by Anderson's creek and W. by Little Pigeon creek; area, 390 sq. m.; pop. in 1870, 17,998. The surface is hilly in the W. part and level in the S., and the soil is fertile. Bituminous coal is abundant. The chief productions in 1870 were 123,663 bushels of wheat, 682,374 of Indian corn, 98,510 of oats, 79,597 of potatoes, 7,878 tons of hay, 3,019,970 lbs. of tobacco, 21,416 of wool, and 49,006 gallons of sorghum molasses. There were 4,892 horses, 683 mules and asses, 3,711 milch cows, 5,720 other cattle, 14,054 sheep, and 23,506 swine; 5 manufactories of carriages and wagons, 5 of furniture, 2 of tobacco and snuff, 10 flour mills, 6 saw mills, and 3 planing mills. Capital, Rockport.

**SPENCER. I. Ambrose,** an American jurist, born at Salisbury, Conn., Dec. 13, 1765, died at Lyons, N. Y., March 13, 1848. He graduated at Harvard college in 1783, studied law, and commenced practice in Hudson, N. Y. In 1793 he represented Columbia co. in the state legislature; in 1795 and for seven consecutive years he was a state senator; in 1802 he was appointed attorney general, in 1804 made a justice of the supreme court, and in 1819 chief justice. He was a member of the constitutional convention of 1821, and was the author of the law abolishing the punishment of death in all cases except treason and murder. He resigned the office of chief justice in 1823, and

resumed practice at Albany. He was for some years mayor of that city, and also represented the Albany district in congress. In 1839 he retired to Lyons. **II. John Canfield**, an American jurist, son of the preceding, born in Hudson, N. Y., Jan. 8, 1788, died in Albany, May 18, 1855. He graduated at Union college in 1806, and in 1807 became private secretary of Gov. Tompkins. He was admitted to the bar in Canandaigua in 1809, was master in chancery and district attorney, a member of congress 1817-'19, and several times of the state assembly and senate. In 1827 he was appointed one of the revisers of the statutes of the state, and in 1839 secretary of the state of New York. President Tyler in 1841 appointed him secretary of war, and in 1843 transferred him to the treasury department. He resigned in 1844, from opposition to the annexation of Texas. He served on many state commissions, and aided in the organization of the asylum for idiots and the improvement of the common school system. He edited De Tocqueville's "Democracy in America," with an original preface and notes (New York, 1838).

**SPENCER. I. George John**, second Earl Spencer, an English bibliophile, born Sept. 1, 1758, died Nov. 10, 1834. Under the courtesy title of Viscount Althorp, he was first lord of the admiralty from 1794 to 1801, and subsequently home secretary. On the death of his father in 1821 he took his seat in the house of lords. He possessed one of the largest and most remarkable private libraries in Europe, the nucleus of which he acquired in 1789 from the Hungarian baron Reviczky. See Dibdin's *Bibliotheca Spenceriana* (4 vols. 8vo, 1814-'15), and *Ædes Althorpianæ* (2 vols., 1822). **II. John Charles**, third Earl Spencer, an English statesman, son of the preceding, born May 30, 1782, died at Wiseton hall, Nottinghamshire, Oct. 1, 1845. He served in the house of commons as Viscount Althorp, during the whig administration of 1806-'7 was junior lord of the treasury, and afterward a leader of the whig opposition until the return of the whigs to power in 1830, when he was appointed chancellor of the exchequer, and became ministerial leader in the house of commons, through which he was instrumental in carrying the reform bill and the poor-law amendment bill. He resigned with his colleagues in November, 1834. About the same time he succeeded his father as Earl Spencer, and devoted himself to farming. He was the first president of the royal agricultural society.

**SPENCER, George** (Father Ignatius of St. Paul), an English clergyman, youngest son of John George, second Earl Spencer, born in London, Dec. 21, 1799, died at Carstairs, Scotland, Oct. 1, 1864. He graduated at Cambridge in 1819, took orders, and became rector of the family living of Brington in 1825. He joined the Roman Catholic church at Leicester in 1830, was ordained priest in 1832, and took charge of the missions of West Bromwich and Dudley. In 1839 he was appointed to an office in Oscott college, became soon afterward its rector, entered the order of Passionists in 1846, and contributed very much toward the extension of his order in Great Britain and Ireland, filling high offices therein till his death. He was chiefly distinguished for his extraordinary zeal in ministering to the spiritual wants of the laboring population, and for his efforts in establishing an association of prayers for the return of England to communion with the church of Rome. For this purpose, from 1838 till 1857, he repeatedly visited Ireland and the Roman Catholic countries on the continent, preaching and lecturing everywhere on this subject. He wrote "Account of my Conversion" (1831), an autobiography and journal embodied by Father Pius in his "Life of Father Ignatius of St. Paul, Passionist" (Dublin and London, 1866), and a "Life of St. Paul of the Cross" (London, 1875).

**SPENCER, Herbert**, an English philosopher, born in Derby, April 27, 1820. His father was a teacher. Herbert was fond of keeping insects and watching their transformations, and for years the finding and rearing of caterpillars, the catching and preserving of winged insects and making drawings of them, were his regular occupations. He also assisted his father in philosophical experiments. At the age of 13 he was sent to study with his uncle, the Rev. Thomas Spencer, rector of the parish of Hinton. Here he remained three years, and made special progress in mathematics. Returning home, he studied perspective with his father, on the principle of independent discovery, the successive problems being put in such order that he was enabled to find out the solutions himself. This was a favorite mode of teaching with his father, who is the author of a valuable little work entitled "Inventional Geometry," on this plan. At 16 Herbert devised a new and ingenious theorem in descriptive geometry, which was published with the demonstration in the "Civil Engineers' and Architects' Journal." At 17 he accepted an engagement under Charles (afterward Sir Charles) Fox as a civil engineer, and began work on the London and Birmingham railway. In 1841 he declined a further appointment, returned home, and spent two years in mathematical and miscellaneous studies. He made a botanical press and a herbarium, and practised drawing and modelling. All the time he had in progress some scheme of invention, improvements in watchmaking, machinery for the manufacture of type by compression of the metal instead of casting, a new form of printing press, and the application of electrotype to engraving, afterward known as the glyptograph. In the spring of 1843 he went to London in quest of literary occupation, but did not succeed, and resumed engineering. His earliest literary contributions were made to the "Civil Engineers' and Architects' Journal," the "Philosophical Magazine," the "Zoist," and the "Noncon-

formist." In the last named journal, in 1842, he began the publication of a series of papers on the "Proper Sphere of Government," which were issued in a pamphlet in 1843. From 1848 to 1852 he was a regular writer for the "Economist," and subsequently contributed to various reviews elaborate papers which were pervaded with the idea, since more distinctly developed, known as the doctrine of evolution. He soon became a firm believer that all organized beings have arisen by development. In 1854 he first conceived of evolution as a universal process, and later he came to the conclusion that it must become the basis of any system of philosophy which represents and conforms to the general method of nature. In 1860 he published a prospectus of such a system, and immediately entered upon its execution. He had already collected his essays upon the scientific aspects of social questions, and had published various volumes leading up to his system. Most of these were revised and enlarged in subsequent editions to present more fully his new philosophy. The fourth division of his system, devoted to sociology, deals with the science of human society from the point of view of evolution expounded and applied to the general phenomena of life and mind in his earlier volumes. In furtherance of this department of his work, he has for several years employed the aid of three assistants in collecting and classifying facts pertaining to all types of society, savage tribes, decayed races, and existing civilizations, which, under the title of "Descriptive Sociology," are intended to form a series of folio volumes, of which three have been published (1876). The following is a complete list of his publications: "Social Statics, or the Conditions essential to Human Happiness specified, and the first of them developed" (London, 1850; New York, 1865); "Principles of Psychology" (London, 1855; revised ed., 2 vols., London and New York, 1870–'72); "Railway Morals and Railway Policy" (London, 1855); "Essays, Scientific, Political, and Speculative" (London, 1857; 2d series, 1863; American ed., "Illustrations of Universal Progress," New York, 1864); "Essays, Moral, Political, and Æsthetic" (New York, 1865; new and enlarged ed., 1874); "Education, Intellectual, Moral, and Physical" (London and New York, 1860); "First Principles of a System of Philosophy" (London, 1862; New York, 1864); "Classification of the Sciences," to which is added "Reasons for dissenting from the Philosophy of M. Comte" (London, 1864; 3d ed., 1871); "Principles of Biology" (2 vols., London, 1864; New York, 1866–'7); "Spontaneous Generation, and the Hypothesis of Physiological Units" (New York, 1870); "Recent Discussions in Science, Philosophy, and Morals," collected from English reviews (New York, 1871; 2d ed., with six additional articles, 1873); "The Study of Sociology" (London and New York, 1873); "Descriptive Sociology: Facts Classified and Arranged" (3 vols. fol., London and New York, 1873–'4); and "The Principles of Sociology," a quarterly serial (London and New York, 1874 *et seq.*). In the system of philosophy series, apart from their publication as separate volumes, "First Principles," "Principles of Biology," and "Principles of Psychology" have been issued in London serially in 34 numbers; so that the sociological division begins with No. 35 under the title "The Principles of Sociology." Nos. 35–38 were published in London and New York in 1874–'5, and the whole work is expected to consist of 15 or 18 parts.

**SPENCER, Ichabod Smith**, an American clergyman, born at Rupert, Vt., Feb. 23, 1798, died in Brooklyn, N. Y., Nov. 23, 1854. He graduated at Union college in 1822, and was principal of the grammar school in Schenectady till 1825, and afterward till 1828 of an academy in Canandaigua, N. Y. He was licensed to preach by the presbytery of Geneva in 1826, and in 1828 was settled as colleague pastor of the Congregational church in Northampton, Mass. From 1832 till his death he was pastor of the second Presbyterian church in Brooklyn; and from 1836 to 1840 extraordinary professor of Biblical history in Union theological seminary, New York, of which he was one of the founders. His best known publication is his "Pastor's Sketches" (two series, New York, 1850–'53), which has passed through many editions, and been translated into French. Since his death there have been published from his manuscripts "Sermons," with a memoir by J. M. Sherwood (2 vols., New York, 1855); "Sacramental Discourses" (1861); and "Evidences of Divine Revelation" (Boston, 1865).

**SPENCER, Jesse Ames**, an American clergyman, born at Hyde Park, Dutchess co., N. Y., June 17, 1816. He graduated at Columbia college in 1837 (from which he received the degree of S. T. D. in 1852), studied theology in the general seminary of the Episcopal church, became rector of St. James's church, Goshen, N. Y., in 1840, and afterward engaged in teaching, and travelled in Europe and the East. In 1849 he was appointed professor of Latin and oriental languages in Burlington college, N. J., and from 1851 to 1857 was editor and secretary of the Episcopal Sunday school union and church book society. In 1863–'5 he was rector of St. Paul's church, Flatbush, L. I., and in 1869 became professor of Greek in the college of the city of New York. He has published "Discourses" (1843); "The New Testament in Greek, with Notes on the Historical Books" (1847); "Cæsar's Commentaries," with notes, lexicon, &c. (1848); "Egypt and the Holy Land" (1849); "History of the United States" (4 vols. 8vo, 1856–'69); "Greek Praxis" (1870); "The Young Ruler and other Discourses" (1871); and "A Course of English Reading" (1873). He has also edited Archbishop Trench's poems (1856), and Xenophon's Anabasis from the manuscripts of Prof. A. Crosby (1875).

**SPENER, Philipp Jakob,** a German theologian, born at Rappoltsweiler, Alsace, in January, 1635, died in Berlin, Feb. 5, 1705. He studied at Strasburg, early lectured on philosophy and history, and was tutor to several of the princes palatine. After attending Swiss and French universities, he began in 1663 to preach at Strasburg. In 1664 he was made doctor of theology, and in 1666 chief of the clergy at Frankfort. While the orthodox Lutherans based their theology on the Bible as explained by the symbolical books, he based it on the Bible as confirmed and explained by personal experiences. He instituted at Frankfort classes for catechizing the young, and his prayer meetings (*collegia pietatis*) and conventicles (*ecclesiolæ in ecclesia*) created a popular and strictly Biblical theology. From his *collegia* sprang the sect of the pietists, so called at first in derision, but finally the name was accepted by themselves. In 1686 he removed to Dresden, where he was appointed chief court preacher and a member of the consistory. His views were violently opposed by the Saxon clergy, especially after the foundation of the new university at Halle, the professorships in which were filled by his disciples, and which became at once the central point of the pietistic doctrines. The faculty of Wittenberg designated in his writings about 300 false doctrines, although he fully adhered to the confession of Augsburg. He defended himself with ability and success; but in 1691 he gladly accepted an invitation from the elector Frederick of Brandenburg to reside at Berlin, as provost, inspector of the church of St. Nicholas, and assessor of the consistory. He wrote *Pia Desideria* (1675; new ed. by Feldner, Dresden, 1846), and other theological as well as genealogical works.—See Hossbach, *Philipp Jakob Spener und seine Zeit* (2 vols., Berlin, 1828; 3d ed. by Schweder, 1861), and Thilo, *Spener als Katechet* (Stuttgart, 1841).

**SPENSER, Edmund,** an English poet, born in East Smithfield, London, probably in 1553, died in King street, Westminster, Jan. 16, 1599. In one of his poems he alludes to his connection with "an house of ancient fame," and it is maintained by Mr. Craik that he belonged to the Spencers of Hurstwood, Lancashire. He was entered a sizar of Pembroke hall, Cambridge, in 1569, and took the degree of bachelor in 1572 and of master in 1576. He there formed a life-long intimacy with Gabriel Harvey, the poet and astrologer. On leaving the university he visited the north of England, where he wrote his "Shephearde's Calendar." Induced by Harvey to go to London, he was introduced to Sir Philip Sidney, who invited him to become his guest, and to whom, in return for his hospitality, he dedicated his "Shephearde's Calendar" (1579). For the next ten years little is known concerning Spenser. He corresponded with Harvey on the innovation of banishing rhymes and introducing the Latin prosody into English verse. Recommended by Sidney to his uncle, the powerful earl of Leicester, he was occasionally employed in small missions, and in 1580 was sent to Ireland as secretary to Lord Grey de Wilton, who was appointed lord deputy of that country. The "Foure Epistles," on satiric poetry and on an earthquake in London, which passed between Spenser and Harvey, and which induced a controversy between the latter and Nash, were published the same year. He returned in 1582, and in 1586 obtained a grant of 3,028 acres of the forfeited lands of the earl of Desmond, in the county of Cork, on condition that he should reside on his estate; and he therefore took up his abode in Kilcolman castle, near Doneraile, where he composed most of the "Faerie Queen," upon which he had been engaged several years. After the death of Sidney, he wrote the pastoral elegy of "Astrophel" to his memory. Raleigh now became his principal patron and friend, and in 1589 persuaded him to return to London to arrange for the publication of his poem. The first three books appeared in 1590, dedicated to Queen Elizabeth, with a letter to Raleigh explaining the work as "a continued allegory or dark conceit." He was presented to the queen, from whom he received a pension of £50, returned to Ireland, and published "Colin Clout's come Home again" (1591); a collection of minor poems entitled "Complaints" (1591); a series of "Amoretti" and the "Epithalamium" (1595), relating to his courtship and marriage; four "Hymns" (1596), the two on love and duty, pervaded by a Platonic doctrine, being among his most exquisite productions; and the fourth, fifth, and sixth books of the "Faerie Queen" (1596). He was married in 1594, but it is not certain whether the lady was the "Elizabeth" of his sonnets, nor whether it was a first or second marriage. In 1596 he presented to the queen his "View of the State of Ireland," a treatise in the form of a dialogue, not published till 1633. He was a conspicuous object for the enmity of the Irish on the outbreak of Tyrone's rebellion, since he was clerk of the council of Munster, and had been nominated sheriff of Cork. When the insurgents rose in Munster in 1598, they attacked Kilcolman, and the poet fled with his wife. The castle was plundered and burned, and an infant child, which had been left behind, perished in the flames. Spenser died at an inn a few months after his arrival in London, it is said for want of bread; but there are circumstances which make this account doubtful. He was buried at the expense of the earl of Essex, and at his own request near the remains of Chaucer, in Westminster abbey. A monument erected to him after 30 years by Anne, countess of Dorset, was restored in 1778 by the fellows of Pembroke hall.—His chief poem, the "Faerie Queen," is unfinished. The Spenserian stanza, in which it is written, is a modification of the Italian *ottava rima*, with the addition of the

Alexandrine line, and the diction was purposely studded with forms and phrases which had become antiquated. Yet Spenser is scarcely surpassed as a master of musical language. The leading story is an allegory, founded on the traditional history of Prince Arthur, who was taken as the ideal of a noble person. Gloriana, the queen of Faerie, who gave name to the poem, is an emblem of virtuous renown. All the personages are symbolical and all the incidents significant of moral truths. The subject of each book is a moral attribute, as holiness, temperance, chastity, friendship, justice, and courtesy, personified by a knight errant, with all human passions. The last great poem of chivalry, it was received with enthusiasm in the adventurous age of Elizabeth. The first canto is much the finest; the allegory in it is so skilfully disguised that it may be disregarded; and it fully exhibits the freshness and power of his genius. An edition of his poems by G. S. Hillard, with a critical introduction, was published in Boston in 1839 (5 vols.). They also form five volumes (1855) in the Boston collection of "British Poets." A variorum edition was published by the Rev. Henry John Todd (8 vols. 8vo, London, 1805). An edition, with glossary, notes, and life, by J. P. Collier (5 vols. 8vo, London, 1862), is probably the most accurate and complete.

**SPERANSKI, Mikhail,** a Russian statesman, born in the government of Vladimir, Jan. 1, 1772, died in St. Petersburg, Feb. 23, 1839. In 1797 he was appointed professor of mathematics at St. Petersburg, in 1801 secretary to the council of the empire, in 1802 was charged with the organization of the ministry of the interior, and in 1808 became assistant minister of justice. He improved the finances, remodelled the method of taxation, increased the educational funds, introduced a new penal code, and reorganized the commission for codifying the laws. In March, 1812, he was forced to resign, and was banished to Nizhni-Novgorod; but in 1816 he was restored to favor, and in 1817 appointed governor of Penza, and in 1819 of Siberia. On the accession of Nicholas in 1825, he was appointed president of the chancery, and resumed the work of codifying the laws. He published all the laws and edicts from 1694 in 45 vols. 4to, and an abridgment in 15 vols. 8vo.

**SPERMACETI** (Gr. *σπέρμα*, sperm, and *κῆτος*, a whale), a solid crystalline fat, extracted from the oily fluids found in a triangular cavity by the right side of the nose and in the upper part of the head of the sperm whale or blunt-headed cachalot, and also in smaller quantities in some other species of the cetacea. The liquid contents boiled out from the head of the sperm whale of ordinary size sometimes amount to more than 12 large barrels full. When cold they concrete into a spongy mass, from which the larger portion of the oil drains away, leaving the crude spermaceti. This filtration is made more effective by compression in bags in a hydraulic press; and the subsequent purification is effected by melting the residue in water and skimming off the impurities, and remelting in a weak potash lye, which removes nearly all traces of the oil. The spermaceti is then melted alone by steam heat, and ladled into pans, where it cools in white, semi-transparent, lamellar cakes. The last traces of oil may be removed by boiling once or more with alcohol, which dissolves the spermaceti, but when cold holds only the oil. Pure spermaceti, called cetine, has a foliaceous texture and a delicate whiteness. It is semi-transparent, friable, unctuous to the touch, and resembles white wax in lustre and hardness. It is without taste and of hardly any odor; of specific gravity ·940; melts at 120°; dissolves readily in hot ether, and in the fatty and volatile oils, separating on cooling. At high temperatures it sublimes without decomposition if protected from the air. By the addition of a few drops of alcohol or of almond oil it may be powdered. Its ready inflammability in connection with its fusibility renders it well adapted for candles, which is the chief use made of it. (See CANDLE.) It has been employed in medicine, combined with sirup or mucilage, to protect the throat in coughs and colds; and triturated with sugar candy with the addition of milk, it forms a simple nutritive mixture. In pharmacy its use is of greater importance as an ingredient in ointments and cerates. It is not readily saponified, and in this change it differs from the other fats in not yielding glycerine, but another base instead, termed ethal, a white, solid substance, fusible at 118°, and possessing the properties of a true alcohol. It is also called cetylic or ethalic alcohol, and is represented by the formula $C_{16}H_{34}O$. The acid, into which also the spermaceti is resolved, is known as the cetylic, ethalic, or palmitic acid, and is represented by the formula $C_{16}H_{32}O_2$.

**SPERMOPHILE.** See PRAIRIE SQUIRREL.

**SPERM WHALE.** See WHALE.

**SPEUSIPPUS,** a Greek philosopher, born in Athens about 380 B. C., died in 339. He was a nephew of Plato, and at his death succeeded him as president of the academy, over which he presided eight years (347–339). He followed partially the philosophic system of his master, but diverged from it in the prominence he gave to empiricism. He adopted Plato's threefold division of philosophy into dialectics, ethics, and physics.

**SPEYER,** or **Speyr.** See SPIRE.

**SPEZIA, La,** a town of N. Italy, in the province and 50 m. S. E. of the city of Genoa; pop. in 1872, 24,123. It is at the N. W. extremity of the gulf of Spezia (anc. *Portus Lunæ*), which is one of the largest and finest harbors in the world, surrounded by lofty mountains and containing within itself many minor ports. Spezia contains the principal naval arsenal of Italy, and is an important station for foreign squadrons. The arrivals and departures of steamers

in 1872, including the ports of Lerici, Fezzano, and Portovenere within the gulf of Spezia, amounted to 461 and 459, and of sailing vessels to 1,118 and 1,124; aggregate tonnage, 93,445. The imports were valued at $1,607,000 (including $867,660 for the navy) and the exports at $533,772. Among the most celebrated products are olive oil and wine.

**SPEZZIA,** or **Spetzia** (anc. *Tiparenos*), an island of Greece, in the archipelago, at the E. entrance of the gulf of Nauplia, and about 2 m. from the coast of Argolis; greatest length 5 m., greatest breadth 3 m.; pop. in 1870, 8,443. It is rocky, but has some fertile patches, which are carefully cultivated. In the war of independence the islanders distinguished themselves in naval engagements with the Turks. The chief place, of the same name, is a pleasant town on the E. shore, with a good harbor; pop. about 3,000. It is a resort for invalids on account of the climate.

**SPHAGNUM.** See MOSSES.

**SPHENOGRAMS.** See CUNEIFORM INSCRIPTIONS.

**SPHERE** (Gr. σφαῖρα), in geometry, a body bounded by a surface, every point of which is equally distant from a point within called the centre. The figure may be generated by the revolution of a semicircle about its diameter as an axis. It is easily shown that if a sphere be enclosed in a right cylinder, the portions of the surface between any pair of planes parallel to the bases of the cylinder are equal in area to the portions of the cylindrical surface between the same planes. Accordingly, the total surface of the sphere is equal to the curved surface of the cylinder. This surface is manifestly equal to the rectangle of the height of the cylinder by the circumference of its base; that is, to four times the base, for the height of the cylinder is equal to the diameter of the base. Hence the surface of a sphere is equal to four times the area of a circle of the same diameter. Its solid content is manifestly equal to that of a pyramid, whose base is equal to the surface of the sphere, and whose altitude is the radius; hence equal to one third of the product of its radius into its surface; or, the cube of the diameter being to the solid content nearly as 300 to 157, the content may be calculated from this proportion, or by multiplying the cube by the decimal ·52333.—In geography, sphere denotes a representation of the earth on a globular surface. (See GLOBE.) In astronomy, it is the concave expanse of the heavens, which appears as the interior surface of a sphere, of which the centre is the earth.

**SPHINX,** a fabulous monster of Greek mythology, which was represented generally as having the winged body of a lion and the breast and head of a woman, but sometimes with a female face, the breast, feet, and claws of a lion, the tail of a serpent, and the wings of a bird; and sometimes the fore part of the body is that of a lion, and the lower part that of a man, with the claws of a vulture and the wings of an eagle; all which forms were used as architectural ornaments. In the legends of the poets the sphinx is said to have been the daughter of Orthus and Chimæra, or of Typhon and Chimæra, or of Typhon and Echidna, and to have come from the most distant parts of Ethiopia. She is also said to have been sent by Mars to avenge the death of his son the dragon slain by Cadmus, or according to others sent by Bacchus or by Pluto; while others again represent her as one of the women who with the daughters of Cadmus were thrown into madness and metamorphosed into monsters. She was ravaging Thebes and devouring those who could not solve a riddle which she proposed to all whom she met, when Œdipus, being offered the crown of Thebes on condition of delivering the country from the monster, solved the riddle, upon which the sphinx destroyed herself. (See ŒDIPUS.)—It is probable that the Greeks derived the idea of the sphinx from Egypt, where from remote antiquity such figures had been used to embellish the avenues which formed the approaches to temples. Among the Egyptians they had the head of a man, bearded and capped, and the body of a lion, thus differing from the Greek sphinxes, which had a female head and the body of a winged lion. Clemens and Plutarch say they were placed before the temples as types of the mysterious nature of the deity. Some sphinxes have the head of a ram, and are called crio-sphinxes, and others the head of a hawk, called hieraco-sphinxes; the former were sacred to Amen or Jupiter Ammon, the latter to Ra, the god of the sun. The great sphinx at the pyramids was supposed by Lepsius to represent King Cephren, the builder of the second pyramid; but an inscription has lately been discovered which renders it probable that it was sculptured even before the time of Cheops, the builder of the first pyramid. The Egyptians called it Hor-em-khu, or Har-ma-khu, "the setting sun," the name of the god to whom it was dedicated, which was converted by the Greeks into Armachis. It is near the eastern edge of the platform on which the pyramids stand, with its head turned toward the Nile. The head measures 28 ft. 6 in. from the top to the chin. The total length of the body, which is that of a lion crouching close to the ground, is 146 ft. Across the shoulders it measures 36 ft., and the paws are extended about 50 ft. Between the paws was built a small temple, which was of masonry, as were the paws, while all the rest of the sphinx seems to be carved out of solid rock. Col. Vyse drilled a hole 27 ft. deep into one of the shoulders, and found that it was one piece of stone throughout. Near the sphinx Mariette discovered a vast temple buried in the sand, which is supposed to have been dedicated to the worship of the divinity of the sphinx. The countenance is now so much mutilated that the outline of the fea-

tures can with difficulty be traced. The head had been covered with a cap, the lower part of which remains, and it had originally a beard, the fragments of which were found below.

The Great Sphinx.

Immediately under the breast stood a granite tablet, and another of limestone on either side resting against the paws. The first contains a representation of Thothmes IV. offering incense and making libation to the sphinx, with a long inscription in hieroglyphics reciting the titles of the king. On the paws are inscriptions of the Roman times, expressive of adoration to the sphinx or to the Egyptian deities.

**SPHINX**, one of the names of the Guinea baboon (*cynocephalus papio*, Desm.). It is rarely seen in menageries, though it is remarkably intelligent; it is probably one of the species represented on the Egyptian monuments. It was known to Pliny. (See Baboon.)

**SPHINX CATERPILLAR.** See Hawk Moth.

**SPHYGMOGRAPH.** See Pulse.

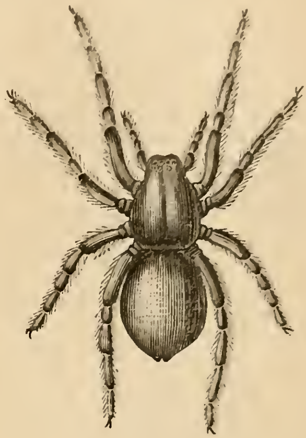
**SPICE ISLANDS.** See Moluccas.

**SPICEWOOD.** See Fever Bush.

**SPIDER**, a division of the insect order *arachnida*, which also includes the mites and scorpions. The general character of the order, which seems intermediate between crustaceans and insects proper, though nearest to the latter in mode of development, are given in the article. Arachnida. The external envelope is usually soft and tough, but not corneous, and is provided with papillæ, spines, bristles, and hairs, giving a furry or velvety, but generally disgusting aspect; the inner membrane of the skin is thin and colorless, and under it is a layer of colored vesicles and granules, the seat of the brilliant hues observed in many species. The body is divided into thorax and abdomen, the head is continuous with the chest, and there are no wings. From the inner surface of the cephalothorax are given off various processes serving for muscular insertions, forming at the bottom a solid horizontal plate, a kind of internal skeleton attached to the sternal plates by ligaments. The muscles are dirty yellow, transversely striated, and in general disposition like those of crustaceans; the principal masses are found in the cephalothorax, acting on the mouth, tactile organs, and legs; in those with an unarticulated abdomen there are numerous interlacing fibres encompassing this part, and sending processes among the organs and to the ventral tendinous ligament. The locomotive organs on the cephalothorax are four pairs of legs, of which the first in some resembles a posterior pair of metamorphosed jaws; each foot usually ends in two claws, but some have only one, and others three or four; each leg has usually seven joints; in some the tarsi have a great number of joints, which can be readily dropped off for the purpose of escape, and are reproduced at the time of the moult. The central part of the nervous system is situated around the œsophagus, sending nerves to the head and limbs; the splanchnic nerves for the viscera are well developed. The antennæ are transformed into the prehensile and masticatory mandibles; a delicate sense of touch resides in the palpi, and in the end of the feet, which are employed in constructing the web; the senses of taste, smell, and hearing have not been satisfactorily localized in any special organs. The eyes are smooth and simple stemmata, variously placed on the cephalothorax according to the mode of life of the species, usually eight, sometimes six, of different sizes, grouped symmetrically on the anterior median line or scattered on its lateral border, and directed accordingly upward or laterally; the diurnal species have the pigment greenish, reddish, or dark, and the nocturnal splendidly lustrous, as in the cats. The cheliceres or fangs have the form of biarticulated antennæ, the basal joint being very thick, and the terminal one a very sharp hook folded under the former when not in use, but capable of erection for defence or seizing prey, and having at the apex the opening of the duct of a poison gland; the first pair of maxillæ are changed into very long tactile or prehensile organs, the upwardly directed prominences of whose basal joints cover the entrance of the mouth, and serve as bruising organs; there is also a tumid hairy upper lip; the borders of the oral cavity may be approximated so as to form a suctorial canal, as well as the very short and horny œsophagus. The stomach is in the cephalothorax, and is divided behind the sucking apparatus into lateral halves extending in an arched manner in front, where they become contiguous or united into a ring, from which are given off four or five pairs of cæca directed toward the insertion of

the legs and palpi; the intestine arises from this annular stomach, traverses the abdomen on the median line, and before ending at the anus forms a cloacal dilatation; salivary glands exist in a cavity above the palate, communicating with the mouth by a slit in the upper lip; the liver is very large, enveloping most of the viscera, of a dirty yellow, made up of numerous branches and closely aggregated cæca, opening into the middle portion of the intestine. The blood is colorless; there is a heart, dorsal vessel with many constrictions, arteries, and vessels returning the blood from the respiratory organs. Respiration takes place both by pulmonary sacs and tracheæ, one or the other penetrating all parts of the body and limbs; there are two sacs occupying the base of the abdomen, containing more or less lamellæ; the blood penetrates to the respiratory system probably by a kind of infiltration. Distinct urinary organs are present, much ramified glandular tubes pouring a whitish or reddish secretion into the cloaca. There are two poison glands at the base of the chelicerес, communicating with their terminal hook. The apparatus which secretes the viscid transparent liquid, hardening into silk on exposure to the air, consists of glandular follicles and tubes, of various forms and arrangement, in the midst of the abdominal organs; in most spiders there are three pairs (in some two) of jointed spinnerets or obtusely conical papillæ behind the anus; the apex of these papillæ is surrounded by stiff bristles and hairs, and is dotted with numerous horny tubes, the prolongation of the excretory ducts; the number of the tubes varies from 1,000 in *epeïra* to less than 100 in the smaller species. The sexes are separate, and the eggs are numerous and spheroidal; a single impregnation is sufficient for several successive generations. There is generally only one brood in a year; the embryos are developed after the deposition of the eggs, and are hatched sometimes in a few weeks, and at others not till the following spring; the eggs are enveloped in a silken bag, from which the young are sometimes helped out by the mother; they resemble the parents except in size, and undergo no metamorphosis but change of skin; life may be prolonged for several years. Only the system of classification of Walckenaer will be briefly given here, as it places stress on the most interesting points in their economy, though not affording a sufficient basis for natural classification. He divides the spinning spiders into terrestrial and aquatic, as follows: I. *Venantes*, always running or leaping near their abode in search of prey, with the families: 1, *latebricolæ*, hiding in holes and fissures, like *mygale;* 2, *tubicolæ*, enclosing themselves in silken tubes (*dysdera*, *segestria*); 3, *cellulicolæ*, living in small cells (*scytodes*); 4, *cursores*, swift runners (*lycosa*, *ctenus*); 5, *saltatores*, leaping with agility (*attus*). II. *Vagantes*, wandering after prey, without fixed residence except while laying eggs, with family 6, *laterigradæ*, walking and running sideways or backward, and occasionally throwing out threads to entrap their prey (*thomisus*). III. *Errantes*, prowling in the neighborhood of their nests or threads, with families: 7, *niditelæ*, going abroad, but making a web whence issue threads to entrap prey (*clubiona*, *drassus*); 8, *filitelæ*, spreading long threads about their prowling places (*pholcus*, *clotho*). IV. *Sedentes*, spinning large webs and lying in wait in the middle or at the side, with families: 9, *tapitelæ*, spinning large webs of close texture in which they dwell (*tegenaria*, *agelena*); 10, *orbitelæ*, spreading orbicular or spiral webs of a regular open texture, living in the middle or at the side (*epeïra*); 11, *retitelæ*, spinning irregular webs of open meshes, remaining in the middle or on the side (*theridion*). V. *Natantes*, swimmers, spreading filaments in water, with family: 12, *aquitelæ* (*argyroneta*). —Spiders are found in every habitable portion of the globe, but are largest in warm climates; the males and females live separately, and the latter are most frequently seen and are considerably the larger; all are carnivorous, devouring living prey, sucking the juices and sometimes swallowing the fragments; the females are generally ready to attack and feed on the males, even in the reproducing season, and both sexes are fond of fighting, the vanquished being devoured; they can support long fasts, and remain torpid during the winter; they are very cleanly, and spend much time in clearing their limbs from dust and dirt by the toothed combs and brushes on the mandibles. In making their webs they accommodate themselves remarkably to circumstances, displaying great perseverance, ingenuity, and almost intelligence; they carefully guard their eggs, sometimes carrying about with them the silken bag which contains them, and are affectionate to their young, which in some cases devour their mother. They descend by their silken threads head downward, but climb up on them head upward, rolling them into a bundle during the ascent; the thread cannot be used a second time for the same purpose. When they wish to go from tree to tree, some let go a thread in the direction of the wind, and when it has reached the object they strengthen and pass over it, in this way travelling long distances without descending to the ground; their tiny cables are very abundantly seen in dewy mornings of spring and autumn; some small gossamer spiders even speed through the air buoyed up by their light threads. They are capable of some domestication; Pelisson, a prisoner in the Bastile, had a pet spider which came regularly, at the sound of a musical instrument, to get its meal of flies; and a spider raiser in France is said to have tamed 800, which he kept in a single apartment for their silk. The supply of the silk of the spider seems to be limited to sufficient to make six or seven webs in a season; it is very strong and very fine, and is used in astronomy for the divisions of the micrometer; ac-

cording to Leeuwenhoek, it takes 4,000,000 of the extremely delicate threads from the thousands of spinnerules to make a filament as large as a human hair; each thread of the spider as used in the web is made up of thousands of smaller ones; one or all the spinnerets may be used as occasion requires. Attempts have been made to render the silk of the spider available for manufacturing purposes, but with little success. (See COBWEB, and SILK SPIDER.) Spiders are eaten by many barbarous tribes of men, as the American Indians, S. Africans, and Australians; they also supply abundant food to many birds, reptiles, and carnivorous insects. They are affected and frequently destroyed by parasitic mites, and their eggs serve to nourish the young larvæ of several species of ichneumon flies; the smallest puncture in the chest or abdomen is fatal from the impossibility of arresting the escape of the nutrient fluids; their colors fade rapidly after death, even in preservative liquids. A single wound from a spider will soon kill the domestic fly; the large crab spiders of South America (*mygale*) leap upon and destroy humming birds and creepers, and produce dangerous and occasionally fatal symptoms in debilitated persons; every physician knows that even the bite of the smaller spiders of temperate climates may pierce the skin in certain localities, and cause painful irritation.—For descriptions and figures of the species of the United States see papers by N. M. Hentz in vols. iv., v., and vi. of the "Boston Journal of Natural History" (1841–'57), now in course of republication, with figures by the same society (1875). The genus *mygale* (Walck.) contains the largest of the spiders, of dark colors, nocturnal, living in galleries which they make in the ground, in clefts of trees, crevices in rocks, or among leaves. The crab or bird spider of South America (*M. avicularia*, Walck.) is about 3 in. long, its legs extending over a space of 8 or 10 in.; the body is very hairy and blackish, and the ends of the feet are reddish; it is very powerful, jumping upon and killing small birds; it spins no web; its cell is in the form of a pointed tube, of a white firm tissue. There are some large species in the southern states, feeding principally on the large orthoptera, believed by the Indians to possess valuable medicinal properties, and eaten accordingly. A large species (*M. Hentzii*) in Texas is called there tarantula; other species in California are called trap-door spiders, from their hollowing a more or less conical nest, about 3 in. long and an inch in diameter, in the clayey soil; the nests are lined with silk, with an accurately fitting lid, so arranged that the inmate can firmly hold it down against ordinary enemies; the cover outside so nearly resembles the surrounding earth in color and roughness as to be recognized with difficulty. For an account of the curious devices in the interior arrangement of these nests, see "Proceedings of the Boston Society of Natural History" for 1875. The species of the genus *lycosa* (Latr.) are well called wolf spiders, for they are the most savage, voracious, and quarrelsome of the family; they make no web, but prowl on the ground by night, running very fast, and hiding in nat-

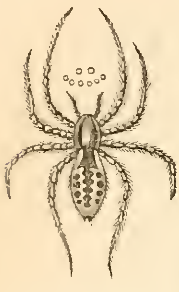


Wolf Spider (Lycosa fatifera).

ural or artificial holes in the ground, which they strengthen with silk; the females carry the cocoon attached to the posterior part of the body, and defend it with the greatest courage, some guarding it under stones; the young when hatched climb on the abdomen of the mother, giving her a monstrous appearance, and are said finally to devour her. One of the largest and most common species is the *L. fatifera* (Hentz), about $1\frac{1}{2}$ in. long, hairy, and bluish black; it is as large as the tarantula of Europe, which belongs to this genus, and is not uncommon in Massachusetts; it must rarely bite persons, from its habits and haunts, though its poison may produce ill consequences if introduced under the skin, not however to be compared with those from the *mygale* of the tropics; it is very savage and tenacious of life. The genus *attus* (Walck.) includes the small species commonly called jumping spiders; they make no web, wander in search of prey, and cast the skin and hibernate in silken-valved recesses; they are common in summer on walls and windows in the sun, walking by jerks, crawling stealthily up to flies, and jumping with rarely failing accuracy when near enough. The best known jumping spider in New England is the *A. familiaris* (Hentz), about $\frac{1}{2}$ in. long, pale gray and hairy, the abdomen blackish with a grayish angular band; it is very common in houses, dwelling in cracks on the outside, and wandering about in the sun in search of food; before leaping at a fly, it fixes a thread to secure itself from falling. It is widely dis-

Jumping Spider (Attus familiaris).

tributed. Its backward gait is as rapid as its forward. The long-legged spider (*pholcus Atlanticus*, Hentz) is about $\frac{1}{3}$ in. long, with a narrow body and very long slender legs, which are easily separated at the will of the animal when seized by them; the color is pale gray; it is common in corners of dark and rarely used rooms, in cellars and churches, spinning a very loose web crossed in all directions, which is very rapidly shaken when touched; the eggs are carried in the jaws, enveloped in a silken bag, and about 200 young are rolled in a ball not larger than a pea; the food consists of very small insects, though they eagerly devour each other, especially when young; they are favorite food for wasps, who store their cells with them as a provision for their young. The European representative is the *P. phalangioides* (Walck.). The common house spider (*tegenaria medicinalis*, Hentz) is found in every house and cellar in the land; the cheliceres are moderate, and the fourth pair of feet the longest; the upper two spinnerets are remarkably larger than the others, and the four anterior eyes in a line curved backward. It is sedentary, making in an obscure corner a large and nearly horizontal web, with a tubular habitation at the upper part; it is not quite an inch long, varying in color from pale brown to bluish black according to the absence of light in its retreat, with a dark band on each side of the thorax, and the abdomen and feet varied with blackish; the specific name is derived from the use formerly made of the web in cases of fever. In *epeïra* (Walck.) the web is either vertical or inclined, and the threads are arranged in a more or less regularly geometrical manner, radiating from the centre, where the animal remains, according to the absence of disturbing causes. The common epeïra (*E. vulgaris*, Hentz) is less than an inch long, with a full body, gray with blackish abdomen, with winding white marks and a white cross in the middle; it may almost be said to be domesticated, its geometrical web being so often met with near the windows of houses. The webs of the spider, like the cells of the bee, are not geometrically perfect; their irregularity can generally be detected even by the unassisted eye.—The long-legged, round-bodied spider, commonly called "father long-legs," is one of the trachearian arachnids, so named from the respiratory organs being radiated tracheæ, receiving air through two stigmatic openings; it is the harvest spider (*phalangium cornutum*, Linn.) in Europe, and an allied species in the United States. The eyes are two; the mandibles end in double pincers; the legs are eight, slender, and when separated from the body exhibit signs of irritability for some time. They are harmless, preying upon mites and small insects, and are very common in the fields.—Many small spiders fly about on their silken threads, carried far by currents of wind.—Of the *arachnida*, the scorpions appeared first in the carboniferous epoch, and the true spiders in the Jurassic age.—See "American Naturalist," vols. v. (May, 1871), vi. (March, 1872), and viii. (October, 1874), for descriptions and figures. See also various articles on spiders by Dr. Burt G. Wilder, in "Proceedings of the American Association for the Advancement of Science," 1873, and the "Popular Science Monthly," April, 1875. For further details see chap. xviii. of Rennie's "Insect Architecture," the works of Kirby and Spence, and particularly the *Histoire des insectes aptères* (*Nouvelles suites à Buffon*), by Baron Walckenaer (vols. i., ii., and iii., 8vo, Paris, 1837–'44). (See MITE, SCORPION, and SILK SPIDER.)



Common House Spider (Tegenaria medicinalis).

Common Epeira (Epeira vulgaris).

**SPIDER CRAB,** or **Sea Spider,** the name of several species of ten-footed short-tailed crustaceans of the crab family, and more particularly of the *libinia canaliculata* of North America and the *maia squinado* of Europe. In *L. canaliculata* (Say) the thorax is densely hairy, with spines on the borders and on the back; the rostrum is grooved at the tip and channelled between the eyes; the anterior feet are unarmed and granulated, the hands elongated, and the fingers white at tip. The body is convex and heart-shaped, 4 in. in diameter, the long legs spreading over 12 to 16 in.; the eyes small and very short; it is blackish green,

Spider Crab (Maia squinado.)

very active, and ferocious-looking; it is often caught in nets, and from the wharves and bridges of New England; it is not used for food. The *M. squinado* (Latr.), or corwich, is reddish, and 4 to 6 in. long; the body is covered with spines and hairs; it is found along the coasts of W. Europe and in the Mediterranean, making its appearance in Great Britain about May and remaining till September, greatly annoying the fishermen by frightening away fish and larger crabs and lobsters from the nets by its constant movements; it is eaten by the poorer classes; the young when first hatched are very unlike their parents; as many as 80,000 eggs have been found on a single female. The ancients believed it to be endowed with reason, and represented it suspended from the neck of Diana of Ephesus as an emblem of wisdom; it is also figured on their medals.—*Lithodes arctica* (Latr.) is also called spider crab; the body is spiny, and the long beak bifurcated; the hands small and unequal, the limbs long and hairy, and the fifth pair imperfect; it is reddish yellow, spreading about 20 in., and a hideous-looking species; it is found on the coast of Norway.

**SPIDER MONKEY, or Coaita.** See MONKEY.

**SPIEGEL, Friedrich,** a German orientalist, born at Kitzingen, near Würzburg, July 11, 1820. After studying at Erlangen, Leipsic, and Bonn, and spending several years in travel, he became in 1849 professor of oriental languages at Erlangen. Besides editing several Persian works, he has published *Einleitung in die traditionellen Schriften der Parsen* (2 vols., Leipsic, 1856–'60); *Die altpersischen Keilinschriften* (Leipsic, 1862); *Eranische Alterthumskunde* (2 vols., Leipsic, 1871–'3); and several grammars and minor treatises bearing on Iranian antiquities, religion, language, literature, and ethnology.

**SPIELHAGEN, Friedrich,** a German novelist, born in Magdeburg, Feb. 24, 1829. He studied at Berlin, Bonn, and Greifswald, and devoted himself to literature. His works are: *Clara Vere* (1857); *Auf der Düne* (1858); *Problematische Naturen* (1860, English translation "Problematic Characters," by Prof. Schele de Vere, New York, 1869), and its continuation, *Durch Nacht zum Licht* (1861; English translation, "Through Night to Light," by the same, New York, 1869); *In der zwölften Stunde* (1862); *Die von Hohenstein* (1863; English translation, "The Hohensteins," by the same, 1870); *Röschen vom Hofe* (1864); *In Reih und Glied* (1866); *Unter den Tannen* (1867); *Hammer und Amboss* (1869; English translation, "Hammer and Anvil," by William Hand Browne, 1873); *Die Pioniere* (1871); *Alle Zeit voran* (1872); *Was die Schwalbe sang* (1873; English translation, "What the Swallow Sang," 1873); *Ultimo* (1874); and *Liebe für Liebe* (1875), a drama, which has been played in Leipsic. He has translated Curtis's "Howadji" (Hanover, 1857), Emerson's "English Traits" (1858), American poems by various authors (Leipsic, 1859; 3d ed., 1871), Roscoe's "Lorenzo de' Medici" (1859), and several of Michelet's works. A collected edition of his works has been published at Berlin (10 vols., 1872–'3).

**SPIESS, Heinrich,** a German painter, born in Munich, May 10, 1832, died there, Aug. 8, 1875. He was the son of an engraver, completed his studies under Kaulbach, whom he assisted in his cartoon of "The Crusaders," and executed a celebrated copy of his "Angel carrying a Dead Child to Heaven." In 1855 he was employed by Kaulbach in decorating the Wartburg, and he was one of the school of artists known as "young Munich," led by Faltz. In 1856 he obtained a prize for his "Jacob Wrestling with the Angel," and in 1861–'2 he painted for the museum of Munich the great frescoes relating to the pilgrimage of Duke Henry the Lion to Jerusalem, and to his quelling the disturbances at St. Peter's at the coronation of the emperor Frederick I.

**SPIKE.** See NAIL.

**SPIKENARD.** The ancients, under the name of *nard* (Heb. *nerd*; Gr. *νάρδος*; Lat. *nardus*), made use of several roots having properties similar to valerian; one having its flowers (or leaves) in spikes was called spikenard (*nardus spicatus*), and, according to Boyle, was the plant now known to botanists as *nardostachys Jatamansi*, which belongs to the valerian family and is found in Bengal; it is now quite out of use except in the East. There were also a leafy nard, a rooting nard, and others designated by the names of the countries producing them.—The plant called spikenard in this country is *aralia racemosa*. Other species of *aralia* are mentioned under GINSENG and SARSAPARILLA. This has a herbaceous, widely branched stem, 3 to 5 ft. high, from a perennial root; the large decompound leaves ternately or quinately divided with heart-ovate leaflets; the flowers, in umbels, which are united to form large panicles, are polygamous or perfect, greenish white, and succeeded by small dark purple berries. The plant is found from Canada southward, and is sometimes seen in gardens of medicinal plants; both root and berries have a warm, aromatic taste, and a tincture of them made with spirits is in some parts of the country a popular domestic stimulant. The root appears to be a stimulant diaphoretic, and was held in high esteem by the Indians.

**SPINACH,** a plant of the *chenopodiaceæ* or goosefoot family, *spinacia oleracea*, the leaves of which are used as food. According to some authors, the botanical and common names are derived from the Latin *spina*, a thorn, as some varieties have prickly seeds; others say that it is called in various languages by names equivalent to *Hispanica*, Spanish. Spinach was not known to the ancients, and it was a novelty in Europe in the 16th century. It is probably a native of western Asia. The plant is cultivated both as an annual and a biennial; it has petioled, ovate or triangular, succulent leaves;

the flower stalks are 2 to 3 ft. high, hollow, furrowed, and branching; the apetalous flowers are diœcious, the male in long spikes, the female in clusters at every joint of the stem; the calyx in the pistillate flowers hardens and forms an involucre to the seeds, and in some

Spinach.

varieties has two or three horns on the sides. But few varieties are known, the principal being the prickly, the smooth-seeded, and the lettuce-leaved.

**SPINAL CORD.** See Nervous System.

**SPINAL DISEASES,** the common appellation of diseases affecting the bony spinal column and the spinal cord and its membranes. The principal diseases of the spinal column are lateral curvature and angular curvature or Pott's disease, sometimes called scrofulous caries of the spine. Lateral curvature is the more common, and usually affects girls between 10 and 20 years of age and women of sedentary habits. Those who take much exercise are not often its subjects, as the symmetry of the spinal column is preserved principally by the action of the muscles. In its early stages lateral curvature is apt to escape detection, the first notice taken of it being generally the prominence of one shoulder, more frequently the right, or some elevation of the hip. The curvature is always double; that is, when a curve has taken place in the upper dorsal region, a complementary curve in the opposite direction will be found in the lumbar region, giving the spine a sigmoid appearance. Lateral curvature is also usually accompanied with more or less rotation of the spinal column, due to the action of the ribs, which are carried down on one side more than on the other. The treatment in slight cases is good diet, pure air, and well regulated exercise, and sometimes the administration of ferruginous tonics. When the curvature is considerable, stays, braces, and bandages will be of service; but they must not take the place of exercise, and should be regarded as expedients rather than curative agents. Posturing and great attention to the position of the body when lying in bed should be employed as the chief hygienic measures.—Angular curvature, or Pott's disease, is caused by inflammation of the bodies of the vertebræ and of the intervertebral substance, usually commencing in the latter. It is often accompanied with tubercle, and some hold that it is essentially a scrofulous disease. The immediate cause of the curvature is caries, and it most commonly shows itself during the period of bodily development, usually attacking the lower dorsal region. Recovery sometimes takes place without pus making its appearance, but "spinal abscess" is a common accompaniment, the pus pointing in the groin, and finding its way from the dorsal region beneath the fascia of the psoas muscle, under Poupart's ligament, forming what is known as "psoas abscess." The pus sometimes burrows beneath the muscles and involves the whole thigh. The abscess sometimes appears above Poupart's ligament, and sometimes in the loin, forming in the latter case "lumbar abscess." When the cervical vertebræ are affected, the abscess appears in the pharynx. Angular curvature is not difficult of diagnosis, as the ill health, suppuration, and deformity are highly indicative. The initiatory symptoms are also not obscure, the principal being the persistent local pain and difficulty in bending the back, accompanied by great general disturbance and hectic fever. After curvature has taken place recovery is always accompanied by anchylosis, from union of newly formed bony tissue. The treatment requires careful attention to the general health, including good diet and the employment of tonics and alteratives, such as iron, quinine, iodine, and cod-liver oil. The local applications of fomentations and leeches and of counter-irritants are also serviceable. Setons, moxas, and mercury, as tending to exhaust the strength, are to be avoided. On getting up, the patient's back should be supported by some kind of mechanical appliance. The abscess should not be opened too hastily, for it may be absorbed; but when it progresses steadily a free opening should be made, under a piece of lint saturated with carbolated oil, to prevent entrance of air.—The principal diseases of the spinal cord, that is, the pathological conditions to which it is subject, are spinal meningitis, myelitis, and spinal apoplexy. These conditions give rise to or aid in developing a variety of symptoms, which in turn are classed as diseases, such as paralysis (including paraplegia and spinal hemiplegia), general spinal paralysis, and locomotor ataxia. The diseases known as progressive muscular atrophy and infantile paralysis, although their causes are not clearly made out, are generally considered to be connected with affections of the spinal cord.—*Spinal Meningitis*, or inflammation of the membranes of the spinal cord, corresponds to inflammation of the corresponding membranes of the brain, and rarely occurs in the arachnoid and pia mater independently of cerebral meningitis, except in cases pro-

duced by injuries or diseases of the spinal column, or structural affections within the spinal canal. The affection is therefore almost always cerebro-spinal. (See BRAIN, DISEASES OF THE.) Fibrinous exudation, serous effusion, and generally pus follow the inflammation, the serum being often tinged with blood. The attack may be acute or chronic. When acute it extends over the whole or greater part of the membranes of the cord, but chronic meningitis is usually limited in extent, and the inflammation is accompanied by fewer pathological changes. Acute spinal meningitis is regarded by many authorities as incurable, while others assert that mild cases sometimes recover. The symptoms are pain in the spine and in the extremities, increased more by movements of the body than by pressure. There are also spasms of the muscles of the back, either persistent or convulsive, often producing that rigid bending of the body backward called *opisthotonos;* also tonic contraction of the thoracic muscles, and consequently difficulty of breathing. These symptoms are followed by paralysis, caused by pressure of the products of the inflammation (fibrinous exudation, effused serum, or pus). The paralysis may be confined to the lower extremities, or it may be general, and it is usually limited to motion, while there is preternatural sensibility. The disease runs a rapid course, often terminating fatally within a week. Apnœa, or suspension of the respiratory function from involvement of the roots of the respiratory nerves, is the usual mode of death. The treatment, in cases not dependent on blood poisoning, comprises the application of cups and leeches, setons, moxas, blisters, antimonial ointment, and croton oil, and also of belladonna and chloroform and the warm bath to relieve pain. Iodide of potassium is often given in large doses to promote absorption of the products of inflammation. The diet should be nutritious, but some authorities interdict the use of animal food.—*Epidemic Cerebro-Spinal Meningitis.* Although there are cases of cerebro-spinal meningitis which are idiopathic, and it is therefore then to be regarded as truly a spinal disease, the vast majority of cases are of epidemic origin, and the spinal lesions are therefore secondary affections, depending upon blood poisoning. The disease is then called epidemic cerebro-spinal meningitis, a dangerous affection which has of late prevailed extensively in different parts of the United States and Europe. From the appearance of certain spots upon the skin during the course of the disease it has been proposed to call it spotted fever; but as these spots are not a constant accompaniment, the proposition has not been adopted. The name was given to an epidemic which prevailed in New England between 1807 and 1816, which is supposed by many to be the same disease, but the identity is not established. Some have regarded epidemic cerebro-spinal meningitis as a variety of typhus, but the greater suddenness of the attack and the absence of the mulberry rash of typhus indicate a difference of origin. The disease usually begins with a chill, followed by great vertigo, violent headache, obstinate vomiting, and muscular stiffness, which soon passes into tetanus. The face is pale, the pupils contracted, the conjunctivæ red, and the skin exceedingly sensitive. The head is strongly drawn back, even at the end of the first or second day, and there is delirium, which soon passes into the stupor of coma. The bodily temperature is variable, the highest occurring in the most rapidly fatal cases. Wunderlich recognizes three forms. One, rapidly fatal, is accompanied by a high temperature, which rises toward the approach of death to 108° F., and continues to rise for some hours after death. A second form is slight, with fever of short duration and very irregular course; a third is protracted, but marked by very great variation of temperature. The pulse at the commencement is usually not more frequent, often slower than normal, and is often intermittent. It increases with the disease, but rarely reaches more than 100 beats per minute until near the fatal termination, when it becomes very small and frequent. The urine is increased in quantity and deposits a large amount of urates, and there is sometimes hæmaturia. In from 20 to 60 hours after the commencement a peculiar eruption usually appears upon the skin of the neck, abdomen, back, arms, legs, and face, composed of distinct dark red or purple spots, somewhat larger than a pin's head. They are not raised above the surface, and do not disappear upon pressure; sometimes they do not become visible till after death. The tongue is moist and creamy until the spasmodic stage is established, when it becomes dry, dark-colored, and covered with sordes. The duration of the disease varies from a few hours to several weeks; cases are reported as terminating fatally in three or four hours, but more than half the deaths occur between the second and fifth days. Convalesence may begin from the fifth day to the fourth week or later, and is always tedious, relapses being common and often fatal. The treatment is various. Bloodletting has been practised, but with unfavorable results, as might be expected from the depression of the vital powers. The use of quinia is regarded with favor, and opium has its advocates; ether and chloroform have been used by inhalation as sedatives; and tincture of cantharides is said to be of service in cases marked by extreme depression. Counter-irritation, by the actual cautery applied along the spine, or by blisters, has been followed by alleviation of symptoms. The use of cold compresses to the head, and of leeches behind the ears, is also recommended.—*Myelitis,* or inflammation of the body of the spinal cord, is similar to cerebritis, or inflammation of brain tissue, and may terminate fatally either in the acute inflammatory stage, or by softening, by unde-

fined suppuration, or by abscess; the most common mode being by softening, the disorganization involving the whole cord or only one column. Acute myelitis, except as a sequel to spinal meningitis, or when caused by a wound, is rare. The symptoms are similar to those of spinal meningitis, and it must be borne in mind that the two diseases are rarely unconnected, one inducing the other, the primary disease being predominant. Paralysis often comes on in a few hours, and is more pronounced than in meningitis. It is usually confined to the lower limbs, but involves the upper extremities when the affection reaches as high as the fifth pair of cervical nerves. When the inflammation is in the upper cervical and occipital sections of the cord, death may take place almost immediately from arrest of respiration. In chronic affections the palsied limbs usually become atrophied, and induration or sclerosis of the cord ensues, caused by an abnormal growth of connective cellular tissue, accompanied by atrophy of nerve tissue. Myelitis attacks subjects of all ages, but more commonly adults, and is more frequent in the male than in the female sex. The treatment depends upon the intensity of the attack; in the majority of acute cases little more can be done than to endeavor to relieve the most urgent symptoms, such as promoting the action of the bowels and preventing retention of urine. Strychnia may be sometimes used in the earlier stages of acute myelitis with advantage, and so may the electric current, and in chronic cases with decided benefit.—*Spinal Apoplexy*, or hæmorrhage within the spinal canal, may be caused by injuries to the spinal membranes, or by degeneration of the cord. Extravasations of blood derived from the membranes are chiefly formed in the lower part of the spinal canal, and the changes found in the substance of the cord, and the blood clot, are similar to those in cerebral apoplexy, as described in BRAIN, DISEASES OF THE. The effusions cause irritation, pain in the back, spasm of muscles below the seat of injury, and finally paralysis. Spinal apoplexy is distinguished from other paralytic affections by observing that the attending paralysis is usually not accompanied by fever or general loss of nervous power, and other symptoms. The treatment is rest and attention to the general state of the health, with moderate counter-irritation.—*Progressive Locomotor Ataxia* (Gr. ἀταξία, want of order). This name has been given to a form of paralysis characterized by disorderly muscular movements in consequence of loss of coördinating power, which has been recognized only within the present century. Duchenne described it in 1858–'9 more fully than any previous author, and gave it its name. Its pathology and location had been pointed out by Dr. Todd, but its causes were more fully investigated by Duchenne. Romberg called the disease *tabes dorsalis*, and it has also been called myelo-phthisis. There is not much loss of muscular power, except as general debility advances, but the diminution of sensation is more marked. The patient has a peculiar gait in walking, throwing the legs out in a jerking and uncertain manner, and when the disease is pretty well advanced throws his arms out like a man balancing on a tight rope. He seems to be somewhat in the condition of one who is walking in the dark over uneven ground. That which has been termed the "muscular sense" is impaired. The harmony of the reflex impressions by which muscular contractions are regulated and the limbs moved and adjusted is so far disordered that either too much or too little contraction is produced at each step. The foot will be thrown out and not properly brought to the ground, and as if to relieve this deficiency the patient by an effort of the will brings the foot down at the next step with too much force. A chief characteristic is the inability to walk or stand with the eyes closed. It needs the assistance of sight to keep the body erect. The walk is uncertain and reeling even with the eyes open, but if the patient shuts them he will fall. As the disease progresses, the upper extremities become affected, and it is difficult for the patient to tie his cravat or button his coat, or perform any motions requiring coördination of muscular movements. There are certain premonitory symptoms which have been relied upon, such as fugitive shooting pains in different parts of the body, of a neuralgic character; but they are often found unconnected with the disease, and often absent when the disease is present. One of the early symptoms is incontinence of urine consequent upon relaxation of the sphincter muscle, and an irritable state of the mucous membrane of the bladder; and there is often increased sexual activity, which however declines in the progress of the complaint, and at last ends in impotence. A characteristic feature of the disease is transient localized paralysis, such as that of the sixth pair of cranial nerves, which supply the external straight muscle of the eyeball, or the third pair, which supply the elevators of the eyelid, and the constrictor of the iris, so that there is drooping of the lid and dilatation of the pupil, one eye being usually affected more than the other, and vision is sometimes impaired or lost. In some cases these paralytic affections are permanent. When the paralysis of the limbs begins on one side, which it frequently does, it is much oftener upon the left than the right side. Before the disease is much advanced, although the gait is irregular and jerking, the patient retains the power to walk considerable distances in spite of the great exertion which he makes. After a time the power of locomotion is lost, the patient is confined to his bed, he becomes unable to feed himself, and speech is difficult, sometimes impossible. The disease is distinguished from ordinary paraplegia, or anterior spinal paralysis, by the careful and circumspect

gait of the latter; and although it has some symptoms in common with general paralysis of the insane, the totality of them will enable a diagnosis to be made. The prognosis is extremely unfavorable; very few cases ever cease progressing, and fewer still recover. The most that can be hoped for is that the disease will remain stationary or progress slowly. Sometimes it develops rapidly, but generally years elapse before the fatal termination, and in most cases death is produced by some intercurrent affection. The most marked pathological condition is induration or sclerosis of the posterior columns of the spinal cord, involving the gray substance and the roots of the posterior nerves. The sclerosis is an abnormal development of the connective tissue, and produces atrophy and degeneration of the nerve fibres. Among the most frequent causes of progressive locomotor ataxia are exposure to wet and cold, mechanical injuries, and syphilis. Severe blows and falls, and the concussion produced by railroad collisions and similar shocks, often occasion that congested condition of the spinal cord which ends in locomotor ataxia. Excessive and continued mental exertion, and anxiety or grief, by producing a hyperæmic condition of the brain and spinal cord, sometimes bring on the disease, especially if there is a constitutional fault. Excessive indulgence in the sexual passion has been regarded as a frequent cause, but some revision of opinion will need to be made on this point. The irritable condition of the cord often produces a morbid sexual desire which has not previously been characteristic of the patient, and in which he has not inordinately indulged, and many are now inclined to believe that the cause in question has been overrated. Males are more often affected than females. Of 60 cases analyzed by Carre, 42 were males and 18 females. It is especially a disease of middle life, between the ages of 30 and 50, although it sometimes occurs before 30, and Trousseau reports a case in a patient 80 years old. The disease is sometimes associated with general paralysis of the insane, sometimes one and sometimes the other disease appearing first. There is no particular plan of treatment established. In Europe and in this country success has seemed to attend the employment of the interrupted galvanic current (faradization), and cases are reported as having been benefited by the continuous current of a powerful battery. (See Medical Electricity.) Long continued and well regulated gymnastic exercises were successfully employed by Eisenmann in two out of six cases. The iodide and the bromide of potassium are beneficial. Counter-irritation with blisters, issues, and cautery has been found of no avail. Moderate exercise and a well regulated nutritious diet, to promote as much as possible the healthy assimilation of tissue, should be regarded as a main indication. Galvanism promises to be a powerful adjunct, but time is still required to measure its importance.

**SPINDLER, Karl**, a German novelist, born in Breslau, Oct. 16, 1796, died at Freiersbach, Baden, July 12, 1855. He was educated at Strasburg, joined in Germany a company of strolling players, and resided from 1832 at Baden-Baden. His reputation rests on his historical romances, *Der Bastard* (3 vols., Zürich, 1826), *Der Jude* (4 vols., Stuttgart, 1827), *Der Jesuit* (3 vols., 1829), and *Der Invalide* (5 vols., 1831). His complete works include 102 volumes (1831–'54), besides minor novels contained in his periodical publication *Vergissmeinnicht* (1830–'55).

**SPINE.** See Skeleton, and Spinal Diseases.

**SPINEL** (Fr. *spinelle*), a mineral, sometimes ranked among the precious stones, occurring in regular octahedrons and dodecahedrons, variously modified; hardness, 8; specific gravity, 3·5 to 4·9. The color is commonly some shade of red, but is sometimes blue, green, yellow, brown, black, and rarely almost white. When pure, it is a compound of magnesia 28, alumina 72; but the magnesia is often replaced to some extent by one or more of the protoxides of iron, zinc, or manganese, or by lime, and the alumina also by peroxide of iron; hence the numerous varieties of the species. These are denominated according to their colors, and some among them are often supposed to belong to other species. The black varieties are called pleonaste; the scarlet, spinel ruby; the rose red, balas ruby; the yellow, or orange red, rubicelle; the violet, almandine ruby; and the green, ceylonite. The *goutte de sang* of the jewellers is of blood-red or cochineal color. The mineral is infusible before the blowpipe alone, and is not attacked by acids. The most valuable spinels are found in Ceylon, Siam, and other eastern countries, in the form of rolled pebbles in river beds. They are also found in New Jersey, New York, and central Massachusetts. Perfect specimens fit for jewelry are rare; if of more than four carats, they are sometimes rated as worth half as much as diamonds of equal size. The red varieties are said to be sold for true rubies, from which they are with difficulty distinguished; and many of the others are often confounded with other precious stones of similar hardness and specific gravity. The optical properties alone may decide without analysis between the colorless spinel and the limpid topaz of Siberia. Dufrénoy was obliged to apply the test of polarization of light to a white cut spinel from India, which was supposed to be either a diamond or a white emerald. He describes one of a clear crimson with a violet tint, weighing 1,129 grains, of great beauty, valued at 100,000 to 110,000 francs.

**SPINK**, a S. E. county of Dakota, recently formed and not included in the census of 1870; area, about 800 sq. m. It is intersected by the Dakota or James river. The surface is rolling.

**SPINNING.** See Cotton Manufacture, Linen, Rope, and Wool, Manufactures of.

**SPINOLA, Ambrosio de,** marquis, a Spanish soldier, born in Genoa in 1569, died near Casale, Piedmont, Sept. 25, 1630. He was a son of the marquis Filippo Spinola, a party leader at Genoa and a rich Levant merchant, and his mother was a princess of Salerno. After filling local offices, he joined his brother Federigo, who had become admiral in the Spanish navy, in the war against the Dutch and English. In 1602 he arrived in the Netherlands with a corps of 9,000 veterans which he had raised and equipped at his own expense, and with which he came to the rescue of the Spaniards under Archduke Albert against Maurice of Nassau. His brother fell in a naval battle, May 26, 1603, and he was desired to succeed him as admiral, but preferred to become chief commander of the Spanish army in the Netherlands. He covered himself with glory in September, 1604, by compelling the surrender of Ostend, which had been besieged since July, 1601. After other operations against Maurice, who regarded him as next in genius to himself, he was in 1609 among the first to favor the truce for 12 years concluded at the Hague. During the truce he commanded Spanish troops in Germany. In 1622 he took Jülich; in the same year he was repulsed at Bergen-op-Zoom, but made a skilful retreat; and in 1625 he captured Breda after a siege of ten months. He afterward reluctantly became commander of the Spanish army in Italy, and died during the siege of Casale.

**SPINOZA** (also written SPINOSA), **Baruch,** or **Benedict,** a Dutch philosopher, born of Jewish parents in Amsterdam, Nov. 24, 1632, died at the Hague, Feb. 21, 1677. He translated his Hebrew name Baruch into Latin as Benedictus. His father, a Portuguese merchant, had fled from persecution to Holland. The son was educated for the rabbinical profession, and gained the admiration not only of the masters of the Hebrew school in Amsterdam, but also of the chief rabbi Morteira, who became his instructor in the Talmud and the Cabala. But he was suspected even before his 15th year of verging toward heresy, and was accused of contemning the law of Moses and denying the immortality of the soul and the reality of angelic communications. Summoned before a rabbinical tribunal, he anticipated excommunication by withdrawing himself from the synagogue. He neglected the repeated summons of the synagogue to trial, and at length in 1656 the *anathema maranatha*, or greater excommunication, was uttered against him. He was already familiar with the Portuguese, Spanish, Italian, German, and Flemish languages, and was studying Latin under the physician Van Ende. This language introduced him not only to Christian learning, but also to the literature and philosophy of classical antiquity, then studied with special enthusiasm, and opened to him the writings of Descartes. The Talmud makes it the duty of scholars to learn some mechanical art. Spinoza had therefore, while in the synagogue, learned the art of polishing lenses, by which he gained his subsistence during the remainder of his life. Exiled from Amsterdam by the magistrates on application of the rabbis, he lived for a short time with a friend in the vicinity, went thence to Rhynsburg, near Leyden, whence in 1664 he removed to Voorburg, near the Hague, and finally yielded to the request of his friends to reside entirely at the Hague, all the leisure time saved from labor being given to philosophy. After the death of his parents his sisters attempted to deprive him of his portion of the inheritance. Having established his rights by law, he contented himself with taking only a bed. In 1673 the professorship of philosophy in the university of Heidelberg was offered to him, the condition being that he should teach nothing opposed to the established religion; but he declined it. When it was proposed to obtain a pension for him from Louis XIV., he replied that he had nothing to dedicate to that monarch. Meanwhile he endured the toil and wants of poverty, and was wont to protract his labors into the night. His first work, *Renati Des Cartes Principiorum Philosophiæ Pars I. et II., More Geometrico Demonstratæ* (Amsterdam, 1663), which contains in an appendix the germ of his *Ethica*, immediately gave him the reputation of a great philosopher. His second work, *Tractatus Theologico-Politicus*, published anonymously in 1670, treats the relation between church and state, and is entirely distinct from his philosophical writings. Religion, he maintained, is neither doctrine nor *cultus*, but is essentially the love of God, the expression of which is piety and obedience, and its worship is virtue. Doctrines belong to the domain of philosophy, actions to that of the state, feelings to that of religion. Absolute freedom should prevail in the first and the last, while the second should be regulated by the state in the interest of order and tranquillity. He therefore advocated a state religion, which should ordain ceremonials, but leave liberty of thought inviolate. He referred for support of his opinions to the Bible, in which he distinguished between the facts narrated and the coloring received from the minds of the writers, and thus laid the foundation of the rationalistic school of interpretation in Germany. Numerous refutations of his work appeared, especially from Cartesian theologians; yet it was read throughout Europe, being published and translated with divers devotional, historical, antiquarian, and even medical titles employed to disguise it. Averse to controversy, Spinoza withheld his other and more important works, which were first published after his death by his friend Ludwig Meyer, a physician of Amsterdam. His health, never vigorous, suffered from unremitted confinement and devotion to study. He sometimes passed entire months without leaving his chamber, occupied only with meditation, conversation with his friends, and answering letters on philosophical sub-

jects. In a letter dated July 15, 1676, he promises further explanations "if my life be continued." After his death his manuscripts were, in accordance with his order, sent to his publisher at Amsterdam, and within a year appeared *Ethica, Ordine Geometrico Demonstrata*, containing his philosophical doctrine, which had been written between 1663 and 1666; *Tractatus de Intellectus Emendatione*, and *Tractatus Politicus*, both of them fragments; a collection of letters to Oldenburg, Simon de Vries, Ludwig Meyer, and Bleyenbergh; and a fragmentary sketch of Hebrew grammar, aiming to give it a logical development.—The whole system of Spinoza is a demonstration from the eight definitions and seven axioms of the first book of the *Ethica*. According to him, it follows from the definition of substance that it is necessary and infinite, that it is one and indivisible, and that it is therefore God, the only self-existent, all-perfect, and absolutely infinite Being. Nothing exists except substance and the modes of its attributes. Substance cannot produce substance, and therefore there is no such thing as creation, no beginning or end, but all things have necessarily flowed from the Infinite Being, and will continue to flow on for ever, in the same manner as from the nature of a triangle it follows, and will follow from eternity to eternity, that the angles of it are equal to two right angles. Of the infinite number of infinite attributes of Deity, only two are known to us, extension and thought, the objective and subjective of which he is the identity. Body is a mode of extension, which being illimitable cannot be divided; thought is also infinite, and mental acts are modes of it. It follows also that God is the only free cause (*causa libera*); all other things and beings move by fixed laws of causation, without free will or contingency. He is the *causa immanens omnium*, not existing apart from the universe, but expressed in it, as in a living garment. As conceived in his attributes simply and alone, he is *natura naturans;* as conceived in the infinite series of modifications which follow from the properties of these attributes, he is *natura naturata*. Between bodies, the modes of extension, and ideas, the modes of thought, there is a constant parallelism. The duality everywhere appears, and a soul belongs alike to animals, vegetables, and minerals. Man is a complex example of this compound. There is no reciprocal influence between the bodily and the ideal world, but a perfect harmony, since it is the same substance, affected in the same manner, but expressed under each of the two attributes. Individual beings, whether ideas or bodies, are modes, the changing forms of substance, to which they are related as wavelets to the ocean. The finite has no existence as such; substance is not made up of modes, but is prior to them; and Hegel therefore remarks that Spinoza rather denies the existence of the material universe than identifies God with it. The human mind has two chief ways of knowledge, the intuitive through the reason, and the imaginative. The imagination, which deals with the objects of experience, represents the world as a multiplicity of individuals. It obtains a partial and inadequate view of the images which appear before it, considers modes as things, and names them man, horse, tree, &c. The reason sees together in their unity what the imagination isolates and individualizes, and attains to adequate or exhaustive knowledge, to universal or divine ideas, which are pure thoughts, not involving the conception of extension, and not consisting in images or words. The mind is passive and in bondage in so far as it is influenced by inadequate ideas, and is active and free in so far as its ideas are adequate. If all objects of knowledge be regarded in their relations to the one absolute Being, the knowledge of particular outward things, nature, life, or history, becomes in fact a knowledge of God; and the more complete such knowledge, the more the mind is raised above what is perishable in the phenomena to the idea which lies beyond them. It dwells exclusively upon the eternal, is occupied with everlasting laws, emancipates itself from the conditions of duration, and secures its immortality, by becoming "of such a nature that the portion of it which will perish with the body, in comparison with that of it which shall endure, shall be insignificant." The law of passion is that all things desire life, seek for energy, for fuller and ampler being. Every single being pursues that which will give it increased vitality. Man gathers life and self-mastery only from the absolute Being; the love of God is the extinction of all other desires; and virtue is the knowledge and power of God in the human soul, the exhaustive end of human aspiration. The ethical principles in which the philosophy of Spinoza results were proposed by him as identical with those of the Christian religion.—The best complete editions of his works in the original Latin are by Paulus (2 vols., Jena, 1802–'3), Gfrörer (Stuttgart, 1830), and Bruder (3 vols., Leipsic, 1843–'6). There are German translations by Berthold Auerbach, with a biographical notice (5 vols., Stuttgart, 1841; new ed., enlarged, 1874), and by J. H. von Kirchmann and Schaarschmidt (1871 *et seq.*); French translations by Émile Saisset (2 vols., Paris, 1843; enlarged ed., 3 vols., 1861), and by J. G. Prat (1863 *et seq.*). Spinoza's newly discovered *Tractatus de Deo et Homine* has been edited by Van Vloten (Amsterdam, 1862; German and Dutch translations, 1870), and commented upon by Sigwart (Gotha, 1866) and Trendelenburg (Berlin, 1867). Among his biographers are Colerus (Dutch, 1698; French, 1706; German, 1733), Lucas (Amsterdam, 1719), Dietz (Dessau, 1783), Philippson (Brunswick, 1790), A. Saintes (Paris, 1842), Van Vloten (Amsterdam, 1862), and R. Willis (London, 1870). See also F. H. Jacobi,

*Ueber die Lehre des Spinoza in Briefen an Mendelssohn* (Berlin, 1785); Herder, *Gott, einige Gespräche* (Gotha, 1787); Sigwart, *Der Spinozismus historisch und philosophisch erläutert* (Tübingen, 1839); Kuno Fischer, *B. Spinoza's Leben und Charakter* (Mannheim, 1868); S. E. Löwenhardt, *Benedict von Spinoza in seinem Verhältniss zur Philosophie und Naturforschung der neueren Zeit* (Berlin, 1872); and *Die Ethik des Spinoza*, with the original text, edited by Hugo Ginsberg (Leipsic, 1875). In 1875 a movement was commenced for erecting a monument to Spinoza at the Hague on the 200th anniversary of his death, Feb. 21, 1877.

**SPIRÆA** (supposed to be from Gr. *σπειρεῖν*, to wind, some kinds being useful to form garlands), a genus of plants of the rose family, comprising about 50 species, widely distributed throughout the temperate and subarctic portions of the northern hemisphere. It includes both herbs and shrubs, some of which have received popular names, while for many cultivated species the botanical name is in common use. The alternate leaves are simple or compound, with mostly manifest stipules; the small white or rose-colored flowers (sometimes diœcious) are in dense or long, loose, terminal panicles or cymes, or in axillary umbel-like corymbs, and consist of a short, persistent, five-cleft calyx, with five equal petals, numerous stamens, and mostly five pistils (two to twelve),

1. Meadow Sweet (Spiræa salicifolia). 2. Hardhack (Spiræa tomentosa).

the ovaries to which become several-seeded pods or follicles in fruit. In some rare cases the parts of the flower are in fours instead of fives. —The most common native species, *S. salicifolia*, is known as meadow sweet and queen of the meadows, and is abundant in moist meadows and on the margins of swamps, where its slender, purplish, very brittle stems form clumps 3 ft. or more high; the variable leaves, mostly wedge-lanceolate, are simply or doubly serrate, acute or obtuse, thin, and mostly smooth; the flowers, in a crowded terminal panicle, are white or sometimes flesh-colored; it remains in flower from July to September, and is sometimes cultivated. A hybrid variety, said to be produced from this and Douglas's meadow sweet (*S. Douglasii*), of the N. W. coast, has longer flower clusters, of a lively rose color, and is a garden favorite on account of its long continued bloom.—Hardhack and steeple bush are common names for *S. tomentosa*, found in low grounds from Canada to Georgia, but more abundant in New England than elsewhere; the stems, smooth and dark bronze-colored when old, are 2 or 3 ft. high and thickly furnished with ovate or oblong serrate leaves, covered on the under surface with a very thick woolly down, which is whitish or slightly rusty, and in marked contrast with the very dark green of the upper surface; the flowers, appearing in July and lasting till autumn, are in a dense, tapering, spire-like panicle, rose-purple, or rarely white. The plant is very astringent, and is used as a domestic remedy, and by physicians as a tonic and astringent in diarrhœa and other bowel complaints.—The largest of our native species, *S. opulifolia*, grows in its different forms from Canada to the gulf states, and west to Oregon and California; it is a rugged shrub, from 4 to 10 ft. high, with long recurved branches and a loose bark, the numerous layers of which, spontaneously separating, have caused it to be called nine-bark; its roundish heart-shaped leaves are often three-lobed and doubly serrate; the abundant white flowers are in umbel-like clusters, and are succeeded by bladdery pods which turn purplish. The golden spiræa (*S. aurea* of the catalogues) is only a variety of this, in which the leaves when young are bright greenish yellow; it is very showy in spring, while the foliage is fresh; this is sometimes used with good effect for ornamental hedges.—Among the many shrubby species in cultivation the most frequent are: the plum-leaved spiræa (*S. prunifolia*), from Japan, with smooth lanceolate leaves, and in the form generally cultivated very double pure white flowers; Reeves's spiræa (*S. Reevesiana* of the catalogues, but properly *S. lanceolata*), from China, with numerous umbels of white flowers; St. Peter's wreath or Italian May, with long recurved branches crowded with small sessile umbels of white flowers; Fortune's spiræa (*S. Fortunei* or *callosa*), from China, with long slender stems bearing flat corymbs of rose-pink or white flowers; *S. ariæfolia*, from Oregon, with terminal panicles of yellowish white flowers; and Thunberg's spiræa (*S. Thunbergii*), from the mountains of Japan, a dwarf species, with small flowers in clusters of three. The tall Chinese shrub, with flowers

several times larger than the others, and formerly called *S. grandiflora*, is now placed in a separate genus, *exochorda*.—Among the herbaceous species, the finest native is the queen of the prairie (*S. lobata*), found wild from Pennsylvania to Kentucky, and common in cultivation, with small flowers of a peach-blossom color. Goats' beard (*S. aruncus*) is another native from New York westward, found also in Europe, with numerous slender spikes of diœcious, whitish flowers. Dropwort (*S. filipendula*), from Europe, has large cymes of white or pink-tipped flowers. The fine herbaceous plant which is often called *spiræa Japonica* belongs to the saxifrage family; its proper name is *astilbe Japonica.*

Dropwort (Spiræa filipendula).

**SPIRAL VESSELS.** See Air Vessels.

**SPIRE,** or **Spires** (Ger. *Speyer* or *Speier*), a town of Bavaria, capital of the district of the Palatinate, on the left bank of the Rhine, at its junction with the Speyerbach, 16 m. N. E. of Landau; pop. in 1871, 13,241. It has a cathedral in the Romanesque style, remarkable for its size and antiquity; it was damaged by the French in 1689, but has been partly restored with great splendor; it contains the tombs of eight emperors, fine monuments, and a hall of antiquities. Very little is left of the imperial palace, where in 1529 the diet was held at which the Reformed princes made the protest from which originated the name of Protestants.—Spire was a Roman military station under the name of Augusta Nemetum (previously Noviomagus), and is said to have had a Christian community in the 2d century, and a bishop in the 3d. In the 7th century it was known under the Latin name of Spira. The town became of great importance as the ordinary residence of the emperors of Germany, and the seat of the imperial chamber or supreme court of appeal and of several diets. The French laid it in ashes May 31, 1689. It was rebuilt in 1699, but never recovered its ancient prosperity. After the French occupation (1801–'14) it was in 1816 given to Bavaria.—The bishopric of Spire, one of the oldest in Germany, long enjoyed the rights of sovereignty, and the prince-bishops, whose castle was at Bruchsal, had an enormous income. More than half of the territory was given to France by the treaty of Lunéville, Feb. 9, 1801, and the rest to Baden in 1802.

**SPIRIT OF SALT.** See Hydrochloric Acid.

**SPIRITUALISM,** a term formerly used to designate the doctrines and religious life of a class of mystics who professed to be under the sensible guidance of the Divine Spirit, and who were distinguished by a habit of spiritualizing the Sacred Scriptures. Jacob Boehm, Miguel de Molinos, Mme. Guyon, and Mme. de Bourignon, though not all ostensibly of the same communion, are representatives of the somewhat numerous class of religionists, particularly of the 17th century, to whose teachings and practice the appellation of spiritualism has been applied. Latterly, however, the word has been employed exclusively to designate the belief of those who regard certain accredited phenomena, physical and mental, as the result of the action of spirits, influencing and using persons of a peculiarly sensitive organization, known as mediums. In France Allan Kardec (the pseudonyme of Léon Hippolyte Denisart Rivail), who specially investigated the American phenomena, defined it as follows: "Properly speaking, spiritualism is the opposite of materialism. Whoever believes he has within him something distinguished from matter is a spiritualist; but it may not follow that he believes in the existence of spirits, or in their communications with the visible world. To designate this latter belief we employ, in place of the words spiritualism, spiritualist, the words spiritism, spiritist." Spiritualists assert that phenomena nearly identical with the manifestations of modern spiritualism appear in many ancient histories, in the Delphic oracles, in the lives of seers and clairvoyants, in the facts of witchcraft in all ages, in the Tedworth occurrences related by Glanvill (1661), in the Camisard marvels in France (1686–1707), in the occurrences in the Wesley family (1716), in Swedenborg's alleged full and open communication with the spirit world and daily converse with spirits and angels more than a century ago, in the records of mesmerism and somnambulism, in the traditions of countless families, and in the innumerable published accounts of remarkable dreams, predictions, and physical phenomena.—Clairvoyance appears to have played an important part in the introduction of modern spiritualism, and a historical sketch of the latter, to be complete, must include some notice of the former. Jung-Stilling (1740–1817), in his writings on pneumatology, noticed that clairvoyants, during their more exalted states of *ecstasis*, professed, with what seemed to him satisfactory evidence, to be in converse with invisible in-

telligences. The same claims to open intercourse with the spiritual world, with many phenomenal evidences which he regarded as establishing their truth, were afterward noted by Dr. Justinus Kerner, and detailed at large in his biography (1829) of one of his patients, Frederica Hauffe, more familiarly known as the seeress of Prevorst, who is said to have been in a magnetic state for most of the time during the last seven years of her life, describing the persons and repeating the language of what she represented to be spirits, and being often accompanied with mysterious rapping sounds. In 1830 Bertrand and other students of mesmerism came upon the borders of spiritualism. The correspondence (1836) between the French mesmerists Billot and Deleuze shows that they were aware of some of the marvels asserted by the later spiritualists. Billot writes that he and his co-sectaries had both seen and felt the spirits. Deleuze declared that the possibility of communicating with spirits had been proved to him, and he also cites the testimony of a distinguished physician concerning clairvoyants who "cause material objects to present themselves." Many instances of alleged intercourse with the invisible world subsequently occurred in France, Germany, and other parts of Europe, and in the United States. In the spring of 1843 the societies of Shakers at New Lebanon and Watervliet, N. Y., and several other communities of that fraternity, almost simultaneously became the subjects of strange psychological experiences, during which certain of the members would lose all personal consciousness, while influences purporting to be the spirits of persons of different nations, who had lived in the world in different ages, took possession of their bodies, and spoke through their vocal organs. None of the phenomena of clairvoyance were more remarkable than those in the case of Andrew Jackson Davis. (See Davis, Andrew Jackson.) Thrown into an abnormal state of mind and body by the process of magnetism, this young man, while professing to be in immediate converse with the spiritual world, dictated a large octavo volume, which was published under the title of "The Principles of Nature, her Divine Revelations, and a Voice to Mankind." In a portion of this book that was dictated in 1845 (pp. 675–'6) the entranced author distinctly predicted that the communication with the spiritual world would ere long assume "the form of a living demonstration." It is noteworthy that, although Davis was almost wholly uneducated, his first and subsequent works, conceived when he was in a clairvoyant state, or while more or less illuminated, as he claims, by the influence of invisible spirits, are written in correct and oftentimes elegant language.—The "spirit-rapping" phenomenon began in March, 1848, in the family of John D. Fox, in Hydeville, Wayne co., N. Y. Besides Mr. and Mrs. Fox, only their two youngest children, Margaret, 12 years old, and Kate, 9 years old, were at home when the family was startled by mysterious rappings that were heard nightly upon the floor of one of the bedrooms, and sometimes in other parts of the house. They endeavored to trace the sounds to their cause, but failed. It is also alleged that a patter of footsteps was sometimes heard, the bedclothes were pulled off, and Kate felt a cold hand passed over her face. On the night of March 31, when the raps occurred, Kate imitated them by snapping her fingers, and the raps responded by the same number of sounds. Kate then said: "Now do as I do; count 1, 2, 3, 4, 5, 6," at the same time striking her hands together. The same number of raps responded, and at similar intervals. The mother of the girls then said: "Count 10;" and 10 distinct raps were heard: "Count 15," and that number of sounds followed. She then said: "Tell us the age of Cathy [the youngest daughter] by rapping one for each year," and the number of years was rapped correctly. In like manner, the ages of each of four other and then absent children were by request indicated by this invisible agent. Mrs. Fox asked if it was a human being that was making that noise, and if it was, to manifest it by making the same noise. There was no sound. She then said: "If you are a spirit, make two distinct sounds." Two raps were accordingly heard. Three weeks afterward, it is said, it was made known by the raps that the body of a murdered man lay buried in the cellar, and the exact spot was indicated where parts of a human skeleton were actually found. The name of the murdered man was given, and it was learned that five years before such a person had visited the house and had suddenly and mysteriously disappeared. After a while the raps occurred only in the presence of the two sisters, Margaret and Kate. The family having removed to Rochester, the raps accompanied them, and new phenomena, including clairvoyance and the movement of ponderable bodies without appreciable agency, were developed. In November, 1849, the Fox girls appeared in a public hall, and the phenomena were freely manifested and subjected to many tests; and a committee appointed for their investigation, after continuing their experiments there and elsewhere for several days, reported that they were unable to trace them to any mundane agency. In May, 1850, the Fox girls arrived in New York; the alleged spiritual manifestations became the subject of extensive newspaper and conversational discussion; their facts were published far and wide; "mediums," through whom they were said to occur, sprang up in different parts of the country, and were multiplied by hundreds and almost by thousands. In that year D. D. Home (see Home, Daniel Dunglas), at the age of 17, became known as a medium, and in the five following years he attained a wide-spread reputation, especially for his materialization, levita-

tion, and other phenomena far surpassing the previous manifestations of ordinary mediums. Some of the most remarkable manifestations through his mediumship occurred in Springfield, Mass., and in Hartford, Conn., at the residences of Henry C. Deming, Isaac W. Stuart, Alfred E. Burr, and others. In 1855 he went abroad, and gave sittings with manifestations in the presence of Napoleon III. in Paris and Alexander II. in St. Petersburg; and both emperors gave him large presents in jewels and money. Nearly contemporary with Home, and since his publicity as a medium, many others in the United States and in Europe have obtained an almost equal celebrity for materializing manifestations. Among the mediums of the alleged spiritual manifestations there have been representatives from all classes and conditions of mankind. The alleged mediums have been classified as rapping mediums; mediums for tipping and turning tables by a slight touch of the finger; for the movement of ponderable bodies without contact; for the production of phosphorescent lights in a dark room; for playing on musical instruments in a manner beyond their ordinary abilities; for involuntary writing, and for writing independent of any apparent aid from human hands; for direct spirit speech, and for impressional speaking and personation; for stigmata; for the diagnosis and healing of disease; for levitation; for producing drawings and colored pictures; for photographing spirits; for the introduction of flowers, fruits, vegetables, and many other things into closed rooms; for the development of other mediums; and finally, what spiritualists consider the crowning marvel of all the manifestations, for the materialization of spirit forms identical in appearance with those of deceased persons. Indeed, the powers that are claimed for mediums are protean in variety. By the raps and tipping of tables, and by the control of the medium's organs to write and speak, the spirits are supposed to express their own peculiar intelligence in a degree of perfection proportioned to the development and passivity of the medium. It is averred that persons while under the spiritual afflatus have often spoken in foreign tongues which they had never learned; and writings in languages to them unknown have been produced in their presence, as we are told, by invisible hands. To all these modes of manifestation there are countless witnesses of high character and intelligence. In the "London Quarterly Journal of Science" for January, 1874, William Crookes, the editor, classifies some of the phenomena exhibited in repeated experiments with the mediums D. D. Home and Kate Fox (afterward Mrs. Jencken) as follows: 1, the movement of heavy bodies with contact, but without mechanical exertion; 2, the phenomena of percussive and other allied sounds; 3, the alteration of weight of bodies; 4, movements of heavy bodies when at a distance from the medium; 5, the rising of tables and chairs off the ground without contact with any person; 6, the levitation of human beings; 7, movements of various small articles without contact with any person; 8, luminous appearances; 9, the appearance of hands, either self-luminous or visible by ordinary light; 10, direct writing; 11, phantom forms and faces; 12, special instances which seem to point to the agency of an exterior intelligence; 13, miscellaneous occurrences of a complex character. The exhibitions which Mr. Crookes and a few friends witnessed were mostly in his own house, in the light; and it is said that the existence of an unexplained force, with its amount and direction, was accurately tested by means of an ingenious apparatus. In the spring of 1874 Mr. Crookes with others began the investigation of phenomena exhibited in London through the mediumship of Florence Cook, afterward Mrs. Corner. It is asserted that in a series of sittings extending through several months a female spirit form, temporarily materialized and not distinguishable from a human being, repeatedly came from a cabinet into the light, conversed, sang, submitted to various tests, and then disappeared. Mr. Crookes, who took several photographs of the figure, says: "It was a common thing for the seven or eight of us in the laboratory to see Miss Cook and 'Katie' (the spirit) at the same time under the full blaze of the electric light." On one occasion Mr. Varley, the electrician, by means of a galvanic battery and cable-testing apparatus, showed to the satisfaction of the spectators that the medium was inside of the cabinet while the supposed spirit form was visible and moving outside. Two years previously the phenomena of materialization appeared at Moravia, N. Y., where Mrs. Mary Andrews was the medium; and Thomas R. Hazard of Rhode Island, the Rev. R. S. Pope of Hyannis, Mass., and other respectable persons present at these sittings, declared that they saw and conversed with the spirits of their deceased relatives and friends. Numerous credible witnesses, prominent among them Henry S. Olcott of New York, who devoted weeks to special investigation, testify that similar phenomena occurred in 1874–'5 at the sittings with the Eddy brothers in Chittenden, Vt. Mr. Mott of Memphis, Mo., Mrs. Anna Stewart of Terre Haute, Ind., and Mrs. Markee of Havana, N. Y., have the reputation of being remarkable mediums for the materialization phenomena. The fraudulent character of some exhibitions has been exposed, notably of that of the Holmeses in Philadelphia in 1874, in which the supposed spirit form called "Katie King" appeared. To this exhibition Robert Dale Owen at first gave full credence, but he ultimately withdrew his confidence, though subsequent investigations threw doubt on the charges of imposture through a confederate. Almost from the time of the first sittings the phenomena of materialized spirit hands and

feet have been common. Instruments have been floated around and spirit voices heard, phenomena supposed to be produced by the exercise of the materializing power. But notwithstanding the accumulated assumed testimony in regard to spirit photographs and materializations, spiritualists themselves are not yet unanimous in admitting them among what they believe to be fully verified phenomena.—Besides the thousands in every grade of society, throughout the civilized world, who are more or less influenced by a belief in the supernatural origin of the manifestations, many persons in Europe and America, distinguished in the walks of science, philosophy, literature, and statesmanship, have become avowed converts, or have admitted the phenomena so far as to believe in a new force not recognized by science, or have testified that the manifestations they have witnessed are not capable of explanation on the ground of imposture, coincidence, or mistake, or at least have considered the subject worthy of serious attention and careful consideration. Among these are: Alexander Aksakoff, Robert Chambers, Hiram Corson, Augustus De Morgan, J. W. Edmonds, Dr. Elliotson, I. H. von Fichte, Camille Flammarion, Hermann Goldschmidt, Dr. Höffle, Robert Hare, Lord Lyndhurst, Robert and Robert Dale Owen, W. M. Thackeray, T. A. Trollope, Alfred Russel Wallace, Nicholas Wagner, and Archbishop Whately. As the organized bodies of spiritualists include but a small proportion of those who wholly or partially accept these phenomena, it is impossible to make even an approximate estimate of their numbers. While spiritualism has its converts from every religious denomination, no small proportion of its advocates are from the ranks of those who previously doubted or totally disbelieved the immortality of the soul, and who affirm that they carry their skeptical tendencies into the investigation of this subject. On matters of speculative theology, there seems to be among them the widest latitude of opinion, though a majority of them perhaps are in their speculations inclined to what may be termed a sublimated naturalism. They tell us that it is not the object of the spirits to teach theological dogmas as by any authority superior to that of man, but rather, by the mental and physical phenomena incidentally presented in the course of their manifestations, to furnish those elements of reasoning from which each one may work out his own conclusions; while we are told that the main object of their manifestations is to furnish actual demonstration of the immortality of the soul and of some of the conditions and laws of the *post mortem* existence.—The books relating to spiritual manifestations may be reckoned by hundreds. The following are a few of the more important: J. Kerner, *Die Seherin von Prevorst* (Stuttgart, 1829; translated by Mrs. Crowe, London, 1845); Allan Kardec, *Le livre des esprits* (Paris, 1853), with a supplementary work, *Le livre des médiums* (1863), the first translated into English by Anna Blackwell under the title, "The Spirits' Book" (Boston, 1875), and the second by Emma A. Wood, "The Book of Mediums" (Boston, 1875); S. B. Brittan and B. W. Richmond, "A Discussion of the Facts and Philosophy of Ancient and Modern Spiritualism" (New York, 1853); John W. Edmonds and G. T. Dexter, "Spiritualism" (2 vols., New York, 1854–'5); Charles Linton, "The Healing of the Nations," with an introduction and appendix by N. P. Tallmadge (New York, 1855); Hudson Tuttle, "Scenes in the Spirit World, or Life in the Spheres" (New York, 1855); E. W. Capron, "Modern Spiritualism, its Facts and Fanaticisms" (Boston, 1855); Robert Hare, "Experimental Investigations of the Spirit Manifestations" (New York, 1856); Louis de Guldenstubbe, *La réalité des esprits et le phénomène merveilleux de l'écriture directe démontrés* (Paris, 1857); Catharine Crowe, "Spiritualism and the Age we Live in" (London, 1859); Robert Dale Owen, "Footfalls on the Boundary of Another World" (Philadelphia, 1860), and "The Debatable Land between this World and the Next" (New York, 1872); D. D. Home, "Incidents of my Life" (London, Paris, and New York, 1862; a second volume with the same title, 1872, and a third announced in 1875); Mrs. A. De Morgan, "From Matter to Spirit" (London, 1863); J. E. de Mirville, *Question des esprits et de leurs manifestations diverses* (Paris, 1863); William Howitt, "History of the Supernatural in all Ages and Nations" (London, 1863); C. W. Upham, "Salem Witchcraft, and a History of Opinions on Witchcraft and Kindred Subjects" (2 vols., Boston, 1867); Epes Sargent, "Planchette, or the Despair of Science" (Boston, 1869), and "The Proof Palpable of Immortality" (1875); Emma Hardinge, "Modern American Spiritualism" (New York, 1870); William Crookes, "Researches in the Phenomena of Spiritualism" (London, 1874); A. R. Wallace, "On Miracles and Modern Spiritualism, three Essays" (London, 1875); and H. S. Olcott, "People from the Other World" (Hartford, 1875). With the exception of these and a few other books, the best portion of the literature of spiritualism is to be found in the various periodicals devoted to that subject, the number of which in 1875, in Europe, America, and Australia, was at least 60.

**SPITZBERGEN**, a group of islands in the Arctic ocean, between lat. 76° 30′ and 80° 30′ N., and lon. 10° and 28° E., and nearly midway between Greenland on the west and Nova Zembla on the east; area estimated at 30,000 sq. m. The principal islands are Spitzbergen, Northeast land, Prince Charles, Edge, and Barentz. Spitzbergen proper, the largest of the islands, is nearly divided N. and S. by two arms of the sea, Weyde bay and Ice fiord, which stretch so far inland that their heads are separated by only a narrow peninsula 5

or 6 m. in breadth. The two divisions are sometimes called respectively West Spitzbergen and East Spitzbergen or New Friesland. E. of Spitzbergen lie Barentz island and Edge island (Russ. *Maloi Brun*), separated from it by a strait called Wybe Jans water, or by the Swedes Stor fiord. Between Edge and Barentz islands is Freeman or Thymen strait, and between Barentz island and Spitzbergen on the north Heley's sound. Hinlopen or Waygat strait separates Spitzbergen from Northeast land, so called from its relative position to the larger island. Its coast line is rugged and penetrated by numerous fiords, and it is surrounded by many islands, the principal of which are High island on the east, the group called the Seven islands on the north, and Low island on the west. Near the southern mouth of Hinlopen strait is Waygat or Wilhelm island, explored by Smyth in 1871. W. of Spitzbergen, and separated from it by Foreland strait, lies Prince Charles island or foreland. Little is known of the interior of Spitzbergen, but many mountains are visible from the coast, some of them 3,000 to 4,000 ft. high, the valleys of which are filled with glaciers. On the W. coast the mountains rise generally within 3 m. of the shore, leaving a level space between them and the sea. The N. shores are not so high, but inland the ice hills gradually rise to an elevation of more than 2,000 ft. Around the South cape or Point Lookout, the S. termination of Spitzbergen, the coast is flat, but it soon rises into a mountain chain which extends northward. The E. coasts have not been thoroughly explored. Spitzbergen feels the influence of two ocean currents flowing from nearly opposite directions: a polar current, which blocks up the E. and N. E. sides with ice and renders navigation dangerous, if not impossible; and a warmer Atlantic current, which flows up the W. coast and keeps it comparatively free from ice. The climate is intensely cold, the mean temperature on the W. coast during the three warmest months not exceeding 34·5°. The longest day in the N. parts is four months, and from Oct. 22 to Feb. 22 the sun does not rise above the horizon; but the long night is relieved by a faint twilight and the occasional brilliant light of the aurora borealis, and the moon and stars shine with great brightness. Winter begins at the end of September, and by the middle of October the cold is intense. Storms are frequent, and great quantities of snow fall. During the short summer the climate is temperate for the latitude, and a scanty vegetation springs up. About 40 species of plants have been classified, the most vigorous of which do not exceed 3 or 4 in. in height. The animals are polar bears, polar foxes, and reindeer. Sea fowl are numerous, and the surrounding waters abound with whales, seals, walruses, and large fish. Marble and coal of good quality have been found. These islands have been visited by whalers for 2½ centuries, and though there is no permanent settlement on any of them, Russian sailors have lived for years at a time on the W. coast. Their sovereignty is claimed by Russia.—Spitzbergen is supposed to have been first seen by Willoughby in 1553, in the voyage in which he perished with his crew. Barentz came in sight of the N. end of the W. coast, lat. 77° 49′, on June 19, 1596. He named it Greenland, and the Dutch navigators who followed him called it Nieuwland. By the English it was called King James's Newland. The name Spitzbergen (pointed mountains) first appears in a tract published by Hessel Gerard in 1613. Henry Hudson visited the N. and W. coasts in 1607, and soon after the seas around Spitzbergen became a favorite fishing ground for whalers, principally English and Dutch. In 1617 a ship of Capt. Edge's fleet explored the E. coast as far as lat. 79°, and discovered Wiche's land E. of Spitzbergen. This was renamed King Karl land in 1870 by Baron von Heuglin, who saw it from off Edge island and supposed he had made a new discovery. It was visited for the first time in 1872 by Nils Jansen, a Norwegian whaling captain. Important additions to our knowledge of Spitzbergen and its surroundings have been made by the Swedish expeditions under Nordenskjöld in 1858, '61, '64, '68, and '72; by B. Leigh Smyth and Ulve in 1871–'2; and by Altmann and Nilsen in 1872.

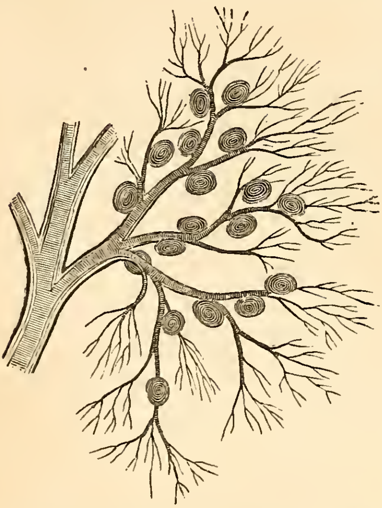
**SPITZ DOG**, a small variety of the Pomeranian dog. It is evidently derived from some of the arctic or wolf dogs, and resembles in its short, ovate, erect, and hairy ears, pointed muzzle, much-curved and bushy tail, the Esquimaux, Hare Indian, Siberian, Lapland, and Iceland dogs, though of smaller size and with finer and longer hair. The hair is long, espe-

Spitz Dog.

cially on the head and neck, and varying from pure white, which is most common, to cream color and occasionally jet-black. It is very active, intelligent, and handsome, an excellent watch dog, with many of the qualities of the shepherd's dog, and probably of the same ori-

gin. It is not improbable that it may have come from a cross between some of the smaller arctic wolf-like dogs and the arctic fox.

**SPLEEN** (Gr. σπλήν), the largest of the vascular or ductless glands, whose probable function is subsidiary to the process of sanguification. It is situated in the left hypochondriac region, below the diaphragm, above the descending colon, between the cartilages of the false ribs and the cardiac extremity of the stomach, to which it is united by short vessels. It is in health from 4 to 5 in. long, and $1\frac{1}{2}$ in. thick, of an elongated flattened form, and about 6 oz. in weight; on the inner surface is a longitudinal groove in which are the blood vessels, posteriorly resting on the vertebral column; below, it is in relation with the left kidney and capsule, and with the pancreas behind. It is soft and spongy, and dusky red.



A portion of the Splenic Artery, its ramifications being studded with Malpighian corpuscles (from the dog). (Magnified 10 diameters.)

Its external surface is covered with the peritoneum; beneath this is a coat of white fibrous tissue with some elastic fibres, from the inner surface of which extends through the entire organ a network of fibrous bands and threads, the trabecular tissue. The splenic artery comes from the cœliac axis, the trunks not anastomosing, but subdividing like the branches of a tree, to which the Malpighian corpuscles are attached as fruits on short peduncles, and ending generally in capillaries with very thin walls, passing in every direction through the organ and into the interior of the corpuscles. The veins are branched like the arteries, have no valves, and their principal stem is one of the trunks of the vena portæ; the nerves form the splenic plexus, and proceed from the solar plexus of the great sympathetic; the lymphatics are few and superficial. The parenchyma consists of a homogeneous mass of colorless nucleated corpuscles and cells imbedded in a granular plasma. The splenic corpuscles, or Malpighian bodies of the spleen, are whitish spherical bodies, about $\frac{1}{70}$ of an inch in diameter, attached to the smaller ramifications of the splenic artery. Each corpuscle consists of a closed sac or capsule, containing in its interior a viscid semi-solid mass of cells, cell nuclei, and homogeneous substance. Each Malpighian body is covered with a network of capillary blood vessels; and small blood vessels also penetrate into its interior, through the investing capsule, and form a vascular capillary plexus in the substance of the body itself.—The precise details of the function of the spleen are unknown. It belongs to the class of "ductless glands," that is, of organs having a glandular texture but no outlet or duct, and not supplying any distinct secretion like those of the glands proper. Their purpose undoubtedly is to effect some necessary change in the blood itself, producing in their glandular tissue some substance which is appropriated and carried away by the blood vessels distributed to them. Thus the veins of these organs are supposed to serve as their excretory ducts. The spleen, though so large, is not directly essential to life, and has been several times removed in the lower animals without an immediately fatal result. It is liable to acute and chronic enlargements in various forms of typhoid and intermittent fevers, and is sometimes excessively enlarged and solidified in the strumous diseases of infancy and childhood.

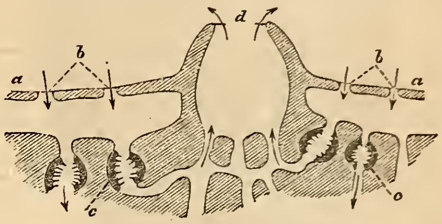
**SPOFFORD, Harriet Elizabeth** (PRESCOTT), an American authoress, born in Calais, Me., April 3, 1835. She was educated at Newburyport, Mass., and in 1865 married Richard S. Spofford of that place. She has published "Sir Rohan's Ghost" (1859); "The Amber Gods, and Other Stories" (1863); "Azarian, an Episode" (1864); "New England Legends" (1871); and "The Thief in the Night" (1872).

**SPOHR, Ludwig**, a German composer, born in Brunswick, April 5, 1784, died in Cassel, Oct. 22, 1859. He received instruction on the violin from Maucourt, and made his début at Brunswick at the age of 12, playing then a concerto of his own composition. At 18 he accompanied the violinist Eck to Russia. At 19 he composed the work since published as his first violin concerto (Opus 1). At 21 he made a tour through Germany, bringing out at one of his concerts the since celebrated composer Meyerbeer. In 1805 he was appointed chapelmaster at Gotha. In 1806 he married Dorothea Scheidler the harpist, and afterward composed many pieces for the harp in connection with the violin. In 1816 he visited Italy on a concert tour, and in 1817 he undertook the directorship of the Frankfort theatre. In 1820 he visited England, and conducted there the philharmonic society's concerts. In 1821 he was appointed chapelmaster at Cassel, where he resided during the remainder of his life. He brought out there his operas *Der Berggeist*,

*Jessonda*, and *Der Alchymist*, his oratorios *Die letzten Dinge* and *Des Heilands letzte Stunden* (known in the respective English versions as "The Last Judgment" and "The Crucifixion"), his symphony *Die Weihe der Töne* or "The Consecration of Tone," and other works. In 1852–'3 he directed the performances of his operas at the royal Italian opera house in London. In 1857 he resigned his office at Cassel. He exercised a decided influence upon the art of music both by his *Violinschule* (fol., Vienna, 1831) and by his compositions. Among these were nine spmphonies, eight operas, a great number of quartets and quintets for stringed instruments, and other chamber music.—See *Louis Spohr's Selbstbiographie* (2 vols., Göttingen, 1862), which has been translated into English.

**SPOLETO** (anc. *Spoletium*), a city of central Italy, formerly capital of a papal delegation of the same name, and since 1860 of a district in the province of Perugia (division of Umbria), on the Mareggia, 60 m. N. N. E. of Rome; pop. in 1872, 20,748. The streets are steep, the city being built around a hill; on the top of this is the citadel, which was built by Theodoric, destroyed by Totila, restored by Narses, and subsequently enlarged. Spoleto has a fine cathedral and many other churches, palaces, and relics of antiquity, including the arch known as the gate of Hannibal, who was repulsed here in 217 B. C. The chief articles of trade are maize, wine, fruit, and silk.—The ancient Spoletium was a flourishing Roman colony. After the fall of the western empire it was taken by the Goths. Under the Lombard kings it became the capital of a duchy, which soon acquired independence and authority over a considerable part of central Italy, and after various changes was in the 13th century annexed to the Roman see. The town was sacked by Frederick Barbarossa, and in 1324 devastated by the Perugians; and it has suffered much from earthquakes.

**SPONGE,** the common name applied to the order *spongida*, of the class of rhizopods, the most characteristic of the subkingdom *protozoa*. Sponges were for a long time regarded as plants, but the best naturalists are now agreed that they belong to the animal kingdom. Prof. H. J. Clark placed them nearest to the compound protozoans known as the flagellate infusoria, and it has been proved by him, and by others since, that the collar round the cilium must be regarded as the sponge animal; Kent classes them between the flagellate infusoria and the rhizopods; and Haeckel stands alone in placing them nearest to the corals or *cœlenterata*. (See "Annual and Magazine of Natural History," London, January, 1870.) A sponge is really an aggregation of separate masses of an amœba-like sarcode, secreting a supporting network of fibro-corneous, calcareous, or silicious matter, the compound mass being traversed by canals opening on the surface. The apparently homogeneous jelly, or sponge flesh, which covers the outside and lines the canals of the living sponge, is made up of an enormous number of sarcode masses, composed of separate sarcoids, each capable of pushing out its pseudopodia, generally with a vibrating cilium, and, if detached, able to move and live independently. Large rounded orifices, or *oscula*, are scattered over the surface of most sponges, which lead into sinuous canals permeating the substance in every direction; water is continually absorbed by the smaller pores of the sponge, filling every part, and, having supplied air and food, is



Diagrammatic Section of Spongilla (after Huxley).
*a a.* Outer or superficial layer of sponge. *b b.* Inhalant apertures, or pores. *c c.* Ciliated chambers. *d.* An exhalant aperture, or osculum. The arrows indicate the direction of the currents.

driven out through the oscula; the currents are kept up by the action of the minute vibratile cilia. In the words of Prof. Huxley, the sponge "represents a kind of subaqueous city, where the people are arranged about the streets and roads in such a manner that each can easily appropriate his food from the water as it passes along." Many sponges contain a large amount of silica, in the form of spicules of various shapes, both formed in their substance and introduced from without; two of the most beautiful of the silicious sponges will be found described under Glass Sponge and Venus's Flower Basket.—There is a gradual passage from the soft sponges of commerce to those of stiff and compact texture, with the fibres loaded with silicious spicula, crumbling easily when dry, and useless in the arts; others are rather of a felted character, usually grayish white. Sponges vary much in form, being irregularly branched, round, pear-shaped, or cup-like, and are fixed by a kind of root at the base, or incrust other bodies, growing mostly in groups attached to all kinds of objects, living or dead, fixed or floating; most are marine, but *spongilla* (Lam.) grows in fresh water; they often have brilliant colors. Some, like *cliona*, instead of incrusting other objects, excavate branching cavities in shells, which they inhabit. Sponges are propagated sometimes by ciliated gemmules, yellowish and oval, arising from the sarcode mass and carried out by the currents; they are mostly formed in the spring, and, after swimming freely about for some time, become fixed and grow. They also produce internal, unciliated, oviform bodies, resembling winter ova, which, when thrown out, swell, burst, and give issue to the locomo-

tive germs within; they are said also to grow by division, or growth of detached portions of the parent body; they are believed to be nourished by minute algæ drawn within their pores. Some live in shallow, others in very deep water; scarce and small in cold latitudes,

Sponge attached to its rocky bed.

they increase in size and number toward the tropics, being most abundant in the Australian seas. According to Dr. Bowerbank, there are 24 genera on the shores of Great Britain. While *spongia* is the type of the corneous sponges, *thethys* (Cuv.) and *Grantia* (Flem.) are types of the silicious and calcareous sponges respectively. (See Protozoa.)—For the latest researches on the sponges see the papers now in course of publication (1876) by Prof. A. Hyatt, in the "Memoirs of the Boston Society of Natural History," with figures and bibliography. Haeckel (*Monographie der Kalkschwämme*, 1872) regards the sponges and acalephs as having been evolved from a common ancestor, which he calls *protascus*, described as a body cavity surrounded by two layers of cells; he compares the sponge to the embryos of higher animals, both vertebrate and invertebrate. In his view, the germ of all animals, and the adult of such forms as hydra, may be reduced to the simple form of the young of a calcareous sponge, which he calls *gastrula;* this he considers the "truest and most significant embryonal form of the animal kingdom."—The sponges of commerce are procured chiefly in the Mediterranean and the Bahama islands; most of them are obtained by diving, to which persons are trained from childhood in the Greek islands; the adhesion to the bottom is generally firm, and the growth slow. To bleach sponges, the finest and softest are selected, washed several times in water, and immersed in very dilute hydrochloric acid to dissolve out the calcareous matters; having been again washed, they are placed in another bath of dilute hydrochloric acid to which 6 per cent. of hyposulphite of soda dissolved in a little warm water has been added; the sponge is left in this bath 24 hours, or until it is as white as snow. Smyrna is the chief place for the export of fine sponges. The coarse sponges used for horses and carriages, &c., are obtained chiefly from the Bahamas; when taken from the water they have a sickish, disagreeable odor, which soon becomes disgusting, like that of decomposing animal matter; they are first buried in dry sand, and when decomposition has ceased are exposed in wire cages to the action of the tide for purification.—Fossil sponges are found in the Trenton limestone, and, if *scolithus* be a mining sponge, even as low as the Potsdam sandstone, and probably were in existence long before the oldest Silurian epoch. *Brachiospongia*, discovered by the Rev. Mr. Hovey in the Birdseye group of the lower Silurian, is characterized by armlike processes radiating from a central cup. *Eospongia* of Billings has been found in the lowest Potsdam.

**SPONTANEOUS COMBUSTION.** See Combustion, Spontaneous.

**SPONTANEOUS GENERATION,** the direct production of living beings from inanimate material, in contradistinction to the ordinary mode of generation, in which young animals or plants appear only as the progeny of other living organisms. The views held by physiologists on the question of spontaneous generation have varied greatly at different times. In the earlier periods of scientific culture, the Grecian naturalists, as represented by Aristotle, recognized among animals three different modes of generation: 1, viviparous generation, as in man and the quadrupeds, where the young were known to be produced alive from the bodies of their parents; 2, oviparous generation, as in birds, reptiles, and fish, where the young were hatched from eggs produced by the female; 3, spontaneous generation, where no connection could be traced between the young animals and any previously existing parents, and where they were consequently thought to be formed by the spontaneous organization of earthy deposits or decaying organic material. Spontaneous generation was therefore regarded as one of the regular and natural methods for the production of living forms; but as a physiological doctrine it rested entirely upon negative grounds, and was due to the incomplete knowledge then possessed by naturalists as to the real origin of many animal species. Maggots, for instance, were thought to be formed by spontaneous genera-

tion from putrefying meat, because they always appeared at a certain stage of its decomposition, although no similar creatures existed in it beforehand, and because there was no other apparent cause for their production. A great change in opinion on this subject was introduced by the discoveries of Francesco Redi in 1668. He exposed fresh meat, during summer weather, in wide-mouthed bottles, protected by pieces of paper fastened over their necks. In the bottles thus secured no maggots were developed, notwithstanding that the putrefaction of the meat went on as usual; while in other similar vessels, unprotected by paper covers, maggots swarmed in abundance at the customary time. It was evident therefore that their origin was due to something introduced from without, and it soon appeared that they were really the progeny of flesh flies, which, attracted by the odor of the meat, hovered over it until they gained access to it, and deposited their eggs upon its surface. The eggs then hatched into maggots, which, after a certain period of growth, became transformed into perfect insects similar to their parents. The idea thus suggested was rapidly carried out by means of further observations on the reproduction and metamorphosis of insects in general. The investigations showed that in what had been supposed to be cases of spontaneous generation the animals were really produced from parents like themselves. The microscope soon brought into view many minute forms of life not previously known. The multiplicity of these forms, their endless variation, their small size, and their different conditions of life made it impossible at first to ascertain their complete physiological history or their mode of origin; and in regard to many of them the idea of spontaneous generation was again adopted. This was especially the case with the class known as *infusoria;* that is, microscopic animals living in water or in watery infusions of organic material, some of the smallest of which received the name of monads. Investigations upon this point were consequently taken up afresh, with a view of determining whether the infusoria in a watery liquid were produced by the ingredients of the solution itself, or by germs derived from without. Experimenters boiled the watery infusions, to destroy the vitality of any animalcules or germs which they might already contain, and afterward kept them, with a due supply of air, in hermetically sealed flasks. If, under these circumstances, living forms still made their appearance in the infusions, they must be attributed to spontaneous generation; if not, they must be regarded as dependent on the preëxistence or introduction of germs. These experiments were tried by different observers, with results which varied according to the nature and extent of the precautions adopted; but the general conclusion, derived especially from the investigations of Spallanzani in 1775, was that a preliminary boiling in closed flasks, for a few minutes, effectually prevented the appearance of all the larger and more highly organized infusoria; while, if the boiling were prolonged from half an hour to an hour, the infusion afterward remained absolutely destitute of all forms of life, even the smallest and simplest. Although at that time the real mode of generation of the infusoria had never been ascertained, nor their eggs detected by the microscope, it was considered certain that these animalcules must require for their production the existence of living germs, and consequently that they did not originate by spontaneous generation. During the early and middle part of the present century the common opinion of naturalists became gradually more decided in opposition to the doctrine of spontaneous generation, owing to the occasional repetition of experiments like Spallanzani's, and also to important discoveries in regard to the sexless internal parasites, such as *cysticercus* and *trichina.* These creatures were found inhabiting the solid tissues of other animals, and furthermore were seen to be incapable of exercising the function of generation. It was difficult therefore to account for their presence in the animal tissues unless by a growth upon the spot, and also to understand how the species could be reproduced by ordinary modes of generation. But continued investigation removed both of these difficulties. It was shown by the researches of Siebold, Küchenmeister, Leuckart, Pagenstecher, and others, that the sexless parasites were in reality the embryonic or youthful progeny of perfectly developed parents; their mode of introduction into the internal cavities and tissues of the body was ascertained; and they were found to acquire after a time sexual organs, and to produce a new progeny by sexual generation. Thus, one by one, a great variety of obscure animal species became more perfectly known; and a complete study of their physiological history revealed in every instance the regular mode of their origin and reproduction. But the class of infusoria still remained somewhat refractory in this respect, and notwithstanding that the question had been for some years regarded as settled, it was reopened in 1858. M. Pouchet, an eminent naturalist and physiologist of Rouen, took the ground that the former experiments in regard to boiled infusions were incorrect, and that in point of fact a preliminary boiling did not prevent the appearance of infusorial life. Pouchet's views and assertions were supported by the testimony of several other experimenters, among the most distinguished of whom have been Mantegazza and Bastian. They were opposed by many others, of equal reputation; and the weight of the discussion turned for a time upon the dissemination of germs in the atmosphere, as the supposed source of life in organic infusions. The most important experiments in this direction were those of Pasteur, from 1860 to 1865. This chemist had been espe-

cially interested in the study of fermentation, which was shown to be a change dependent on the presence and growth of microscopic vegetable cells. He boiled a suitable organic infusion in glass flasks, the necks of which were drawn out and sealed while ebullition was going on, thus excluding completely the atmospheric air. Afterward, when the flask and its contents had become cooled, the air was readmitted through the neck of the flask, by breaking off its narrow end. But this operation was done, with different sets of flasks, in different localities, in order to determine whether the difference of locality had any influence upon the subsequent appearance or non-appearance of life within the flask. The bearing of these experiments upon the question at issue was as follows. If it were the constituent gases of the atmosphere alone which excited the spontaneous growth of living forms by the necessary supply of oxygen, then the production of these forms should follow with the same readiness in all localities, because the gaseous constitution of the atmosphere is everywhere the same. But if, in order to produce life, the atmosphere must also bring with it certain organic germs, then the locality might make a difference in the result, because these floating particles would naturally vary in abundance in different regions. Investigation showed a manifest difference, according to the place where the air was admitted to the flask. In one of the most significant of Pasteur's experiments, a flask containing an organic infusion was boiled, sealed, allowed to cool, and afterward carried to the valley of Chamouni in Savoy, where its neck was opened and the air admitted on the Montanvert, 6,000 ft. above the sea level. It was immediately resealed, brought back to Paris, and kept for four years perfectly unchanged. It was then reopened and again exposed to the air, and in three days afterward contained a growth of microscopic vegetation. These experiments were considered by Pasteur and his associates as demonstrating the existence in the atmosphere of extraneous particles, the introduction of which into an infusion was the necessary condition of infusorial life. A further difficulty now began to be appreciated in this method of investigation. It had at first been taken for granted that a boiling temperature would necessarily destroy the vitality of both the infusoria and their germs. But this gradually became a matter of doubt, especially as the length of time during which the boiling was continued evidently had an influence on the subsequent appearance of life in the infusion. It was found necessary to determine more exactly the limits of this influence; and among the most valuable experiments in that respect were those of Jeffries Wyman in 1867. He showed that, in infusions of a certain constitution, the minute forms known as *bacteria* might appear in closed flasks after boiling; that the longer the boiling was continued, the fewer the instances in which bacteria were afterward developed; and that they never made their appearance in infusions which had been boiled continuously for five or six hours. These results were variously interpreted by different observers; a certain number still maintaining that bacteria might often be developed after the application of a heat sufficient to destroy their previous vitality.—In the modern renewal of the question of spontaneous generation, dating from Pouchet in 1858, another element has had its influence upon this discussion; that is, the idea of evolution, as accounting for the present existence of organic life upon the earth. It is assumed that there was once a period in the history of the earth when, from its elevated temperature and the different combination of its chemical elements, life could not possibly exist upon it; that, as living beings subsequently made their appearance, they must necessarily have originated by the spontaneous organization of inanimate materials; and that these primitive and imperfect structures have gradually, by modification and descent, given rise to all the forms of animal and vegetable life now inhabiting the globe. Some of those who accept the evolution doctrines believe that the conditions necessary for a spontaneous production of life have long since passed away, with the earlier stages of the world's history; others maintain that these conditions still exist, and are effective for the continued creation of bacteria and their allied forms. It is common to meet with expressions, among writers of this class, which declare that spontaneous generation is not so much a matter of question or experiment as a logical sequence of the doctrine of evolution. The stricter school of physiologists maintain, on the contrary, that it is a subject to be investigated on its own merits, by means of observation and experiment, like any other question relating to the phenomena of life.—Of late years the experimental evidence bearing on this topio has received an important addition from the independent researches of naturalists in regard to the infusoria. Some of the forms originally included in this group have been found, on more extended examination, to possess a higher organization, and have been by common consent transferred to the class of worms. Like others of this class, they reproduce their species by sexual generation, and often contain living embryos in the interior of their bodies. The infusoria proper are now known to be mostly ciliated animalcules; that is, they are provided with minute, vibrating, hair-like appendages, by which they perform rapid movements of locomotion. They have also been shown, principally by the labors of Stein, Balbiani, Engelmann, and Claparède and Lachmann, to perform the act of sexual generation, and to produce their young by means of fertile eggs, from which embryos are developed. The more minute and lowly forms, on the other hand, usually included under the general term bacteria, do not belong to the animal kingdom,

but are microscopic vegetables. They have a remarkable power of multiplication by division or doubling of their cells; and certain species appear to be the active agents in causing the putrefactive decomposition of albuminoid organic substances. The more modern investigations on spontaneous generation with boiled infusions have been almost exclusively confined to this class. But even in bacteria there are indications of a reproduction by germs. Cohn in 1872 observed certain bodies in connection with bacteria, which he regarded as resting spores; that is, spores which do not immediately germinate, but remain quiescent for a certain interval and afterward become developed under other conditions. These resting spores were more fully described in 1874 by Billroth, whose description has been confirmed by Stimson in 1875. According to Billroth, although the vitality of bacteria is destroyed by boiling, their resting spores will withstand this temperature, and are afterward capable of development into active forms. This may explain the occasional appearance of microscopic life in organic solutions which have been subjected to ebullition.—For the most complete recent defence of the doctrine of spontaneous generation, see "The Beginnings of Life," by H. Charlton Bastian, F. R. S. (2 vols., London and New York, 1872).

**SPONTINI, Gasparo Luigi Pacifico,** an Italian composer, born at Majolati, near Ancona, Nov. 14, 1774, died there, Jan. 24, 1851. At the age of 13 he entered the conservatory of La Pietà at Naples, and was for a time a teacher there. In 1796 he produced *I puntigli delle donne*, which was followed during the succeeding 10 years by 12 other operas, tragic and comic. In 1803 he went to Paris, where his first great work, *La Vestale*, was brought out in December, 1807, and at once established his reputation throughout Europe. It was succeeded in 1809 by another work of equal vigor, *Fernando Cortez.* The success of these works obtained for Spontini in 1810 the directorship of the Italian opera. He accepted the post of director general of music at the court of Prussia in 1820, and remained at Berlin for 22 years. In 1842 he returned to Paris, and near the close of his life resumed his residence in his native village. He received the title of count of Sant' Andrea from the pope, and that of doctor of philosophy and arts from the university of Halle, and was made a member of the French institute.

**SPOONBILL,** the common name of the wading birds of the family *plataleidæ*, characterized by a much depressed bill, very broad, and dilated at the end in the shape of a rounded spoon. In the genus *platalea* (Linn.) the bill is long, straight, thin, slightly bent downward at the tip, the mandibles in close opposition and the edges not lamellar; nostrils basal and in the lateral groove; wings long, second quill the longest; tail short; legs longer than in the typical waders, tibia bare for nearly one half; tarsi not much longer than middle toe, covered with small hexagonal scales; toes webbed at the base, the outer longer than the inner, the middle not pectinated, and the hind one only partly resting on the ground; claws short and obtuse. There are about a half dozen species, found in all quarters of the globe, migrating to warm climates at the approach of winter; they frequent marshy inlets of the sea, and the borders of lakes and rivers, wading about in search of fish fry, worms, frogs, and aquatic insects; they can swim and dive. The nest is made either on trees or among rushes in swampy places, and composed of coarse sticks; the eggs are two to four, whitish. The roseate spoonbill (*P. ajaja*, Linn.) is about 30 in. long, and $4\frac{1}{3}$ ft. in alar extent; the bill is 7 in. and covered with a soft skin; the head is of moderate size, bare, the skin yellowish green; the neck is long and slender, and the body compact and muscular. The prevailing color is rosy red, paler in front, and nearly white on the neck; lesser wing coverts, upper and lower tail coverts, and lower part of throat, bright carmine; tail feathers ochrey yellow; the young have the head feathered, the carmine tint wanting, and the tail rosy. It is found in the southern Atlantic and gulf states, and is very abundant in the breeding season on Indian river, Florida; it does not go above North Carolina, nor far from the sea. These birds are essentially nocturnal, though they often feed by day when the tide suits; they are fond of the company of herons; they fly with the neck and legs extended, and rise rapidly to a great height; they alight easily on trees, and can walk on the large branches. The breeding time in the Florida keys begins in February, the young

European Spoonbill (Platalea leucorodia).

being out of the nest by April 1; the nest is usually in the top of a mangrove, coarsely made; the eggs are commonly three, elongated, $2\frac{1}{2}$ by $1\frac{1}{2}$ in., white, sprinkled all over with

bright rufous spots, forming a ring near the large end; they breed and are commonly seen in flocks. The flesh is oily and poor eating; the beautiful feathers of the wings are made into fans in Florida. The European spoonbill (*P. leucorodia*, Linn.) is about the same size, white with reddish yellow patch on breast, pale yellow naked space around eyes and throat, and a yellowish white, long occipital crest; it is rare in England, but common in Holland and S. Europe and all over Africa.

**SPORADES** (Gr., the scattered), the lesser islands of the Grecian archipelago surrounding the group of the Cyclades, divided into the northern, western, and eastern Sporades. The northern group includes the islands of Skiatho (in antiquity Sciathus), Scopelos, Khilidromi (probably Icus), and Skyros; these lie off the N. E. coast of Negropont or Eubœa, and belong to the kingdom of Greece. The western group, which also belongs to Greece, lies off the E. coast of Argolis, and includes Hydra (Hydrea), Spezzia (Tiparenos), Poros (Calauria), Ægina, and Kuluri (Salamis). The eastern group belongs to Turkey, and lies off the S. W. coast of Asia Minor; it includes Psara or Ipsara (Psyra), Scio (Chios), Samos, Nikaria (Icarus or Icaria), Patmos, Leros, Calymno (Calymna), Stanko (Cos), Stampalia or Astropalia (Astypalæa), and Scarpanto (Carpathus). The Sporades of the ancients included only the eastern group, and this with the exception of the northernmost islands.

**SPOTSWOOD, John**, a Scottish prelate, born in Edinburghshire in 1565, died in London, Nov. 26, 1639. He graduated at the university of Glasgow at the age of 16, and at 20 succeeded his father as minister of Calderkirk. At first he strenuously opposed episcopacy, but soon yielding to the court party, he began to favor it in a moderate form. In 1603 he was one of five clergymen selected by James I. to accompany him to London for his coronation, and while there was appointed to succeed Beatoun as archbishop of Glasgow. From this time he earnestly sought to establish episcopacy in Scotland, incurring much odium among the great body of the Scottish people. In 1609 he was appointed an extraordinary lord of session, but was obliged to remain subject to the ordinary church courts till 1610, when he and two other Scottish bishops received episcopal ordination at the hands of English bishops. He became primate of all Scotland in 1615, and in 1633 placed the crown on the head of Charles I. as king of Scotland. He had for some years been the head, first of one of the two courts of high commission for trying offences against the church, and then of the two combined; and in 1635 he was appointed lord high chancellor of Scotland. Contrary to his own inclinations, as alleged, but by order of the king, he introduced a new liturgy and book of canons, which so aroused Scottish indignation that he retired in 1637 to Newcastle, and finally to London. He wrote a "History of the Church of Scotland, from the Year 203 to the Close of the Reign of James VI." (fol., London, 1655), and one or two smaller works.

**SPOTTED FEVER.** See Fevers, vol. vii., p. 168.

**SPOTTSYLVANIA**, an E. county of Virginia, bounded N. E. by the Rappahannock and S. W. by the North Anna river, and drained by the Mattapony; area, about 450 sq. m.; pop. in 1870, 11,728, of whom 4,659 were colored. The surface is hilly and the soil fertile. Granite and freestone are abundant. It is intersected by the Rappahannock canal and the Richmond, Fredericksburg, and Potomac railroad. The chief productions in 1870 were 56,050 bushels of wheat, 104,210 of Indian corn, 50,832 of oats, 132,502 lbs. of tobacco, 4,527 of wool, and 30,678 of butter. There were 906 horses, 1,388 milch cows, 1,684 other cattle, 1,928 sheep, and 3,662 swine. Capital, Spottsylvania Court House.

**SPOTTSYLVANIA COURT HOUSE, Battles at.** See Wilderness.

**SPRAGUE, Charles**, an American poet, born in Boston, Oct. 26, 1791, died there, Jan. 14, 1875. At the age of 13 he entered a mercantile house as clerk, and subsequently became a partner. In 1820 he became teller in the State bank; and in 1825, on the establishment of the Globe bank, he was appointed its cashier, an office which he held till 1865. From 1821 to 1830 he gained five prizes for prologues to be recited at the opening of theatres in New York, Philadelphia, Salem, and Portsmouth. In 1823 he obtained the prize for the best ode to be recited at the exhibition at the Boston theatre of a pageant in honor of Shakespeare; and in 1830 he pronounced an ode at the centennial celebration of the settlement of Boston. In 1829 he delivered a poem on "Curiosity" before the Phi Beta Kappa society in Cambridge, considered his best production. A collection of his writings was published in New York (1841; new ed., 1850), and a complete revised collection in Boston (1850; new ed., 1855).

**SPRAGUE, William Buell**, an American clergyman, born in Andover, Conn., Oct. 16, 1795, died in Flushing, N. Y., May 7, 1876. He graduated at Yale college in 1815, studied in the theological seminary at Princeton, and in August, 1819, was ordained pastor of the first Congregational church at West Springfield, Mass., as a colleague of the Rev. Joseph Lathrop, whom he succeeded as pastor in 1820. In 1829 he was installed pastor of the second Presbyterian church at Albany, N. Y. He resigned this charge in 1869, and removed to Flushing, N. Y. He made large collections of pamphlets and autographs, the former of which he presented in 1875 to the state library at Albany. He published "Letters to a Daughter" (1822), republished under the title "The Daughter's Own Book;" "Letters from Europe" (1828); "Lectures to Young People" (1830); "Lectures on Revivals of Re-

ligion" (1832); "Hints on Christian Intercourse" (1834); "Lectures illustrating the Contrast between true Christianity and various other Systems" (1837); "Life of E. D. Griffin" (1838); "Life of Timothy Dwight, D. D., President of Yale College," in Sparks's "American Biography" (1845); "Letters to Young Men, founded on the History of Joseph" (2d ed., 1845); "Aids to Early Religion" (1847); "Words to a Young Man's Conscience" (1848); "Women of the Bible" (1850); "Visits to European Celebrities" (1855); "Annals of the American Pulpit," a collection of biographies of leading clergymen of all the denominations (9 vols. 8vo, New York, 1856–'69); and "Memoirs of Rev. John and W. A. M'Dowell, D. D." (1864).

**SPRAT,** a small fish of the herring family, and genus *harengula* (Val.). There are teeth on the jaws, tongue, palate, and pterygoid bones, but none on the vomer; the branchiostegal rays are six or seven. There are about ten species, of which the most common is the English sprat (*H. sprattus*, Val.), called garvie in Scotland; it is 5 or 6 in. long, with the body proportionately deeper than in the herring, and the edge of the abdomen strongly serrated; the scales are large, round, and deciduous; the upper part of head and back dark blue, with green reflections, passing into silvery white on the gill covers, sides, and abdomen; dorsal and caudal dusky, other fins white. It is found on the coasts of Great Britain and Sweden; it ascends the rivers in large shoals in November, after the herrings have disappeared. Though smaller than the herring, it furnishes in winter an abundant, cheap, and wholesome food, and is generally eaten fresh. The fishery is prosecuted by drift or stationary nets, and with most success in dark and foggy nights. Several species in the West Indian seas are called sardines.

**SPRAT, Thomas,** an English prelate, born at Tallaton, Devonshire, in 1636, died at Bromley, Kent, May 30, 1713. He was educated at Oxford, and became chaplain first to the duke of Buckingham, and afterward to Charles II. In 1668 he was made prebendary of Westminster, in 1680 canon of Windsor, in 1683 dean of Westminster, and in 1684 bishop of Rochester. He was clerk of the closet to James II., and in 1686 was made one of the commissioners for ecclesiastical affairs. He published "The Plague of Athens" and "The Death of Oliver Cromwell," poems (1659); "The History of the Royal Society," of which he was one of the original fellows (1677); a history of the Rye House plot (1685); and a volume of sermons (1710); and he edited Cowley's "Poems," with a life in Latin (1668), afterward in English with additions.

**SPRENGEL, Kurt,** a German physician, born at Boldekow, Prussia, Aug. 3, 1766, died in Halle, March 15, 1833. He took his degree at Halle in 1787, and became professor there of medicine, and in 1797 also of botany. His works include *Versuch einer pragmatischen Geschichte der Arzneikunde* (5 vols., Halle, 1792–1803; 3d ed., 1821–'8; 4th ed. by Rosenbaum, 1846 *et seq.*); *Handbuch der Pathologie* (3 vols., Leipsic, 1795–'7; 4th ed., 1815); *Institutiones Medicæ* (6 vols., 1809–'16; new ed. of the last 5 vols., 1819); *Historia Rei Herbariæ* (2 vols., Amsterdam, 1807–'8); *Geschichte der Botanik* (2 vols., Altona and Leipsic, 1817–'18); and *Neue Entdeckungen im ganzen Umfange der Pflanzenkunde* (3 vols., 1819–'22).

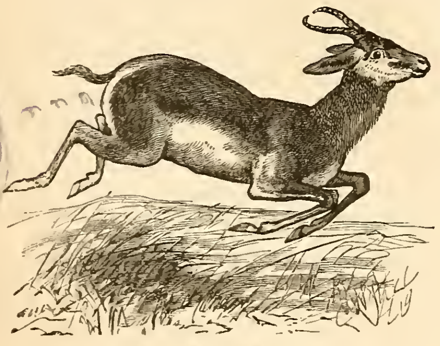
**SPRENGER, Aloys,** a German orientalist, born at Nassereut, Tyrol, Sept. 3, 1813. After studying at Vienna, he went in 1836 to London, where he assisted the earl of Munster in his work on the "Military Science of the Mohammedan Nations." He joined the East India service, in 1845 became president of the college of Delhi, and in 1850 examiner at the college of Fort William, Calcutta, government interpreter, and secretary of the Asiatic society. He published in the *Bibliotheca Indica* translations from the Arabic and Persian, besides works in the Urdu dialect, and a "Life of Mohammed" (vol. i., Allahabad, 1851). He returned to Europe in 1857, became professor of oriental languages in Bonn, and published *Das Leben und die Lehre des Mohamad* (3 vols., Berlin, 1861–'5; 2d ed., 1868 *et seq.*).

**SPRING,** in astronomy, one of the four seasons of the year, beginning for the northern hemisphere at the time of the vernal equinox, or on March 21, and ending at the time of the summer solstice, or June 21. In the United States the spring is regarded as including March, April, and May. (See SEASONS.)

**SPRING. I. Samuel,** an American clergyman, born at Northbridge, Mass., Feb. 27, 1746, died in Newburyport, March 4, 1819. He graduated at Princeton college in 1771, and in 1775 became a chaplain in the continental army, and accompanied the expedition under Col. Arnold to Canada. In 1777 he was ordained pastor of a church in Newburyport. He was a man of great influence and weight of character, and as the leading minister of the Hopkinsian party was active in promoting the union of the two parties in the Congregational churches, effected by the establishment of the Andover theological seminary, and also in originating the American board of commissioners for foreign missions. **II. Gardiner,** an American clergyman, son of the preceding, born in Newburyport, Mass., Feb. 24, 1785, died in New York, Aug. 18, 1873. He graduated at Yale college in 1805, and taught and studied in Bermuda nearly two years. After his return he was admitted to the bar in December, 1808, and practised more than a year. He then studied at Andover seminary, and was ordained as pastor of the Brick church (Presbyterian) in Beekman street, New York, Aug. 10, 1810, in which office he continued till his death. In 1856 he removed with his congregation to the new church on Murray hill. During the last years of his life Dr. Spring seldom preached, his place being filled

by an assistant. His works, chiefly courses of sermons and lectures, are: "Essays on the Distinguishing Traits of Christian Character" (1813); "Fragments from the Study of a Pastor" (1838); "Obligations of the World to the Bible" (1844); "The Attraction of the Cross" (1845); "The Bible not of Man" (1847); "Discourses to Seamen" (1847); "The Power of the Pulpit" (1848); "The Mercy Seat" (1849); "First Things" (2 vols. 8vo, 1851); "The Glory of Christ" (2 vols., 1852); "Contrast between Good and Bad Men" (2 vols., 1855); "Pulpit Ministrations" (2 vols., 1864); and "Personal Reminiscences of the Life and Times of Gardiner Spring" (2 vols., 1866).

**SPRINGBOK** (*antidorcas euchore*), a true antelope of the fields, coming near the gazelles in size and habits, so named from the extraordinary leaps of 7 to 10 ft. in height which it makes when alarmed. They wander in search of food in immense herds over the vast open plains of S. Africa, an easy prey to man and the carnivora. The general color is cinnamon brown above, white below, with



Springbok (Antidorcas euchore).

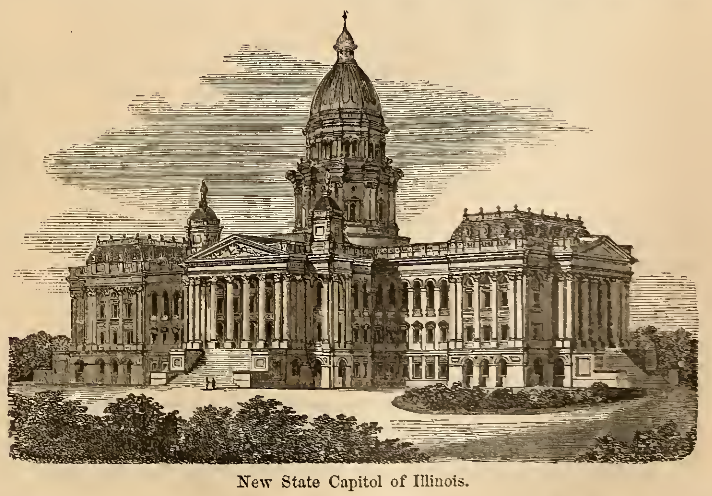
long white hairs on the croup very conspicuous when jumping; its flesh and skin are much esteemed. The horns in the adult are lyrate.

**SPRINGFIELD,** a city and the shire town of Hampden co., Massachusetts, on the E. bank of Connecticut river, opposite the town of West Springfield, with which it is connected by a railroad and a highway bridge and by ferry, 80 m. W. by S. of Boston, and 120 m. N. N. E. of New York; pop. in 1850, 11,766; in 1860, 15,199; in 1870, 26,703, of whom 6,930 were foreigners; in 1875, 31,053. It is noted for the great variety of its skilled industries, mostly dependent on steam power, and for the richness of its churches, of which five are built of stone and are of considerable architectural merit. Portions of the city are elevated and hilly, but along the river it is level. It is well built, and has wide streets shaded with elms and maples. The city hall is a noble building in the Romanesque style, and has a large public hall which will accommodate 2,700 persons. There are several other public halls, of which the music hall, seating 1,200, is the largest. The court house is a fine granite building, which cost $200,000. The city library contains 36,500 volumes. The new library building is one of the handsomest public edifices in the city. It is of brick, with facings of granite and Ohio stone, and cost with land about $100,000. Besides the library it contains a museum of natural history and antiquities. The new high school building is a fine structure of pressed brick, with trimmings of gray Ohio sandstone, three stories above the basement. Hampden park, on the bank of the Connecticut, contains 60 acres, with a costly dike to protect it from the spring freshets, and has a celebrated race course. The Springfield cemetery contains about 40 acres, with a great variety of shade trees and fountains. Springfield is an important railroad centre, four lines meeting in one large depot, each having extensive connections, viz.: the Boston and Albany, the New Haven, Hartford, and Springfield, the Connecticut River, and the Springfield, Athol, and Northeastern. The United States armory employs from 500 to 700 men, chiefly in the manufacture of rifles and carbines. During the civil war about 3,000 men were employed. The arsenal, offices, storehouses, and principal shops occupy nearly the highest ground in the city, on State street, and command a fine view of the Connecticut valley. The grounds (72 acres) are enclosed with an iron fence and beautifully laid out with trees, shrubbery, and flowers. The arsenal contains about 275,000 stand of arms. The heavier work is done at the shops on Mill river. The germ of the armory existed during the revolution, but it was not formally established till 1794. Among the more important private manufactories are one of railroad cars, one of sporting arms, one of revolvers, several of steam engines, boilers, &c., two of gold chains, one of gold leaf, one of gold rings, three of buttons, two of card and glazed paper, one of blankets, one of cartridges, two of desks and counters, three of elevators, four of envelopes, one of corrugated iron, one of filters, several of furniture, three of hand stamps, four of hardware, one of gas machines, one of gilt moulding, several of harness, saddlery, and trunks, one of levels, two of mattresses, one of sewing machine needles, one of paint, three of paper boxes, one of collar paper, three of paper collars, two of rubber goods, one of sieves, two of show cases, one of skates, two of slippers, one of spectacles and thimbles, two of steam pumps, one of watches, one of woollens, five of brick, and one of boots and shoes, two cotton mills, and two brass founderies. The Morgan envelope company also manufacture fancy stationery and writing materials, and print the postal cards for the government. There are five book-publishing houses; eight national banks, with an aggregate capital of $2,950,000; three savings banks, with deposits to the amount of $8,500,000; and three insurance companies (two fire and one life). The city is divided into eight wards, and is governed by a mayor, a board of

aldermen of one member from each ward, and a common council of 18 members. Water is supplied by works recently erected, there being three reservoirs for low service, with an aggregate capacity of 110,577,000 gallons, and one for high service, with a capacity of 2,132,-817,000 gallons. The expenditures in 1874 amounted to $781,847, viz.: pauper department, $23,153 17; highways, $117,310 83; salaries, &c., $110,118 79; erection and repair of school houses, $81,849 78; fire department, $35,735 55; interest, $58,742 77; police, $29,046 63; sewers, $45,004 80; miscellaneous, $228,815 30. The valuation of property was $38,336,778; interest-bearing debt at the close of the year, $1,794,875. The principal charitable institutions are the almshouse, city hospital, home for women, and home for children. The public schools are under the general management of a committee of one member from each ward, and under the immediate supervision of a superintendent. In 1873-'4 there were 26 school houses, with a high school, 140 teachers, and an average attendance of about 4,000; current expenses, $110,185 79, of which $85,593 41 were for teachers' wages. Two newspapers with daily and weekly editions and two weeklies are published. There are 26 churches, viz.: 1 Adventist, 3 Baptist, 6 Congregational, 1 Episcopal, 5 Methodist, 5 Roman Catholic, 1 Spiritualist, 1 Swedenborgian, 1 Union Evangelical, 1 Unitarian, and 1 Universalist.—Springfield was first settled in 1635 by emigrants from Roxbury, who on May 14 drew up and signed an agreement for self-government. The place was first named Agawam, the Indian name of a river of West Springfield, which with several adjacent towns of the present day was then included in its boundaries. In 1637 a church was formed. In 1638 the settlers chose William Pynchon magistrate, and in April of the same year named the settlement Springfield, from the name of his residence in England. Mr. Pynchon returned to England in 1652; but his son John remained, and in 1662 erected the famous "Pynchon house," the first brick house in the Connecticut valley, and long a fortress against the Indians. In 1675, during King Philip's war, the Indians burned the settlement, destroying about 30 houses and 25 barns. The growth of the town was slow till the opening of the Boston and Albany railroad in 1838. It was made a city in 1852.

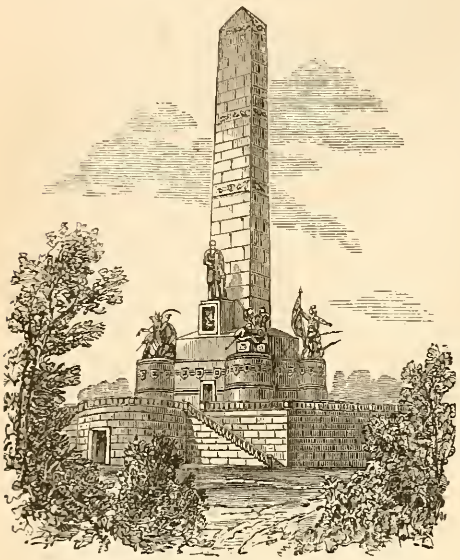
**SPRINGFIELD,** a city and the capital of Clark co., Ohio, at the junction of Lagonda creek with Mad river, 45 m. W. of Columbus and 70 m. N. E. of Cincinnati; pop. in 1850, 5,108; in 1860, 7,002; in 1870, 12,652, of whom 2,169 were foreigners. It is in the heart of one of the richest and most populous agricultural regions in the Union, and is well laid out and handsomely built. Six lines of railroad intersect here, viz.: the Cleveland, Columbus, Cincinnati, and Indianapolis; Cleveland, Sandusky, and Cincinnati; Columbus, Springfield, and Cincinnati; Little Miami (Springfield branch); Springfield and Jackson (narrow-gauge coal road); and Atlantic and Great Western. A large trade is carried on in wheat, flour, Indian corn, and other produce, and many cattle and swine are shipped to eastern markets. Water power is abundant, and about 80 factories are in operation, employing 4,000 hands. These include flouring mills, iron founderies, machine shops, manufactories of agricultural implements, linseed oil mills, and a paper mill. More than 30,000 mowers and reapers are manufactured annually. Limestone is largely quarried and burned. Four national banks have an aggregate capital of $900,000. There are six large public school buildings, including a fine new high school house. The Springfield seminary is a flourishing institution. Wittenberg college, under the auspices of the Evangelical Lutheran church, was opened in 1845; in 1874-'5 it had 10 instructors, 163 students (100 in the collegiate department), and a library of 6,000 volumes. Springfield has a free public library of 4,000 volumes, a daily, a tri-weekly, and five weekly newspapers, two monthly periodicals, and 20 churches.

**SPRINGFIELD,** a city and the capital of Illinois, and seat of justice of Sangamon co., 178 m. S. W. of Chicago; lat. 39° 48′ N., lon. 89° 33′ W.; pop. in 1840, 2,579; in 1850, 4,533; in



New State Capitol of Illinois.

1860, 9,320; in 1870, 17,364, of whom 4,456 were foreigners; in 1875, 25,116. It is on a beautiful prairie, 5 m. S. of Sangamon river. Its streets are broad, intersect each other at right angles, and are tastefully adorned with shade trees. From the beauty of the place



Lincoln Monument.

and its surroundings, it is termed the "Flower City." The capitol, in a square near the centre of the city, is one of the finest buildings of the kind in the country. Other noteworthy buildings are the United States court house and custom house and post office building, the county court house, state arsenal, high school house, and several handsome churches and commodious hotels. A new state house is nearly completed. Two miles N. of the city is Oak Ridge cemetery, a picturesque and well kept burying ground of 72 acres, containing the remains of Lincoln and a monument to his memory which cost $206,550, dedicated on Oct. 15, 1874. Springfield is the point of intersection of the Springfield and Northwestern, the Gilman, Clinton, and Springfield, the Ohio and Mississippi, the Chicago, Alton, and St. Louis, and the Toledo, Wabash, and Western railroad lines. There are coal mines in the vicinity, and the surrounding country is very productive. The trade is extensive, and the manufactures are important. The principal establishments are flouring mills, founderies and machine shops, rolling mills, breweries, woollen mills, a watch factory, and manufactories of woodwork, brooms, cordage, harness and saddlery, carriages and wagons, furniture, washing machines, and sash, doors, and blinds. There are three national banks, a private bank, a savings institution, and an insurance company. The city is governed by a mayor and 18 aldermen (3 from each ward). It is supplied with water from Sangamon river. It contains three academies and five public schools (one high and four ward schools), the latter having in 1874-'5 2,530 pupils enrolled, and an average attendance of 1,876. There are two daily and four weekly (one German) newspapers, a library association, and 22 churches, viz.: 4 Baptist, 1 Christian, 1 Congregational, 2 Episcopal, 1 Jewish, 3 Lutheran, 4 Methodist, 4 Presbyterian, and 2 Roman Catholic.—Springfield was laid out in 1822, was made the state capital in 1837, and a city in 1840.

**SPRINGFIELD**, a town and the county seat of Greene co., Missouri, on Wilson creek and the Atlantic and Pacific railroad, 195 m. in direct line S. W. of St. Louis; pop. in 1870, 5,555, of whom 1,090 were colored; in 1875, about 8,000. It is on a table land 1,500 ft. higher than St. Louis. Its trade and manufactures are important. The principal establishments are four flouring mills, two planing mills, a cotton mill, a woollen mill, a carriage factory, two iron establishments, two wagon factories, and the railroad shops. There are two hotels, two national banks, good public schools, a daily and four weekly newspapers, and 13 churches. It is the seat of Drury college (Congregational), founded in 1873.—Springfield was known as an Indian trading post and frontier village as early as 1820. It was incorporated in 1830. Its prosperity dates from the close of the civil war. In the autumn of 1861 and the early part of 1862 it was alternately in the possession of the federal and the confederate forces; and several fights occurred in the town and its vicinity, in one of which (Aug. 10, 1861) the federal general Nathaniel Lyon was defeated and killed.

**SPRUCE**, the name for coniferous trees of a section of the genus *abies*, which includes those with scattered leaves and pendent cones, the scales of which are persistent. (See Fir, Hemlock Spruce, and Pine.) The needle-shaped leaves are four-sided, and point in every direction; the cones hang from or near the ends of the branches, the scales remaining attached to the axis;

Black Spruce (Abies nigra).

the seed parting freely from the wing, and without balsamiferous vesicles; the anther cells opening lengthwise. The black, or as it is often called double spruce (*A. nigra*), extends from Maine to Wisconsin and further southward along the higher ranges, and in Canada reach-

es northward to 65°, it being partial to cold, swampy localities among the mountains. Its straight, tapering trunk, often 75 ft. high, bears a handsome conical head, if it has room to develop; but in a crowded forest the trunks are branchless, save a small tuft at the summit. The very short leaves, rarely more than half an inch long, are erect, stiff, and very dark green; the cones are 1 to 1½ in. long, dark purple when young, but when ripe (in November) pale brown; the seeds are shed the following spring, but the cones remain several years; the scales of the cones are uneven on the margin, and often notched or toothed. The wood is very strong, light, and durable, and is much used in ship building, not only for masts and spars, but in the hull, where it outlasts oak; it is much used for the sides of ladders, for the smaller timbers in house building, and for shingles. The recent shoots of this species are used in this country for making domestic beer. The tree is sometimes planted for ornament, and young specimens are very regular in form; but they get ragged as they grow older. The color of the foliage is rather sombre, and the so-called red spruce is merely a form of this with larger and redder cones and the wood tinged with red. The white or single spruce (*A. alba*) has a range similar to the preceding, and extends even further north than that; Richardson found it within 20 m. of the Arctic sea. The leaves are somewhat longer than those of the black spruce, and of a pale glaucous green; though the leaves are attached equally on all sides of the shoots, yet on the horizontal branches they curve upward in such a manner as to appear two-ranked; the cones, about 2 in. long, fall the first winter, and their scales have a firm, even edge. The wood of this is also valuable, some considering it not inferior to that of black spruce, and superior to it for spars; the long roots are remarkably tough, and the Indians prepare from them thongs or threads with which to sew their birch-bark canoes. The white spruce, when young, is of a regular conical shape, very compact, and its pale but lively green color makes a most effective contrast when it is planted near evergreens with darker foliage. In the forests of northern Michigan and Wisconsin, the lumbermen distinguish a blue spruce, which has more bluish leaves, while its cones are more like those of the black spruce. Several species are peculiar to the Rocky mountains and the Pacific coast; notable among these is Menzies's spruce (*A. Menziesii*), discovered by Douglas in northern California; it is abundant in Alaska, and extends eastward to the Rocky mountains, where it is known as balsam; it is a subalpine species, rarely found at a less elevation than 7,000 ft., and prefers low marshy soils or the margins of streams. It reaches 100 ft., but the average height is 60 or 70 ft.; it has a straight trunk and a regular pyramidal outline; the leaves are broader than in eastern species, silvery whitish beneath, very stiff, and almost spine-like; the cylindrical cones are about 3 in. long, their pale and thin scales irregular on the margin. The wood is very compact, but rather coarse-grained and resinous, and the trunks taper too rapidly to saw up to advantage. As an ornamental tree it is likely to become popular; it is quite hardy near Boston and in other northern localities; its growth in rich moist soils is very rapid. Engelmann's spruce (*A. Engelmanni*), 80 to 100 ft. high, was first discovered by Dr. Parry in the Rocky mountains, where it occurs from New Mexico to the head waters of the Columbia and Missouri, forming almost the entire

Norway Spruce (Abies excelsa).

forest growth of some of the mountain slopes, and is most luxuriant at the altitude of 9,000 to 10,000 ft.; much higher than this it becomes dwarfed; it resembles the eastern black spruce. Patton's spruce (*A. Pattoniana*) is a fine species found in the mountains of upper California and northward, and is described as reaching the height of 150 ft. and over.—Of the exotic spruces none is so well known as the Norway (*A. excelsa*), which is indeed the popular evergreen of this country; it is indigenous throughout northern Europe and Asia, in Russia and Siberia extending beyond the arctic circle, especially abundant in Norway, Sweden,

and the neighboring countries, and further south in the Alps, Pyrenees, and other ranges. It reaches a height of 120 to 150 ft. and a diameter of 3 to 5 ft., requiring a century to attain this development; when not crowded, its long stout branches spread out regularly on every side, forming a perfect pyramid; its dark green leaves are larger than in our black and white spruces, rigid and curved, and the conspicuous terminal cones are 6 or 7 in. long and pendent at maturity. The wood of the Norway spruce is of great value for many uses; sawn into boards, it forms a large part of the deals used for floors and other inside work, box making, cheap furniture, &c., while the round timber serves for masts, spars, scaffoldings, and framework; the wood is very durable, especially when the bark is left on; the bark is used for tanning. The resin of the tree rarely exudes spontaneously, but is obtained by removing a strip of bark, an inch or more wide and deep, and 3 ft. long, from the south side of the tree; the following year the groove is found filled with the turpentine, which is scraped off, and the groove enlarged by the removal of a thin strip of bark from each side of it; the product so obtained is one of the several turpentines called frankincense or thus (see FRANKINCENSE), and when melted in boiling water and strained it forms the true Burgundy pitch. (See PITCH.) The Norway spruce being so largely raised from seeds, there are numerous deviations or sports from the normal form, of which 20 or 30 are in cultivation; some vary in foliage, others are dwarfs, while a few are curious monsters; in var. *inverta* the branches are turned directly downward, and in var. *monstrosa* there is such a strong indisposition to branch, that it will throw up a leader 10 or 15 ft. high and perfectly naked. *A. obovata* from Siberia, and *A. orientalis* from the Black sea, are too near the Norway in appearance to be popular.—The Himalayan spruce (*A. Smithiana*), found high up the Himalaya mountains, and also in China and Japan, is a remarkably handsome species; it is not quite hardy at Philadelphia, but valuable further south.

**SPURGEON, Charles Haddon,** an English preacher, born at Kelvedon, Essex, June 19, 1834. His father and grandfather were preachers in the Independent denomination. At the age of 16 he became an usher at Newmarket, and subsequently at Cambridge. Not long after going to Cambridge he connected himself with a "lay preachers' association" there, and before he was 18 became pastor of a small Baptist congregation at Waterbeach. In 1853 he was called to the New Park street Baptist chapel in Southwark, London, to which his preaching attracted such crowds that the congregation removed first to Exeter hall, and then to Surrey music hall. In 1861 a new chapel capable of seating between 5,000 and 6,000 was completed for his congregation in Newington Butts. Mr. Spurgeon has received more than 13,000 persons into his church, and has erected 36 chapels in London, supplied with ministers trained in a college of his own founding. His sermons have been printed weekly, and 16 volumes have been published collectively, besides a volume entitled "Gems: Brilliant Passages from the Discourses of C. H. Spurgeon" (1859). He has also published "The Saint and his Saviour" (1857); "Gleanings among the Sheaves" (2d ed., 1868); "John Ploughman's Talk, or Plain Advice for Plain People," and "Evening by Evening: Readings for the Family and the Closet" (1869); "Feathers for Arrows, or Illustrations from my Note Book" (1870); "Types and Emblems" (1875); and "Lectures to my Students" (1875). Since 1865 he has edited a journal, "The Sword and Trowel."

**SPURZHEIM, Johann Gaspar,** a German phrenologist, born at Longwich, near Treves, Dec. 31, 1776, died in Boston, Mass., Nov. 10, 1832. In 1795 the French invasion interrupted his studies at the university of Treves, but he continued them at Vienna. Here he became the most eminent pupil of Gall, whom he afterward aided in the development and popularization of his doctrines. In 1805 he joined him in his travels and lectures in various parts of Europe, settled with him in Paris in 1807, and was intimately associated with him till 1813. He then delivered lectures in London, which were attacked by Dr. John Gordon in the "Edinburgh Review." In reply Spurzheim demonstrated at Edinburgh, before hundreds of Gordon's students, the fibrous character of the brain, which the latter had denied. After residing several years in Paris, he resumed his lectures in Great Britain in 1825, and in 1832 went to Boston, where he delivered several lectures. Besides his share in the most important publications of Gall, and several works of his own in French, he published "The Physiognomical System of Dr. Gall and Spurzheim" (London, 1815); "Outlines of the Physiognomical System" (1815); "View of the Elementary Principles of Education" (Edinburgh, 1821; enlarged ed., London, 1828); "Phrenology in connection with the Study of Physiognomy" (London, 1826); "The Anatomy of the Brain, with a General View of the Nervous System" (1826); "Outlines of Phrenology" (1827); and "Sketch of the Natural Laws of Man" (1828).—See "Memoir of the Life and Philosophy of Spurzheim," by Andrew Carmichael (Dublin, 1833).

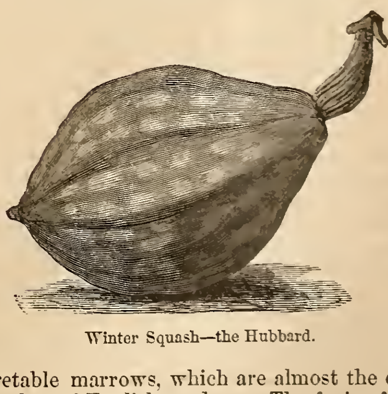
**SPY,** in war, one employed to penetrate the enemy's lines and ascertain his condition and plans. Spies have always been employed in warlike operations, and writers on the laws of war lay down the principles which are to regulate their conduct. Though thus recognized, a stigma is attached to their employment as one to which falsehood and treachery are indispensable, and a captured spy is not admitted to the privileges of a prisoner of war, but is put to an ignominious death. The difficulty of

determining who is to be treated as a spy is sometimes very great. Presumptively one who is within the enemy's lines in disguise or wearing the enemy's uniform is a spy; but the dress is only a circumstance indicative of an intent to deceive, and other circumstances might be equally conclusive. One belligerent may employ the subjects of the other as spies, but a peculiar infamy attaches to one who to a discreditable occupation adds the atrocious crime of treason. A spy is not restricted to obtaining information; he may inflict injury upon the enemy, so that he do not resort to assassination, poisoning, or other means which, in the words of Vattel, "affect the common safety of human society." Inciting a spy to such atrocity would subject a commander and his forces to retaliation. An employment at once so dangerous and so discreditable cannot be forced upon any one; the commander must usually procure his spies by heavy rewards.

**SQUASH,** the name of several species and varieties of *cucurbita*, of the order *cucurbitaceæ* or gourd family, called by the North American Indians *askutasquash.* The characters of the family are given under GOURD, and those of the genus under PUMPKIN. In no genus of cultivated plants is there more difficulty in tracing varieties to the species from which they are derived, or in ascertaining the countries in which they originated, than in *cucurbita*, and in this country the terms pumpkin and squash are used very indefinitely, large forms of what are evidently squashes being called pumpkins. Naudin, who experimented with over 1,200 living plants, could make but four distinct species, to all of which he ascribes an eastern origin; only three of these are cultivated in this country. On the other hand, Roger Williams and other writers on early New England history found some *cucurbita* in general cultivation among the Indians, and we derive from them the common name by which the plants are known in this country. One species, *C. ovifera*, is cultivated for ornament as orange gourd, mock orange, egg gourd, or fancy gourd, and rarely in vegetable gardens as egg squash, to be eaten while young; this, which in cultivation presents a great variety of shapes and markings, grows wild in Texas, and Gray thinks it is probably the original of all the crook-necked squashes, vegetable marrows, and even the common pumpkins. It will serve the present purpose to enumerate the leading varieties in cultivation, without attempting the difficult task of tracing them to their original species.—The ordinary early summer squashes are also called bush squashes; the vine has lost its tendency to run a long distance, the tendrils have disappeared, the petioles or leaf stalks are much longer than in any others, and the fruits all have angled stems; the most common of these are the scalloped bush sorts, in which the fruit is somewhat hemispherical with an expanded edge, which is deeply and regularly scalloped; of these there are varieties with the rind pure white, yellow, green, green striped with white, and yellow marked with green; from their peculiar shape they are often called "patty-pans," and in Virginia they are known as cymlings. Another very distinct bush variety is

1. Crook-neck Squash. 2. Scalloped Squash.

the summer crook-neck, in which the fruit is about 8 in. long, largest near the base and tapering toward the stem, where it is usually curved; the skin is bright yellow, and nearly covered with warty protuberances; this is the best of the early varieties, all of which should be used while the rind is tender.—The late varieties all have strong running vines, extending 12 ft. or more, and taking root at the joints; they differ in their times of ripening and in their keeping qualities, but all of them, even if taken when quite young, are better for the table than any of the bush sorts. The Canada crook-neck is small, with a curved neck, and cream yellow or darker when ripe; the skin never gets very hard. The winter crook-neck is many times larger, and though not so fine in quality is more generally cultivated, and both with care will keep the year round; both have angled stems, which indicate a relationship with the bush sorts, as have the various



Winter Squash—the Hubbard.

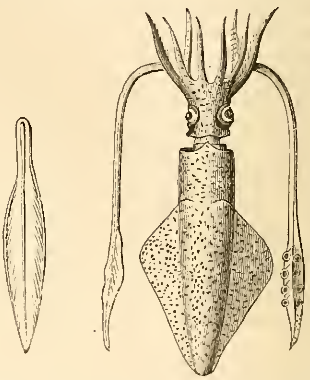
vegetable marrows, which are almost the only squashes of English gardens. The fruit of the marrows is elliptical, 9 in. or more long, and of a pale straw color; there are several sub-varieties. The autumnal or Boston marrow has an egg-shaped fruit, pointed at each end,

the stem large and fleshy, skin never becoming hard; color reddish at maturity; quality excellent. This has for a long time been regarded as the best of all winter varieties, but it is excelled by the Hubbard, which is somewhat similar in shape and in character of stem; the color of the often ribbed rind is clay-blue or olive-green, and it becomes so extremely hard that it requires to be cut with a hatchet; the flesh is thick, dry, and sweet; it keeps till spring. The Butman is similar in form, skin white and green, and regarded as the finest of all. The Yokohama, from Japan, is a singularly flattened variety, with a much warted green skin, which turns to orange; this has a very long and angled stem. The turban variety is of good quality, and is remarkable for a projection of a portion of the fruit beyond the line which shows where the calyx tube was attached to the ovary.

**SQUASH BUG,** a well known hemipterous insect, the *coreus tristis* (De Geer). It is about three quarters of an inch long, with a triangular head; the general color is ochre yellow, rendered dusky above by numerous black dots; the sharp edges of the abdomen project beyond the closed wing covers; on the back of the head, behind the eyes, are two glassy raised eyelets. They appear by the last of June or beginning of July, when the squash vines have put out a few leaves, pair, and soon begin to lay their eggs; they conceal themselves by day, and in the evening fasten their eggs in little patches on the under side of the leaves by a gummy substance; the eggs are soon hatched, and the young, pale ashy and with large antennæ, appear in successive broods during summer, pass through their last change, attain their full size in September and October, and pass the winter and spring in a torpid state in crevices. The loss of sap from the punctures of these insects causes the leaves to become brown, dry, and wrinkled, when they are deserted for fresh ones. When irritated, and particularly when crushed, they give out a strong, nauseous odor. It is best to destroy them before they have laid their eggs.

Squash Bug (Coreus tristis).

**SQUID,** a cephalopodous mollusk, of the dibranchiate order, tribe *decapoda*, family *teuthidæ*, of which the typical genus is *loligo* (Lam.). The body is elongated, tapering behind, with a pair of terminal fins; branchiæ two; arms eight, with two rows of pedunculated suckers, and two very long tentacles; the internal shell, or *gladius*, is reduced to a horny quill-shaped plate, with two lateral expansions; the ink bag is well developed, and its secretion jet black. They are good swimmers, all marine, and never leave the water; they can creep head down on the cephalic disk; the ova are enclosed in long, gelatinous, cylindrical sheaths, called sea grapes, and may be nearly 40,000 in number; the sight is good, and the movements are rapid. They are sometimes called calamaries, from the internal pen-like bone and ink bag, and the general cylindrical form like an ancient escritoire. The small species are gregarious, but the large hooked squids are solitary and oceanic. The common squid of the New England coast, the *L.* [*ommastrephes*] *illecebrosa* (Lesueur), is from 6 to 12 in. long; the colors vary rapidly, with the will of the animal, from yellowish white to bluish, violet, brown, red, and orange, in spots or general tint. They swim rapidly backward by dilating and contracting the sac-like body, and forward by the terminal fin; they devour numbers of small fish and crustaceans, and are eaten by larger fishes, and used as bait by cod fishers. Squids are found from Norway to New Zealand; the *L. vulgaris* (Lam.), common about the shores of Great Britain, and used in Cornwall as a bait for cod, attains a length of 1 to 1½ ft. The occurrence of large squids on the North American coast has within a few years directed attention to old stories of the gigantic mythical *kraken* of Pontoppidan. Prof. Steenstrup has collected many instances of gigantic squids on the coasts of northern Europe from 1549 to the present time; they have also been found in tropical and southern waters, and were known to Aristotle and Pliny. It is proved that the sperm whale feeds chiefly upon these large squids, and many interesting fragments have been obtained from the stomach of this cetacean. In 1872 one was found floating dead on the Grand Banks, 15 ft. long, 4⅝ ft. in circumference, and the longest arms 9 ft.; this was probably the *architeuthis monachus* (Steenstrup), or the sea monk. (See "American Naturalist," February, 1873.) In October, 1873, one was seen, and a piece of an arm cut off, near the coast of Newfoundland; the body was about 10 ft. long, with a diameter of 2½ ft., head 2 ft. long, and caudal fin 22 in. wide. The creature being wounded attacked the boat, when the fisherman cut off one of the arms with his axe, about 20 ft. long and at least 10



Common Squid of Great Britain (Loligo vulgaris).

ft. from the body, the whole arm being more than 30 ft., and the total length of the animal about 44 ft. The most characteristic features are: the irregularity of the rows of lingual teeth, the very simple internal shell or pen, embryonic form of caudal fin, and clusters of small suckers and tubercles on long arms; the first three indicate a low rank in the family, below *loligo* and *ommastrephes;* it may be a modification of the Jurassic *teudopsis* preserved by its oceanic habitat to the present time, like other huge marine types having a mesozoic aspect. (See SEA SERPENT.) Probably some of these great squids of the genus *architeuthis* attain a total length of 50 ft., including the long tentacles; the largest known is probably the *A. princeps* (Verrill), from Newfoundland.

**SQUIER, Ephraim George,** an American archæologist, born in Bethlehem, N. Y., June 17, 1821. He early became an engineer and a journalist. In 1845 he made a survey, in conjunction with E. H. Davis, M. D., of the ancient monuments of the Mississippi valley, the results of which were published in 1848 in "Ancient Monuments of the Mississippi Valley," being vol. i. of the "Smithsonian Contributions to Knowledge;" and in 1848 he explored the aboriginal monuments of the state of New York. In 1849 he was appointed chargé d'affaires to Guatemala; in 1853 assisted in the survey of an interoceanic railway route through Honduras, for the construction of which he formed a company; in 1863-'4 was United States commissioner to Peru to adjust claims, devoting many months to exploring the ancient monuments of that country; and in 1868 was for a time United States consul general to Honduras. At intervals he has edited newspapers at Albany, N. Y., Chillicothe, O., Hartford, Conn., and New York, and has several times visited Europe. Besides the above mentioned work and numerous archæological papers contributed to American and European scientific periodicals, he has published "Aboriginal Monuments of the State of New York" (4to, Washington, 1851, being vol. ii. of the "Smithsonian Contributions"); "Antiquities of the State of New York" (8vo, Buffalo, 1851), with a supplement on the antiquities of the west; "Nicaragua, its People, Scenery, Ancient Monuments, and proposed Interoceanic Canal" (2 vols. 8vo, New York and London, 1852); "The Serpent Symbol, or Worship of the Reciprocal Principles of Nature in America" (8vo, New York, 1852); "Notes on Central America," &c. (1854); "Waikna, or Adventures on the Mosquito Shore," under the *nom de plume* of Samuel A. Bard (12mo, 1855); *Question Anglo-Américaine*, &c. (8vo, Paris, 1856); "The States of Central America," &c. (8vo, New York, 1857); "Report of the Survey of the Honduras Interoceanic Railway" (4to, London, 1859); "Translation, with Notes, of the Letter of Don Diego de Palacio (1571) to the Crown of Spain on the Provinces of Guatemala, San Salvador, &c." (New York, 1860); "Monograph of Authors who have written on the Aboriginal Languages of Central America" (1861); "Tropical Fibres and their Economic Extraction" (1861); "Is Cotton King? Sources of Cotton Supply" (1861); "Honduras, Descriptive, Historical, and Statistical" (London and New York, 1870); and "Peru: Incidents of Travel and Exploration in the Land of the Incas" (New York, 1876). Most of his books have been translated into German, French, and Spanish.

**SQUILL** (Lat. *squilla* or *scilla*), a drug consisting of the sliced and dried bulbs of the *scilla maritima* of Linnæus, but the plant has been separated from this genus and is now the *urginea maritima* of Baker; it belongs to the lily family, and is a native of the Mediterranean region. It has a large, pear-shaped, onion-like bulb, sometimes weighing 4 lbs.; the leaves are long, flat, and spreading; the scape about 2 ft. high, terminated by a long dense raceme of white flowers. It is not rare in cultivation as a window plant, but has no great beauty. The only preparation given the bulbs is to slice them transversely and dry the pieces in the sun; there are two varieties, the white and the rose-tinted bulbs, the later making a dark-colored and less esteemed product. As found in the shops, squill is in the form of horn-like, curved strips, which can only be pulverized by thorough drying, and unless the air be excluded from the powder it absorbs moisture and soon becomes a solid mass. The taste is mucilaginous, bitter and acrid; its properties

Squill (Urginea [Scilla] maritima).

are ascribed to a principle called scillitine, which has not yet been isolated. Squill is one of the oldest of medicines, and its use is mentioned by the earliest writers; some antiquaries think that the onion which the Egyptians regarded as sacred was really the squill bulb.

Its medicinal effects are diuretic and expectorant, and in large doses emetic and purgative. It is largely employed as an expectorant in domestic practice, for croup and similar affections of children. Vinegar or dilute acetic acid is found the best solvent of the active principles of squill; the drug is first exhausted by the acid, and the vinegar of squill thus obtained is made into a sirup with sugar.

**SQUILL** (*squilla*, Fabr.), a genus of crustaceans of the division *stomapoda*, so called from having the feet placed around the mouth. The body is elongated and generally slender, the head distinct from the thorax, the carapace leaving uncovered four of the thoracic rings, and the abdomen terminating in a wide caudal fin of several plates adapted for swimming. The antennæ of the first segment of the body are long, ending in three many-jointed filaments, cannot be bent under the head, and are inserted below the eyes near the median line; the antennæ of the second segment are shorter, more external, having at the base a large ciliated plate, and terminate in a single many-jointed filament; the eyes are at the end of movable appendages. The mouth is toward the posterior third of the carapace, and has an upper and under lip, a pair of mandibles, and two pairs of jaw feet arranged around it; the third pair of feet are prehensile, strong, bent back on themselves, serrated and spined, and used very much like the first pair of feet in the soothsayer (*mantis*); the next three pairs are directed forward, applied against the buccal apparatus, and inserted close together, with a wide, rounded, ciliated plate at the end; the last three thoracic limbs are slender, with styliform process and ciliated, the segments to which they are attached resembling those of the abdomen. Most of the rings of the body are complete, very nearly equal, and movable on each other; the carapace is nearly quadrilateral, longitudinally divided by two more or less distinct grooves; the first five abdominal rings have large false feet, to the posterior part of the base of which are attached the respiratory organs in the shape of floating, ramified, and fringed gills, which are kept constantly in motion. The heart extends almost the length of the abdomen and thorax, a little dilated anteriorly, sending off lateral branches to each ring; the venous sinuses in which the blood is collected before going to the gills are very large; the stomach advances far into the head. There are many species, all marine, most abundant in the tropics, but occasionally seen as far north as the English channel; they are usually met with far from shore and in deep water; they swim rapidly; they are voracious and carnivorous. The best known species is the *S. mantis* (Fabr.), 6 or 7 in. long, pale yellowish gray, found in the Mediterranean.

Squill (Squilla mantis).

**SQUINTING** (Lat. *strabismus*), a deformity consisting in a want of parallelism between the visual axes of the eyes. Except in cases where it is caused by paralysis, spasmodic or hydropical affections, or irritation of the brain, it is not a disease, and is not accompanied with pain. Ophthalmic surgeons notice three degrees of squinting: 1, where there is but a slight convergence or divergence from the normal axis, such as is ordinarily called a "cast of the eye;" 2, where the inclination is strongly marked, but less than half the cornea is thrown under the eyelid or within the orbit, which is the most frequent variety; 3, where the cornea is nearly or quite thrown under the eyelid or within the orbit, common among those who are born blind, but rare in the case of those who can see. The surgeons also distinguish it according to the departure from the normal axis; as convergent, where the pupil is drawn toward the nose; divergent, where it is drawn toward the outer corner of the eye; ascendent, where it is drawn upward; and descendent, where it is drawn downward. Of these, the convergent form is by far the most frequent, and next in order the divergent and ascendent. The descendent is the rarest of all. Squinting may also be double or single as one or both eyes are affected; it may be congenital, *i. e.*, existing from birth, or accidental, occurring from accident or improper treatment of the eye; the former is rare. It may be also continuous, or rarely intermittent. When not due to one of the causes mentioned above, it depends in a large majority of cases on parallel rays of light not focusing on the retina. To correct this the eye turns in, as in so doing the power of accommodation is increased, because the same nerve which supplies the internal rectus also supplies the muscle of accommodation. (See EYE.)—The treatment prior to 1839 consisted in attempting by various methods to strengthen the weaker muscles, bandaging the normal eye, and compelling the constant use of the other; or by the use of goggles, spectacles, &c., in which all except the centre was opaque. In 1838 Stromeyer described the operation of dividing one of the *recti* muscles, but without having tried it on the living subject. In 1839 Dieffenbach, an eminent surgeon of Berlin, performed it successfully, and

was followed by many English and French surgeons. The operation has now become very common, though the best surgeons admit that there are three classes of cases in which it should not be performed, viz.: those in which the position of the eye is fixed, those which result from the paralysis of the antagonist muscle, and those occurring in infants before dentition. The operation is not difficult nor particularly dangerous, and is generally successful. There are two methods of performing it, the ordinary or that of Dieffenbach, where the conjunctiva is divided and the muscle to be severed is laid bare, and the subconjunctival, where the conjunctiva is divided to a much less extent. The latter is generally preferred.

**SQUIRREL,** the popular name of the rodents of the family *sciuridæ*, which is very numerous in species, and widely spread over the world, except in Australia. They are characterized by a broad head, the frontal bone being dilated into a post-orbital process; the muzzle wide, from the development of the frontal and nasal bones; eyes large and prominent, ears moderate, and whiskers long; the hind feet five-toed, the fore feet four-toed, with a wart-like thumb, all the fingers and toes with compressed and curved claws; the fur is generally soft, especially in the northern species, and the tail is long, hairy, expanded laterally in the arboreal genera, and shorter and bushy in the terrestrial, and in both carried gracefully over the back; the upper lip is cleft, the cæcum large, clavicles perfect, enabling them to use the fore limbs to convey food to the mouth, and the tibia and fibula distinct; some have a membrane extended between the fore and hind limbs. (See Flying Squirrel.) The incisors are $\frac{2}{2}$, smooth in front, brown or orange, the lower compressed and sharp; molars $\frac{5-5}{4-4}$, rooted, tuberculate, with projecting transverse striæ enamelled continuously, the anterior upper one the smallest and sometimes deciduous. The food is chiefly vegetable, though some American species are known to suck eggs and destroy young birds. The family is very abundant in North America, nearly one third of all the species being found here; the prairie dogs and prairie squirrels are peculiar to this continent, as well as most of the flying squirrels. (See Prairie Dog, and Prairie Squirrel.)—The genus *sciurus* (Linn.) is the type of those of the family which live in trees; the species of the United States are hard to determine from the tendency to variation in color (red, gray, and black being the predominating tints), and the diminution in size in the southern states. Baird gives it as a general rule that, when a squirrel has the fur of the throat or belly annulated, it is a variety of some species which normally has the under parts uniformly white or reddish to the roots, or the latter plumbeous. The bones of the red-bellied squirrels are generally red, and of the white-bellied white. The largest of the North American species is the fox squirrel of the southern states (*S. vulpinus*, Gmel.), about 2¼ ft. long, of which the tail is 15 in.; the head is rather slender and pointed, and the tail rather cylindrical; the upper molars are permanently four. The color varies from a gray above and white below, through various shades of rusty, to uniform shining black; the fur is coarse and harsh, and the ears short; the ears and nose are white in all its varieties. It is found from North Carolina through the S. Atlantic and gulf states to Brazos river in Texas. The gray variety is the *S. capistratus* (Bosc), and the black the *S. niger* (Linn.) and the black squirrel of Catesby. It prefers elevated and open pine ridges where there are occasional oak, hickory, and other nut trees; the nest for the winter and breeding seasons is made in a hollow tree, and in summer in the forks between the branches. The young are born in March and April, and fed by the parents for four or five weeks. The food consists of acorns, nuts, fruit of the pine cones, green corn in summer, buds and roots in spring, and whatever it can get in winter, as it does not appear to lay up any winter stores, or to resort to any hoards previously buried. When alarmed, it makes for a hollow tree; it is a swift runner, defends itself boldly, and is very tenacious of life; it is generally seen toward the middle of the day; it is easily domesticated, but is less active in the cage than the smaller species; its flesh is frequently eaten. The cat squirrel (*S. cinereus*, Linn.), the fox squirrel of the middle states, is 25 or 26 in. long, of which the tail is about 14 in.; the head is very broad, the muzzle short and cat-like, the body thick and heavy, and the tail large and flattened; the color varies from light gray tinged with rusty above and white below, to grizzly above and black below; it is never pure black; the ears are low and broad, and never white; the hair is less coarse and stiff than in the preceding species. It is found chiefly in the middle states, rarely in southern New England; it is rather a slow climber, and of inactive habits; it becomes very fat in autumn, when its flesh is excellent. The species called fox squirrel in the western and southwestern states (*S. Lodovicianus*, Harlan) has a very full and broad tail; it is rusty gray above and ferruginous below. The common gray squirrel (*S. Carolinensis*, Gmel., and *S. migratorius*, Aud. and Bach.) is about 22 in. long, of which the tail is 12 in.; the upper molars are permanently five. The general color is gray above and white below, with a yellowish brown wash on the back and sides; the region behind the ears has usually a white woolly tuft; there is a black variety, the *S. niger* of Godman. The ears are very high, narrow, and acute, the tail flattened, feet large, claws strong, thumb a rudimentary callosity; the palms naked, and soles mostly so in summer; whiskers longer than the head. It is found extensively over the United States, being much the smallest at the south. The young are four

to six, born in May or June. They are easily domesticated and gentle in confinement, and are often kept as pets in wheel cages; they do not lay up any great amount of winter stores, being partially torpid at this season and requiring but little food; they are very fond of nuts, and of green corn and young wheat, on which last account wars of extermination are often waged against them, whole villages turning out to hunt them. At irregular periods they sometimes collect in large troops in the northwest, migrating eastward, crossing rivers and mountains, and committing great destruction in the fields in their course. Many of this species have been domesticated in the public parks of northern cities, where they drive

Common Gray Squirrel (Sciurus Carolinensis).

away the birds by destroying their eggs and young. The California gray squirrel (*S. fossor*, Peale) is as large as the fox squirrel, but more slender; it is grizzled bluish gray and black above and white below; tail black, white on the exterior, and finely grizzled below; back of ears chestnut. It represents on the west coast the gray squirrel of the east. It runs very swiftly on the ground, not readily taking to trees when pursued; like the other squirrels, it has a kind of bark; the food consists principally of nuts, which it sticks in holes of pine trees bored by woodpeckers, resembling pegs placed in the wood. The red or Hudson bay squirrel (*S. Hudsonius*, Pall.) has been described under CHICKAREE.—The common European squirrel (*S. vulgaris*, Linn.) is about 14 in. long, of which the tail is about one half; the color is reddish, chestnut brown on the back, white below, becoming gray in winter in the north, and yielding then the much prized fur called minever; the ears are tufted, and the hair on the tail is directed to the two sides. It is found throughout Europe and N. Asia; it feeds in summer on buds and shoots, especially the young cones of the pine, and in winter on a supply of nuts which it gathers in autumn and hides in some hollow tree. It is an excellent climber, and makes a nest of moss, leaves, and fibres very neatly interwoven, in a hole or fork of a tree, and well concealed; a

Common European Squirrel (Sciurus vulgaris).

pair live together, frequenting the same tree for many years; the young are born in June, and remain with their parents till the following spring; they are torpid in the very coldest days. The largest of the squirrels is the Malabar squirrel (*S. maximus*, Schreb.), 33 in. long, as large as a cat; it is black above, the sides and top of head chestnut, and lower parts pale yellow; it lives in palm trees, feeding on the cocoanut.—The ground squirrels (*tamias*, Illig.) have been described under CHIPMUNK.

**SQUIRREL, Flying.** See FLYING SQUIRREL.

**SQUIRREL CORN.** See DICENTRA.

**STAAL, Marguerite Jeanne Cordier de Launay de,** baroness, a French writer, born in Paris about 1690, died at Gennevilliers, near Paris, June 16, 1750. She was a daughter of a poor painter named Cordier, was educated in an abbey at Évreux till 1710, was afterward an inmate of the priory of St. Louis at Rouen, and finally became a maid to the duchess du Maine. With her she was implicated in the conspiracy of Prince Cellamare, the Spanish ambassador at Paris, against the duke of Orleans, and for giving the regency to the king of Spain. After being confined in the Bastile from December, 1718, to 1720, she resumed her former post in the duchess's petty court at Sceaux, and retained it even after her marriage in 1735 with the aged baron de Staal. Her memoirs (3 vols., 1755) passed through many editions, and with her correspondence are included in her complete works (2 vols., 1821). An extract from the memoirs, entitled *Deux années à la Bastile*, appeared in 1853.—See Sainte-Beuve's *Derniers portraits littéraires* (1852).

**STADE,** a town of Prussia, capital of a district in the province of Hanover, on the Schwinge, 4 m. above its confluence with the Elbe, and

20 m. W. of Hamburg; pop. in 1871, 8,693. It is of great antiquity, and was ruled by local counts until the close of the 12th century, when the last count became archbishop of Bremen. The Elbe dues raised at Stade caused the Hansa in 1267 to enter upon hostile proceedings. The dues were restored in 1688 under Swedish domination, and increased by George I., as elector of Hanover, after the annexation of the town in 1719, together with the duchy of Bremen, to his dominions; and they were not finally abolished till 1861, when Hanover received a compensation for them of 3,100,000 thalers, Great Britain and Hamburg respectively contributing one third, and other maritime nations the remainder. The fortress was captured by the Prussians, June 18, 1866.

**STADIUM** (Gr. *στάδιον*), originally a Grecian course for foot races at the places where games were celebrated, and sometimes in the gymnasia of cities where there were no games. The most celebrated stadia were those at Olympia, Delphi, Thebes, Epidaurus, and the Panathenaic at Athens. The stadium was an oblong area terminated at one end by a straight line, and at the other by a semicircle, with ranges of seats rising above one another in steps around the circumference. The length of the stadium at Olympia was 600 Grecian ft., equal to 606 ft. 9 in. English; and from continual reference to it as a comparison, this length became used throughout Greece as the standard of measurement for itinerary distances, and was subsequently adopted by the Romans, chiefly for nautical and astronomical measurement. The stadium at Ephesus was 685 ft. long and 200 ft. wide, and it was used not only as the arena for foot races, wrestling, and pugilistic combats, but also for combats with wild beasts.

**STADTHOLDER** (Dutch, *stadhouder*, city holder or governor), the title given by certain of the United Provinces of the Netherlands to William of Orange, who thereupon became the chief magistrate or president of those provinces and commander-in-chief of their forces. In 1587 Maurice, his son, was appointed stadtholder of the United Provinces, and the dignity continued in the house of Orange, with occasional intermissions during which the states general governed without a stadtholder, till 1747, when William IV., of a collateral branch of the Orange family, was declared hereditary stadtholder. After the restoration of the Orange family in 1814, the title was exchanged for that of king.

**STAËL-HOLSTEIN, Anne Louise Germaine Necker de**, baroness, a French authoress, born in Paris, April 22, 1766, died there, July 14, 1817. She was the only child of the finance minister Necker (originally of Geneva), whom she idolized, and whose fondness mitigated the excessive austerity which her mother brought to bear upon her education. She early displayed her literary genius and brilliant conversational power, which was much stimulated by her precocious discussions with the many learned friends of the family. She became especially interested in the celebrated Matthieu de Montmorency; but her mother arranged for her a conventional marriage with the Swedish ambassador, Baron de Staël-Holstein, which at the age of 20 made her the centre and, owing to her commanding presence and intellect, the oracle of a distinguished society. She hailed with delight the revolution of 1789, but deplored its excesses; and after devising a plan for the safety of the royal family, which was not acted upon, she saved Montmorency and other friends from the guillotine, though barely escaping herself. After joining her parents at Coppet, she went to London, where she at once (1793) published an appeal in behalf of Marie Antoinette. Here she met Talleyrand, whom she afterward helped to return to France and to enter the ministry of foreign affairs. Under the directory she was conspicuous in Paris as a leader of the constitutional party in conjunction with Benjamin Constant, and her influence was so great that Joseph Bonaparte offered to obtain for her 2,000,000 francs due to her father from the treasury, in the hope of overcoming her prejudices against his brother Napoleon; but she resisted, though she subsequently accepted the money from Louis XVIII. She was not permitted to remain in Paris, and took refuge with Mme. Récamier. When she returned to the more immediate vicinity of the capital, a work published by her father (1802) served as a pretext for her banishment 40 leagues from Paris, and she went to Germany. At Weimar she became acquainted with Goethe, Schiller, the brothers Schlegel, and others, and at Berlin with the royal family of Prussia. In the spring of 1804 she hastened home to attend her father in his last illness, but when she reached Coppet he was dead. Broken-hearted and out of health, she sought relief in her memorable journey to Italy. In the summer of 1805 she returned to Switzerland in company with August Wilhelm von Schlegel, her mentor in regard to Germany, and the instructor of her children. She now alternately resided at Geneva and Coppet, her château in the latter place (now belonging to Baron Rothschild) being a resort of her friends, and especially for some time of Mme. Récamier. For a time she was tolerated in France, but having in 1807 removed to the vicinity of Paris to confer with her publishers about *Corinne* and secretly visited the capital, she was ordered back to Coppet. In 1810 she made an equally unsuccessful attempt to bring out her book on Germany, taking up her residence in the country house of her friend Montmorency. She was ruthlessly expelled, and although thousands of copies had been issued with the sanction of the censorship, the work was confiscated, no motive being assigned excepting that "it was not French," probably referring to its excessive appreciation of German thought.

On the birth of the emperor's son (1811) it was intimated to her that she might soften him by commemorating the occasion; she replied that she wished the child to receive the care of a competent nurse; and this and other remarks of hers becoming known to Napoleon, he actually converted her residence at Coppet into a prison. Schlegel was not permitted to remain; Mme. Récamier, Montmorency, and the duke de Broglie were not tolerated in Paris for having visited her; and she was forbidden to go beyond two miles from her house. Her position became intolerable, and as the seaports were closed to her, she could only escape, in the spring of 1812, by pretending to take a little walk from which she never returned. She went across the Swiss and Tyrolese mountains, and finally reached Vienna. As Napoleon's emissaries beset her even here, she made a tedious journey through Galicia and the duchy of Warsaw to Moscow, and thence to St. Petersburg, where the imperial family received her with open arms; but she vindicated her patriotism at a banquet, when on a toast being proposed for the victory of Russia over France, she exclaimed: "Not over France, only over her oppressor." During her visit at Stockholm her youngest son Albert fell in a duel (1813), shortly before her departure for London, where she attended to the publication of her work on Germany. She returned to Paris on the fall of Napoleon in 1814, but left it on his return from Elba. In 1816 she made an unsuccessful attempt to restore her health by another journey to Italy. Schlegel was with her to the last, and Chateaubriand first met Mme. Récamier at the deathbed of Mme. de Staël. Her remains were removed to the family vault at Coppet.—Of her three children by her first husband (from whom she was separated for several years, though she rejoined him in his last illness, and who died on May 9, 1802), Auguste (author of *Lettres sur l'Angleterre*, 1826, and other writings) survived her till Nov. 11, 1827, and Albertine, wife of the duke Achille de Broglie, till September, 1838. She had one child by her second husband, Albert Jean de Rocca, a French officer and military writer, who died in January, 1818, in his 31st year. It seems that on meeting him at Geneva, whither he had retired after being severely wounded in the peninsular war, she became interested in him, and in 1811 she married him secretly, in order, as she said in her will, which first disclosed the fact, to retain the name identified with her fame.—Mme. de Staël's versatility was remarkable. She excelled in every branch of prose composition, as a linguist, in a measure as a vocalist and dramatist, and in private theatricals; and she was especially celebrated for bold and suggestive generalizations, a masculine grasp of thought, an irrepressible flow of ideas and language, and for a love of humanity and constitutional liberty after the model of England. Her best known works are: *Delphine*, a novel in which she idealizes herself (4 vols., Geneva, 1802); *Corinne, ou l'Italie* (3 vols., Paris, 1807); and *De l'Allemagne* (3 vols., London, 1813), which first fully revealed to the French the achievements of modern German literature. These works have passed through many editions and translations, as well as most of her other writings, which include *Lettres sur les écrits et le caractère de J. J. Rousseau* (1788); *Réflexions sur la paix* (1794); *De l'influence des passions sur le bonheur des individus et des nations* (1796); *De la littérature considérée dans ses rapports avec les institutions sociales* (1800); *Considérations sur les principaux évènements de la révolution française* (3 vols., 1818; new ed., 2 vols., 1861); and *Dix années d'exil* (1821; new ed., 1861). Her complete works were edited by her son Auguste (17 vols., 1820–'21), with a notice by Mme. Necker de Saussure; and her daughter threw additional light upon her mother's life in her notes accompanying an edition of her brother's *Œuvres diverses* (5 vols., 1828–'9). Mme. de Staël's correspondence with the grand duchess Louisa of Saxe-Weimar from 1800 to 1817 appeared in London in 1862, and other letters of hers were published by Saint-René Taillandier (1863).—See Sainte-Beuve's *Portraits de femmes* (1844), Baudrillart's *Éloge de Mme. de Staël* (1850), and "Life and Times of Mme. de Staël," by Norris (London, 1853).

**STAEMPFLI, or Stämpfli, Jakob,** a Swiss statesman, born at Schüpfen, canton of Bern, in 1820. He is the son of a farmer, and acted as a servant in France in order to acquire the language. Subsequently he studied law in Bern, and became an advocate and an ultra-radical journalist. In 1846 he and Ochsenbein were the chief promoters of the revision of the constitution, and in the same year he presided over the financial department in the council of state. In 1847, as representative of the canton of Bern in the diet, he was prominent in pushing on the war with the seven Catholic cantons which had formed the Sonderbund, and in insisting upon the expulsion of the Jesuits. In 1848 he failed of election to the national council, on account of his objections to the new constitution. In 1849, 1851, 1859, and 1862 he was president of the republic, and in the intervals he was vice president and minister of war; and he resumed the latter office in 1863. In 1865 he retired, and in 1872 he was one of the arbitrators at Geneva under the treaty of Washington.

**STAFFA,** a small uninhabited island of Scotland, one of the inner Hebrides, Argyleshire, about 8 m. W. of Mull. It is irregularly elliptical, about 1½ m. in circumference. Its surface is an uneven plateau, elevated from 50 to 144 ft. above the sea. It is covered with a rich soil and luxuriant grass, and is pastured by black cattle. The upper rock is composed of a shapeless basaltic mass, with occasional small columns, resting upon a columnar basalt, hard, grayish black, compact, and of perfectly

regular forms, which has for its foundation a conglomerate trap or tufa. This columnar basalt, strongly resembling architectural designs, is indented with numerous caves, of which the most remarkable is that known as Fingal's cave. (See FINGAL'S CAVE.) The other principal caves are the Boat cave, the Cormorant cave, so called from the number of these birds which visit it, and the Clam Shell cave, which derives its name from the peculiar form in which the basaltic columns are inclined, giving it the appearance of a shell of the genus *pecten;* it is 30 ft. high, 16 to 18 ft. broad, and 130 ft. long. Buachaille or the Herdsman is a conical pile of columns rising 30 ft. above the water, and resting on a bed of horizontal columns over which the high tide rises. Between the Herdsman and Fingal's cave stretches the Great Causeway, formed by the ends of hexagonal upright columns.

**STAFFORD. I.** An E. county of Virginia, bordering on the Potomac, bounded S. W. by the Rappahannock, and drained by Aquia and other creeks; area, 335 sq. m.; pop. in 1870, 6,420, of whom 1,485 were colored. The surface is hilly, and the soil along the Potomac is moderately fertile. Gold has been discovered, and excellent granite and freestone are found. The Richmond, Fredericksburg, and Potomac railroad intersects the county. The chief productions in 1870 were 30,763 bushels of wheat, 99,057 of Indian corn, 39,586 of oats, 1,070 lbs. of tobacco, and 3,174 of wool. There were 942 horses, 1,408 milch cows, 1,893 other cattle, 1,428 sheep, and 3,393 swine. Capital, Stafford Court House. **II.** A W. central county of Kansas, intersected in the N. W. by the Arkansas river; area, 900 sq. m. It is not included in the census of 1870. The surface consists chiefly of undulating prairies.

**STAFFORD,** the county town of Staffordshire, England, on the left bank of the Sow, 125 m. N. W. of London; pop. in 1871, 14,437. The town is situated on low ground, and is mainly well built of stone or brick. A Norman castle, several times demolished and rebuilt, once occupied a commanding position not far distant. Since 1810 a massive castellated structure has occupied its place. Among the prominent public buildings are the county hall, a jail, infirmary, lunatic asylum, library, and mechanics' institute. A free grammar school was established in 1556. The church of St. Mary is the most costly and conspicuous. The Trent Valley railway and a canal are near. There are extensive manufactures of leather, boots and shoes, and cutlery. Public markets are held for the sale of cattle, horses, wool, and cheese.

**STAFFORD, Henry,** duke of Buckingham. See BUCKINGHAM, EARLS AND DUKES OF.

**STAFFORD, William Howard,** viscount, an English statesman, born Nov. 30, 1612, executed on Tower hill, Dec. 29, 1680. He was the second son of Thomas, earl of Arundel, and in right of his wife, as successor of her brother, was created Baron Stafford, and in November, 1640, Viscount Stafford. He was brought up in the Roman Catholic faith, and adhered during the civil war to the royal cause; but after the restoration he was frequently in opposition to the court. He was singled out by Titus Oates, the contriver of the "popish plot," as one of his chief victims. Oates deposed before the house of commons that upon the subversion of the kingdom by the Jesuits Lord Stafford was to be paymaster of the army; and the accused nobleman was committed to the tower, Oct. 30, 1678, with several other Catholic peers. After two years his trial for alleged high treason began, Nov. 30, 1680, lasting a week. He defended himself with ability, shaking confidence in Oates's evidence; but Dugdale and Tuberville swore so positively that Stafford had incited them to assassinate the king, that a verdict of guilty was pronounced by a vote of 55 to 31. He was executed three weeks afterward; but the popular feeling so changed after his trial that when he protested his innocence on the scaffold the spectators cried: "We believe you, my lord. God bless you, my lord." His eldest son was created earl of Stafford.

**STAFFORDSHIRE,** an inland and nearly central county of England, bordering on the counties of Chester, Derby, Leicester, Warwick, Worcester, and Salop; area, 1,138 sq. m.; pop. in 1871, 858,326. The river Trent traverses it in a S. E. direction, and has several considerable tributaries. Much of the surface consists of moorlands, elevated in some places 1,000 ft. above the sea. Staffordshire is an important manufacturing county, and coal, iron, copper, and lead mines are worked extensively. The leading manufactures are iron, hardware, and earthenware, of which last it is the chief seat in England, and which gives name to a division of the county called the Potteries. The pottery works established by Josiah Wedgwood are in this county. The ale breweries of Burton-upon-Trent are very extensive and celebrated, and there are cotton mills, glass works, and tanneries. The county has a network of roads, canals, and railways. The principal towns are Stafford, the capital, Lichfield, Burton-upon-Trent, Wolverhampton, Dudley, Tamworth, Walsall, Uttoxeter, Stoke-upon-Trent, Hanley, Burslem, and Newcastle-under-Lyme.

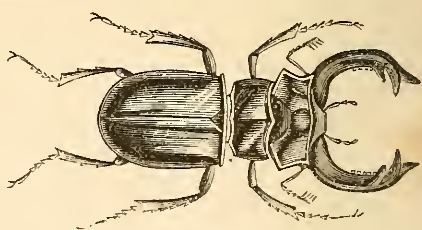
**STAG,** the common name of the red deer of Europe (*cervus elaphus,* Linn.) and its congeners. It is about 4 ft. high at the shoulders, and of a general reddish brown color, tinged with grayish in the winter; on the rump is a pale spot extending a little above the tail; there is a blackish dorsal line, and on each side often a row of pale fulvous spots; the hair is brittle, and in old animals forms a kind of mane on the neck; the tail is moderate, the tear bag well developed, suborbital pit large, and the hoofs narrow, triangular, and compressed. The antlers are large and rounded, with an anterior basal and a median anterior snag, and the apex divided into two or more branches

according to age; they are peculiar to the males, shed in the spring, and reproduced, sometimes to a weight of 24 lbs., by August. (For family characters see DEER.) It is strong,

Stag (Cervus elaphus).

swift, and vigilant, with a very acute sense of smell; it was formerly found in herds in the forests of the mountainous regions of temperate Europe, but is now rare except in the least inhabited parts, like the highlands of Scotland, where stag hunting is still a favorite sport with the privileged few. This in old times constituted the noble art of *venerie*, as distinguished from the more plebeian chase of the fallow deer and other species which resort to the plains more than the woods. Gestation continues eight months; the young or calf is dropped in May, and is yellowish with white spots; the male is called a stag or hart, and the female a hind. The venison is coarser than that of the fallow deer. It has been found fossil, with bones of the elephant and other ungulates, in the Kirkdale cavern, the peat bogs of Ireland, and similar recent formations. It is represented in North America by the larger wapiti. (See WAPITI.) Other stags are found in India, N. Africa, and Japan.

**STAG BEETLE**, the common name of the family *lucanidæ*, of the lamellicorn pentamerous coleoptera, of which the type is the genus *lucanus* (Linn.). Many of the species are of considerable size, and have received their name from the large and powerful mandibles with which the males are furnished. The stag beetle of Europe (*L. cervus*, Linn.) is 2 in. long, exclusive of the mandibles, and is the largest and most formidable of the British beetles; the color is black, with brown elytra; the head is wider than the body; the mandibles corneous, arched, with three large and several smaller teeth, and used as instruments of offence; antennæ bent, pectinated, and 10-jointed, tibiæ dentated along outer edge, and the tarsi ending in two hooks. They live in the trunks of trees by day, flying abroad at night, often into houses; the females are smaller, with narrower head and much shorter mandibles. They are also called horn beetles and flying bulls. According to De Geer, they feed principally on the sweet juice spread over the leaves of the oak and exuding on the bark, which they obtain by means of the brushes of the under jaws; they are said to seize caterpillars and soft-bodied insects, and to suck their juices; they are very strong, and can pinch the finger pretty hard, but do not use their mandibles in this way unless provoked, and their punctures are not poisonous; they live only a short time in the perfect state, perishing soon after laying their eggs in the crevices of bark near the roots of trees. The larvæ are large and fleshy grubs with very thick body, arched, with 13 rings, and having a brown scaly head armed with two strong jaws with which they gnaw wood, reducing it to a coarse powder, and often doing much damage by boring into the trunks and roots of oaks and beeches; there are six scaly feet, attached to the first three rings; they are said to be six years in coming to their growth, and by some are regarded as the *cossus* of the Romans, a worm-like grub, according to Pliny, obtained from the oak and considered



European Stag Beetle (Lucanus cervus).

delicious food. The largest of the New England species is the *L. capreolus* (Linn.), usually called horn bug; it is about 1¼ in. long, without the mandibles, the latter being sickle-shaped and toothed; the body mahogany brown, smooth and polished. They appear in July and August. The larvæ are 3 in. long when full grown, straw-colored, with yellow head, brown jaws, and nine stigmata; they live in the trunks and roots of apple trees, willows, and oaks, and are sometimes injurious.

**STAG HOUND.** See HOUND.

**STAGIRA**, previously **Stagirus**, an ancient town of Macedonia, in Chalcidice, on the Strymonic gulf. It was founded by a colony from Andros in the middle of the 7th century B. C., and was originally named Orthagoria. It was destroyed and rebuilt by Philip, the father of Alexander. It is chiefly known as the birthplace of Aristotle.

**STAHL, Friedrich Julius**, a German jurist, born in Munich, Jan. 16, 1802, died at Brückenau, near Kissingen, Aug. 10, 1861. He was of a Jewish family named Schlesinger, but adopted the name Stahl in 1819 on becoming a Christian. He was professor of law at Erlangen and Würzburg, and from 1840 at Berlin. In 1848 he founded with Bethmann-Hollweg the German church diet, of which he was vice president till 1859, and was a leader of the high Lutheran party. As a member of the Prussian chamber of deputies (1849), of the Erfurt parliament (1850), and from 1854 of the upper house of the Prussian legislature, he advocated feudal principles. His most important work is *Philosophie des Rechts* (2 vols., Heidelberg, 1830–'37), in which he develops his famous theory of a "Christian state," which is to aid the church by the secular arm in extending Christianity. In *Die Kirchenverfassung*, &c. (Erlangen, 1840), he declared himself in favor of an episcopal form of church government. In 1855 he had a controversy with Chevalier Bunsen, which attracted general attention in literary circles. His last great work was *Die lutherische Kirche und die Union* (Berlin, 1859).

**STAHL, Georg Ernst**, a German chemist, born in Anspach, Oct. 21, 1660, died in Berlin, May 14, 1734. He took his degree at Jena in 1684, and after giving private lectures there, he was physician to the duke of Weimar from 1687 to 1694, and subsequently professor at Halle till 1716, when he settled in Berlin with the title of royal physician. He was among the first to raise chemistry to an equality with the other natural sciences. In his *Theoria Medica Vera* (Halle, 1707; new ed. by Choulant, 3 vols., Leipsic, 1831–'3; translated into German by Ideler, 3 vols., Berlin, 1832–'3) he supposed the existence of an *anima* or immaterial principle resident in the body, creating its organization, and governing all its processes with reference to the final purpose of preserving life. Every corporeal movement, he said, is the product of a spiritual order. He elaborated also the phlogistic theory which prevailed till the time of Lavoisier, and gave it its name, although its principles had been previously broached by Becher (see HEAT, vol. viii., p. 567), in development and defence of which he published *Zymotechnia Fundamentalis* (1697), and *Experimenta et Observationes Chemicæ* (1731). His works have been translated into French, with commentary by T. Blondin (*Œuvres médico-philosophiques et pratiques*, Paris, 1858 *et seq.*).—See *Le vitalisme et l'animalisme de Stahl*, by A. Lemoine (1864), and CHEMISTRY, vol. iv., p. 360.

**STAHR, Adolf Wilhelm Theodor**, a German author, born in Prenzlau, Prussia, Oct. 22, 1805, died Oct. 3, 1876. He completed his studies at Halle, in 1826 became a teacher there, subsequently taught in the gymnasium in Oldenburg, and in 1852 settled in Berlin. In 1855 he married the authoress Fanny Lewald. His works include *Aristotelia* (2 vols., 1830–'32); *Ein Jahr in Italien* (3 vols., 1847–'50); *Die preussische Revolution* (1850; 2d ed., 1852); *Torso, oder Kunst, Künstler und Kunstwerke der Alten* (2 vols., 1854–'5; English translation in the "Crayon," New York, 1858–'9); *G. E. Lessing, sein Leben und seine Werke* (2 vols., 1859; 6th ed., 1869; English translation, Boston, 1866); *Herbstmonate in Oberitalien* (1859; 2d ed., 1871); *Bilder aus dem Alterthum* (4 vols., 1863–'6); with his wife, *Ein Winter in Rom* (1869; 2d ed., 1871); *Lebenserinnerungen* (1870 *et seq.*); *Tacitus' Geschichte der Regierung des Kaisers Tiberius übersetzt und erklärt* (1871); *Goethe's Frauengestalten* (for Kaulbach's *Goethe-Gallerie*; 4th ed., 2 vols., 1872); and *Tiberius' Leben, Regierung und Charakter* (1874). A collective edition of his works was commenced at Berlin in 1871.

**STAIR, Lord.** See DALRYMPLE.

**STAMFORD**, a town and borough of Fairfield co., Connecticut, on Long Island sound and the New York and New Haven and New Canaan and Stamford railroads, 34 m. N. E. of New York; pop. in 1870, 9,714. The town extends from the sound N. W. to the New York state line, a distance of 10 m., in which there is a series of elevations running N. E. and S. W., affording sites for four villages, High Ridge, Long Ridge, Hunting Ridge, and North Stamford. The greater part of the population resides in the borough of Stamford, which has a small harbor, made accessible to steamboats by a canal. The borough is supplied with water brought 10 m., is lighted with gas, and has paved sidewalks. The nearness to New York, attractive scenery, and wholesome air have made the town the residence of many business men from that city. The chief factories are the Stamford manufacturing company, producing extract of logwood, liquorice, &c.; a lock factory, a billiard table factory, a woollen mill, a stove foundery, a carriage factory, rolling mills, camphor refineries, and manufactories of shoes, fire brick, edge tools, wire, &c. The town contains two national banks, two savings banks, 16 public schools, including a high school, two weekly newspapers, and 14 churches.

**STAMMERING**, a term generally applied to all kinds of defective utterance, but more correctly restricted to the organic or symptomatic defects, in distinction from stuttering, which is properly an idiopathic or functional difficulty. Both stammering and stuttering may nevertheless be treated under the common title. The causes which lead to stammering are usually, though not always, organic; harelip, cleft palate, elongation of the uvula, enlargement of the tonsils, a deficiency or unusual position of the teeth, tumors of the tongue or cavity of the mouth, and inflammation or ulceration of the parotid glands, are the most frequent of these causes. Where the defect results from functional disturbance, its principal causes are general debility, paralysis either local or general, tetanic or other

spasms; a rheumatic or neuralgic affection of the muscles of the face, jaw, tongue, lips, &c., or of the vocal cords; a condition of intoxication; chorea; or in some cases a habitual imitation of stammering. Occasional stammering may be produced by a temporary confusion of mind, without any anatomical defect of the vocal organs. Stuttering is seldom or never organic. The stutterer is often in perfect health, and the vocal organs are not in any way diseased or deformed. His difficulty consists in the momentary inability to pronounce certain words or syllables. The stoppage of sound usually takes place at the first syllable, though occasionally at the second or third. Words beginning with *k*, *t*, *g*, *d*, *p*, *b*, or *m* usually give the stutterer the most trouble, because they require the closing of the lips or the pressing of the tongue against the roof of the mouth for their enunciation, and an immediate reopening for the vowel which follows; while he keeps the lips closed, and compresses the cavity of the mouth in the attempt to force out the sound. Most stutterers can sing without difficulty, the action of the vocal organs being much less frequently interrupted in singing than in speaking. Stutterers may be classed under two heads, mental or psychical and physical. Under the stimulus of pleasant or joyful emotions, the first class experience little difficulty in conversation; under depressing influences, their utterance is seriously disturbed. The physical stutterer is rendered worse by unpleasant weather, great fatigue, vicious indulgence, and the excessive use of tobacco or alcoholic drinks. The number of bad stammerers is estimated by Colombat at 1 in 5,000; but the number having some degree of impediment is not probably less than 1 in 500. Only about one tenth of these are females.—The proper treatment of either stuttering or stammering is indicated by the cause which induces it. In the case of the stammerer there should be a thorough investigation for an organic cause. The clipping of the uvula, the removal of a portion of the tonsils, or the excision of a wedge-shaped piece from a tongue too large for the mouth, the use of electrical or other remedies for the cure of paralysis, the cauterization of ulcers in the mouth, the removal of irregular or the insertion of false teeth, and the administration of tonics for debility, have each resulted in the cure of cases of stammering; but no one of these will answer for all or perhaps a majority of cases. In stuttering also, the cause will indicate to some extent the method of cure. The muscles must be educated to uniform obedience to the will, and the will trained to steady and intelligent control over the muscles and nerves. A course of lessons in enunciation, by a capable teacher, will often effect a complete cure. Dr. J. M. Warren of Boston lays down the rules that treatment for impediments of speech should be commenced between the ages of 8 and 12; and that "little permanent advantage will be gained, in the majority of cases, unless the treatment be resolutely persevered in for one or two years."

**STAMP ACTS,** laws for the raising of revenue by requiring the use of government stamps on the paper or parchment by means of which business is transacted or privileges conferred, or upon packages of goods put up for sale, &c. Such laws were introduced into England, in the reign of William and Mary, from Holland, and from that time to the present have been a favorite mode of raising revenue. Each stamp represents a tax of a certain sum which must be paid to obtain it, and its payment is enforced by imposing penalties on those who undertake to evade the tax, and by declaring the transaction in which it should have been made use of invalid if the stamp is not obtained and used. The name of stamp act was made odious in America by the attempt in 1765 to tax the colonies in this form; but after the Union was perfected by means of the constitution a few stamp duties were for a time laid. During the civil war of 1861–'5 stamp taxes were laid on almost every form of legal instrument, bank drafts and checks, conveyances of land, &c., and on the packages of a great variety of manufactured goods. Many of these have since been taken off, but the stamp taxes on manufactures are generally retained. (See TAXES.)

**STANCHIO.** See Cos.

**STANDISH, Miles,** a soldier of New England, born in Lancashire, England, about 1584, died in Duxbury, Mass., Oct. 3, 1656. He had served in the Netherlands, and on coming to Plymouth with the first company in 1620 he was chosen captain by the pilgrims, though not a member of their church. He had great courage, energy, and determination, with a fiery temper, and rendered important services to the early settlers. He commanded frequent expeditions against the savages who annoyed the settlements, and by the boldness and skill of his attacks inspired them with great awe of his military prowess. He visited England in 1625 as an agent for the colony, and brought supplies in 1626. He then settled at Duxbury, and for the remainder of his life held the office of magistrate or assistant for that town. In 1649 he took part in the settlement of Bridgewater. The corner stone of a monument to his memory was laid on Captain's Hill, Duxbury, Oct. 7, 1872. The singular circumstances of his marriage are the subject of a celebrated poem by Longfellow, "The Courtship of Miles Standish."

**STANFIELD, Clarkson,** an English painter, born in Sunderland about 1798, died at Hampstead, May 18, 1867. He followed the sea in early life, and was afterward distinguished as a theatrical scene painter. In 1827 he exhibited at the British institution his first large picture, "Wreckers off Fort Rouge;" in 1832 he was elected an associate of the royal academy, and in 1835 an academician. He painted nearly

every kind of landscape, but as a painter of sea pieces he enjoyed a unique reputation. His works include "Wreck of a Dutch East Indiaman on the Coast of Holland;" "The Victory, bearing the Body of Nelson, towed into Gibraltar;" "The Abandoned;" "The Battle of Trafalgar;" "The French Troops fording the Magra;" "The Battle of Roveredo;" "The Pyrenees;" and "St. Sebastian during the Siege under the Duke of Wellington." Among his latest works were "The Worm's Head" (1864), and "The Bass Rock" (1865). He was a prolific designer for illustrated works, and published a series of lithographic copies of his sketches, "The Moselle, the Rhine, and the Meuse" (fol., 1838).

**STANFORD, John**, an American clergyman, born at Wandsworth, England, Oct. 20, 1754, died in New York, Jan. 14, 1834. He was brought up in the church of England, but united with the Baptist church, and in 1786 emigrated to the United States, spent a few months at Norfolk, Va., and then opened an academy in New York. In 1787 he became pastor of the first Baptist church, Providence, R. I., and while there wrote a history of that church. He resumed teaching in New York in 1789, and a Baptist church having been formed through his exertions in 1794, he served as its pastor till about 1800, continuing his school till 1813. He published "The Domestic Chaplain" (1806); "Description of New York City" (1814); and "The Aged Christian's Companion" (1829).

**STANHOPE. I. James**, earl, a British statesman, born in 1673, died in London, Feb. 5, 1721. He was the son of Alexander Stanhope, a brother of the second earl of Chesterfield. Entering the military service at an early age, he was in 1694 commissioned a captain in the foot guards. After serving in Flanders till the peace of Ryswick, he participated in the disastrous expeditions of 1702 and 1704 to the Spanish peninsula; and in 1705, being then a brigadier general, he shared in the earl of Peterborough's brilliant Spanish campaign. In 1706 he was sent by Queen Anne as envoy extraordinary to the king of Spain (the archduke Charles). In 1707 he was made major general, and in 1708 commander-in-chief of the British forces in Spain, and reduced Minorca and captured Port Mahon. After gaining further important successes in Spain, he was surprised by the duke of Vendôme at Brihuega on Dec. 8, 1710, and forced to surrender next day with about 4,000 men. Returning to England, he took his seat as a whig in parliament, to which he had been regularly returned since 1702. George I. on his accession appointed him one of his principal secretaries of state, Viscount Townshend being the other. In April, 1717, he was made first lord of the treasury, and a few months afterward raised to the peerage as Baron Stanhope of Elvaston and Viscount Stanhope of Mahon. In 1718 he resumed his office of secretary, Sunderland becoming first lord of the treasury, and was created Earl Stanhope. He went to Paris and Madrid to avert hostilities with Spain, but without success; and he was afterward employed in similar missions. On Feb. 4, 1721, while replying with much heat to an attack upon the ministry by the duke of Wharton, he burst a blood vessel. **II. Charles**, third earl, grandson of the preceding, born in August, 1753, died in December, 1816. Succeeding to his family honors in 1786, he became noted for his radical opinions, and in his discussions carried the principles of the whigs so far that none of them dared follow him; and in the latter years of his life he used to be called "the minority of one." He invented the printing press which bears his name, suggested improvements in canal locks, and contrived two calculating machines. He also studied electricity, and in 1779 published his theory of what is called the return stroke. His principal works are a reply to Burke's "Reflections on the French Revolution," and an "Essay on Juries." **III. Philip Henry**, fifth earl, an English author, grandson of the preceding, born at Walmer, Kent, Jan. 31, 1805, died at Bournemouth, Hampshire, Dec. 24, 1875. He graduated at Oxford in 1827, and from 1830 to 1852 was a member of parliament under his courtesy title of Lord Mahon. He held office during brief periods in the cabinets of the duke of Wellington and Sir Robert Peel, and he introduced and carried the copyright act of 1842. He has published "Life of Belisarius" (8vo, 1829); "History of the War of Succession in Spain" (8vo, 1832); "History of England from the Peace of Utrecht to the Peace of Versailles, 1713–'83" (7 vols., 1836–'54); "Spain under Charles II." (8vo, 1840); "Life of Louis, Prince of Condé" (18mo, 1845); "Historical Essays contributed to the Quarterly Review" (8vo, 1849); a "Life of Joan of Arc" (1853); a "Life of William Pitt" (4 vols. 8vo, 1861–'2); and "History of England, comprising the Reign of Anne, until the Peace of Utrecht" (1870). He has edited "The Letters of Philip Dormer Stanhope, Earl of Chesterfield" (1845; 2d ed., 5 vols. 8vo, 1853), in conjunction with Mr. Cardwell, and "Memoirs by the Right Hon. Sir Robert Peel, Bart." (2 vols., 1856–'7). Lord Stanhope succeeded to his title in 1855. Since 1846 he has been president of the society of antiquaries. In 1858 he was elected lord rector of the university of Aberdeen, and in 1872 one of the six foreign members of the academy of moral and political sciences at Paris, in place of Mr. Grote.

**STANHOPE, Lady Hester Lucy**, an eccentric English woman, born in London, March 12, 1776, died at Jun, in the Lebanon, June 23, 1839. She was the eldest child of Charles, third Earl Stanhope, by Hester, daughter of the great earl of Chatham. When about 20 years of age she entered the family of her uncle William Pitt, with whom she lived until

his death in 1806, acting as his private secretary and sharing his confidences. Pitt having recommended his niece to the care of the nation, she received a pension of £1,200, which proving inadequate to support her according to her former rank and style, she retired to solitude in Wales. Indulging in dreams of a great destiny in the Orient, she repaired in 1810 to Syria, and visited Jerusalem, Damascus, Baalbec, and Palmyra. The Arabs, who were struck by her powers and display of wealth, treated her as a queen, and she skilfully acted the part of a modern Zenobia. She established herself in 1813 at the deserted convent of Mar Elias, beside the little village of Jun, and within eight miles of Sidon. Here, wearing the dress of an emir, weapons, pipe, and all, she ruled her Albanian guards and her servants with absolute authority. The old convent, perched upon an isolated eminence among the wildest scenery of the Lebanon, was soon converted into a fortress, garrisoned by Albanians, and became a refuge to all the persecuted and distressed who sought her assistance. So powerful was the influence which she wielded in the surrounding country, that Ibrahim Pasha, when about to invade Syria in 1832, was constrained to solicit her neutrality. After the siege of Acre in the same year, she is said to have sheltered several hundred refugees. She practised astrology and other secret arts, and promulgated some peculiar religious sentiments which she held to the last. That her mind was diseased on certain points is clear from the fact that she kept in a magnificent stable two mares, on which she fancied she was to ride into Jerusalem with the Messiah at his next coming. During the latter years of her life she was constantly harassed by debts, and she died with no European near her, and surrounded by a crowd of native servants, who plundered the house almost before life had left her body. She was buried in the garden adjoining her residence. Her "Memoirs as related by Herself" (3 vols. 8vo), and "Travels" (3 vols. 8vo) by Dr. Meryon, who had been her physician for several years, were published soon after her death.

**STANHOPE, Philip Dormer.** See CHESTERFIELD.

**STANISLAS I. LESZCZYNSKI,** king of Poland, born in Lemberg, Galicia, Oct. 20, 1677, died in Lunéville, France, Feb. 23, 1766. He was palatine of Posen, and had held an office at the Polish court, where he won the friendship of Charles XII. of Sweden, who in 1705, after defeating Augustus II., procured his election to the throne of Poland; but he lost the crown by Charles's defeat at Poltava in 1709, when Augustus was restored. While attempting to join Charles at Bender, Stanislas was in 1713 taken prisoner by the hospodar of Moldavia and delivered to the Turks; released in 1714, he served as governor of Zweibrücken till the death of Charles XII. in December, 1718. The regent Philip of Orleans now granted him a pension and permission to reside at Weissenburg, Alsace. His prospects improved in 1725 through the marriage of his daughter Maria with Louis XV., who initiated, after the death of Augustus II. in 1733, a war for the Polish succession; but Augustus III. retained the throne through Russian intervention, although Stanislas had been reëlected as king. The latter was obliged to retire to Dantzic, where he was besieged by a Russian army, and after a bold resistance of several months escaped in June, 1734. In accordance with the preliminary peace of 1735 he resigned his claims to the Polish throne, but retained his royal title, recovered his estates, and received Lorraine and Bar, which after his death were to be united to France; and in the interval he received a pension of 2,000,000 francs for relinquishing the revenues of those duchies. His brilliant court at Lunéville and Nancy became celebrated through his munificent patronage of public and charitable works, of letters and art, and through his associations with Voltaire and other eminent personages. Nancy is indebted to him for her finest monuments, and he was styled *le bienfaisant.* His death was caused by his garments taking fire while he was reading. His essays on philosophy, politics, and morals have been printed under the title of *Œuvres du philosophe bienfaisant* (4 vols. 8vo and 4 vols. 12mo, 1765).

**STANISLAS AUGUSTUS,** king of Poland. See PONIATOWSKI, and POLAND, vol. xiii., p. 647.

**STANISLAUS,** a central county of California, bounded N. in part by the Stanislaus river, and intersected by the San Joaquin and Tuolumne; area, 1,350 sq. m.; pop. in 1870, 6,499, of whom 306 were Chinese. It is for the most part level, but the E. portion is undulating, while a strip a few miles wide on the W. border rises into the Coast range, which here has a general altitude of about 2,000 ft. There is little timber. The soil is very productive. Gold mining is carried on to some extent in the E. part. It is traversed by the Visalia division of the Central Pacific railroad. The chief productions in 1870 were 1,650,725 bushels of wheat, 15,700 of Indian corn, 632,950 of barley, 749,263 lbs. of wool, 52,625 of butter, and 15,191 tons of hay. There were 10,137 horses, 1,139 mules and asses, 2,271 milch cows, 4,316 other cattle, 118,460 sheep, and 14,593 swine. Capital, Modesto.

**STANKO.** See COS.

**STANLEY.** I. A S. W. county of North Carolina, bounded E. by the Yadkin and S. by Rocky river; area, about 300 sq. m.; pop. in 1870, 8,315, of whom 1,289 were colored. The surface is mountainous and the soil generally fertile. Gold and silver have been found in considerable quantities. The chief productions in 1870 were 63,575 bushels of wheat, 118,788 of Indian corn, 42,037 of oats, 10,435 of sweet and 5,294 of Irish potatoes, 12,459 lbs. of tobacco, 8,294 of wool, 20,164 of honey, and 11,515 gallons of sorghum molasses. There

were 1,333 horses, 332 mules and asses, 1,725 milch cows, 2,963 other cattle, 5,705 sheep, and 9,349 swine. Capital, Albemarle. **II.** A S. W. county of Dakota, recently formed and not included in the census of 1870; area, about 1,450 sq. m. It is bounded N. E. by the Missouri river, and is intersected by the Big Cheyenne and Titon rivers, tributaries of the Missouri. The surface is rolling.

**STANLEY, Arthur Penrhyn,** an English clergyman, born in Alderley, Cheshire, Dec. 13, 1815. His father was Dr. Edward Stanley (1779–1849), rector of Alderley for 32 years, bishop of Norwich from 1837, and author of "Familiar History of Birds" (2 vols., 1835), &c. The son was educated at Rugby, and in 1838 graduated at University college, Oxford, where he subsequently resided for 12 years as tutor. In 1851 he was appointed canon of Canterbury, and he was regius professor of ecclesiastical history at Oxford from 1856 to 1864, when he was made dean of Westminster. He is a leader of the "Broad Church" party. He has published "Life and Correspondence of Thomas Arnold, D. D." (2 vols. 8vo, 1844), which has passed through numerous editions, and been translated into several foreign languages; "Sermons and Essays on the Apostolical Age" (1847); "The Epistles of St. Paul to the Corinthians, with Critical Notes and Dissertations" (2 vols. 8vo, 1855; 4th ed., 1874); "Historical Memorials of Canterbury Cathedral" (8vo, 1855; 5th ed., 1869); "Sinai and Palestine, in Connection with their History" (8vo, 1856; 20th ed., 1874); "Lectures on the History of the Eastern Church" (8vo, 1861); "Lectures on the History of the Jewish Church" (part i., Abraham to Samuel, 1862; part ii., Samuel to the Captivity, 1865; part iii., 1876); "The Bible, its Form and Substance" (1862); "Scripture Portraits, and other Miscellanies" (1867); "Historical Memorials of Westminster Abbey" (1867; 4th ed., 1874); "The Three Irish Churches," a historical address (1869); "Essays on Church and State" (1870); "The Athanasian Creed" (1871); and "Lectures on the History of the Church of Scotland" (1872). In November, 1874, he was elected lord rector of the university of St. Andrews.

**STANLEY, Edward Henry Smith,** lord. See Derby, earl.

**STANLEY, Henry M.,** an American traveller, born near Denbigh, Wales, in 1840. His original name was John Rowlands. At the age of three he was sent to the poorhouse at St. Asaph, where he remained till he was 13, receiving there a good education. For a year he was a teacher at Mold, Flintshire, and then shipped at Liverpool as a cabin boy on a vessel bound to New Orleans. There he found employment with a merchant named Stanley, who subsequently adopted him and gave him his name. His benefactor died intestate, and young Stanley at the outbreak of the civil war enlisted in the confederate army, was taken prisoner, volunteered in the United States navy, and subsequently became an acting ensign in the iron-clad Ticonderoga. After the close of the war he travelled in Turkey and Asia Minor, and in 1866 visited Wales. He gave a dinner to the children in St. Asaph poorhouse, telling them in a speech that whatever success he had attained, or would attain in the future, he owed to the education he received there. In the spring of 1867 he returned to the United States, and in 1868 accompanied the British expedition to Abyssinia as correspondent of the "New York Herald." In 1869 he was sent to Spain in the same capacity, and on Oct. 17 of that year was commissioned by the proprietor of the "Herald" to find Dr. Livingstone. After attending the opening of the Suez canal, he visited Constantinople, Palestine, the Crimea, the valley of the Euphrates, Persia, and India, and sailed from Bombay Oct. 12, 1870. He arrived at Zanzibar Jan. 6, 1871, and set out for the interior of Africa on March 21, with 192 followers. He found Dr. Livingstone at Ujiji on Lake Tanganyika, Nov. 10, explored with him the northern portion of the lake, and began his return voyage on March 14, 1872. He arrived in England late in July, and gave an account of his expedition before the British association at Brighton, Aug. 16. On Aug. 27 the queen sent him a gold snuff box set with diamonds, and on Oct. 21 he was banqueted by the royal geographical society. In November he published "How I found Livingstone" (London and New York). In 1873 he received the patron's medal of the royal geographical society. After the death of Livingstone, Mr. Stanley was commissioned by the proprietors of the "New York Herald" and the London "Telegraph" to explore the lake region of equatorial Africa. As reported in his letters to those journals, he left the coast in November, 1874, at the head of 300 men, diverged from the usual road at Upwapwa, reached the western frontier of Ugongo on Dec. 31, struck direct across an almost level plain, and at Tchiwyu, in the Urimi country, about the latitude of Ujiji, he found the waters flowing northward. Thence he followed the course of the river Shemeeyu for 350 m., and reached Kagehyi, on the Victoria N'yanza lake, Feb. 27, 1875, having lost 194 men by death and desertion. He launched a boat conveyed in pieces from the coast, and circumnavigated the lake, assisted by 30 canoes lent him by Mtesa, king of Uganda. His circumnavigation covered about 1,000 m.; he minutely explored the inlets, and found that the opinion of Burton and Livingstone, based on native reports, that N'yanza is a collection of lagoons, is wrong, and that Speke and Grant were right in declaring it to be one large lake, containing many islands. On April 17 he started to complete his exploration of the W. side of the Victoria N'yanza. He proposed next to cross the intervening country and explore the Albert N'yanza.

**STANLEY, Thomas,** an English author, born in Hertfordshire in 1625, died in London, April 12, 1678. He was educated at Cambridge, and resided for several years in the Middle Temple. He published "Poems and Translations" (1649); "History of Philosophy, containing the Lives, Opinions, Actions, and Discourses of the Philosophers of every Sect" (3 vols. fol., 1655–'62; Latin translation by Olearius, Leipsic, 1711); and an edition of Æschylus with a commentary and a Latin version (1663; new ed. by Dr. Butler, 4 vols. 4to, Cambridge, 1809). In 1814–'15 appeared an edition of his poems with a biographical memoir by Sir Egerton Brydges.

**STANSTEAD,** a S. county of Quebec, Canada, bordering on Vermont; area, 407 sq. m.; pop. in 1871, 13,138, of whom 5,763 were of English, 3,212 of French, 2,599 of Irish, 1,016 of Scotch, and 408 of German origin or descent. It contains Lake Massawippi and a part of Lake Memphremagog, and is traversed by the Stanstead, Shefford, and Chambly, the Massawippi Valley, and the Grand Trunk railways. Capital, Stanstead.

**STANTON. I.** A N. E. county of Nebraska, intersected by Elkhorn river; area, 432 sq. m.; pop. in 1870, 636; in 1875, 1,157. The surface consists chiefly of rolling prairies. The chief productions in 1870 were 15,640 bushels of wheat, 9,255 of Indian corn, 6,548 of oats, 3,630 of potatoes, 8,645 lbs. of butter, and 943 tons of hay; value of live stock, $27,521. Capital, Stanton. **II.** An unorganized S. W. county of Kansas, bordering on Colorado; area, 720 sq. m. It is drained by tributaries of the Arkansas river. The surface is rolling.

**STANTON, Edwin McMasters,** an American statesman, born in Steubenville, Ohio, Dec. 19, 1814, died in Washington, D. C., Dec. 24, 1869. He was a student in Kenyon college from 1831 to 1833, was admitted to the bar in 1836, began practice in Cadiz, Harrison co., Ohio, and soon afterward was elected prosecuting attorney for the county. After acquiring a large circuit practice he removed to Steubenville. From 1842 to 1845 he was reporter of the decisions of the supreme court of the state, and prepared vols. xi., xii., and xiii. of the Ohio reports. In 1845 he successfully defended Caleb J. McNulty, clerk of the house of representatives, tried in the criminal court of Washington for embezzlement. In 1847 he removed to Pittsburgh, Pa., but for nine years afterward retained also an office in Steubenville. His first appearance before the supreme court of the United States was as counsel for Pennsylvania in the case of the state against the Wheeling and Belmont bridge company, and thereafter his practice in that court increased so much that in 1856 he removed to Washington. In 1858 he went to California as counsel for the government in certain land cases, and his services were specially important in the examination of Spanish and Mexican archives in their bearing upon titles. He was also engaged in several leading patent cases. In 1859 he was one of the counsel for Daniel E. Sickles, tried for the murder of Philip Barton Key. In December, 1860, he was nominated attorney general of the United States, and served to the close of President Buchanan's administration, when he resumed the practice of his profession. In January, 1862, he was appointed secretary of war. His labors in this department were indefatigable, and many of the most important and successful movements of the war were originated by him. He continued as secretary after the succession of Andrew Johnson; but his support of congressional measures which were vetoed and repassed, and his opposition to Johnson's plan of reconstruction, led the president (from whom the power of removal had been taken by the tenure of office act), on Aug. 5, 1867, to request his resignation. He refused to resign, but on Aug. 12 he gave way under protest to Gen. Grant as secretary *ad interim.* On Jan. 13, 1868, the senate reinstated him. On Feb. 21 the president appointed Gen. Lorenzo Thomas secretary of war *ad interim*, and Mr. Stanton refusing to vacate, the impeachment of the president followed. (See JOHNSON, ANDREW.) Upon the president's acquittal, May 26, Mr. Stanton resigned. The senate in confirming his successor adopted a resolution that Mr. Stanton was not legally removed, but relinquished his office; and subsequently congress passed a vote of thanks to him for the great ability, purity, and fidelity with which he had discharged his duties. Although his health was much shattered by his arduous labors in the war department, his circumstances compelled him to resume the practice of the law, and he argued several important cases. On Dec. 20, 1869, he was nominated by President Grant as an associate justice of the supreme court of the United States, and was immediately confirmed by the senate; but he died after a brief illness from dropsy, before his commission was made out.

**STAR** (Gr. ἀστήρ, ἄστρον), a luminous body beyond the solar system, not nebulous. The study of the stars includes two chief divisions: 1, the determination of the exact position and changes of position of individual stars; 2, the inquiry into the laws according to which the stars are distributed throughout space, or rather throughout that portion of space within which, by means of the telescope, astronomers are able to carry on their researches. In the infancy of astronomy the stars were divided into constellations, chiefly for the sake of convenient reference, though partly also, as we learn from Aratus, Manilius, and others, because of fanciful ideas connected with mythological and astrological superstitions. Unfortunately, this rough and imperfect method of distributing the star groups has continued to our own time, but with a modification of the method of indicating particular stars. Originally the brighter stars received different names; but Bayer introduced the plan of assigning to the

stars of each constellation, in the order of their brightness, the letters of the Greek alphabet. Since his day cataloguers of stars have introduced several new methods, more or less incongruous. For instance, Flamsteed numbered the stars in each constellation according to their right ascension in his time; Piazzi numbered stars in hours of right ascension, the first in each hour being called 1, the next 2, and so on; W. Struve numbered all the stars he dealt with (in forming a catalogue of double stars), from 0h. 0m. 0s. onward, till the complete circuit of the sphere had been made in right ascension; variable stars have received the letters R, S, T, &c., for each constellation, in order of discovery, the letters A, B, C, &c., from the other end of the alphabet, having been already employed in continuation of Bayer's system; and still other methods have been introduced, to the confusion of learners. Moreover, the regions occupied by the different constellations have not been definitely assigned; some astronomers include the new constellations added by Bode and others, while many only allow the constellations of Ptolemy, Hevelius, and Halley (in the southern hemisphere) to appear in the maps, omitting generally the constellations Antinous, Cerberus, and Scutum Sobieskii from Hevelius's list, and Robur Carolinum from Halley's. Similar confusion exists as respects the method of indicating the brightness of stars. Astronomers agree in dividing the stars visible to the naked eye into six orders of brightness called magnitudes, from the first magnitude or brightness to the sixth, the faintest which ordinary eyesight can perceive in dark and clear nights without telescopic aid; but for the fainter or telescopic stars four different methods of classification have been employed by Sir J. Herschel and Admiral Smyth in England, and by W. Struve and Argelander on the continent. The relation between the magnitudes of these different systems is indicated in the following:

| Herschel. | | Smyth. | | Struve. | | Argelander. |
|---|---|---|---|---|---|---|
| 6·4 | = | 6 | = | 5·7 | = | 5·9 |
| 7·0 | = | 6·5 | = | 6·3 | = | 6·4 |
| 7·4 | = | 7 | = | 6·5 | = | 6·8 |
| 7·8 | = | 7·5 | = | 6·9 | = | 7·5 |
| 8·2 | = | 8 | = | 7·4 | = | 8·0 |
| 8·8 | = | 8·5 | = | 7·9 | = | 8·6 |
| 9·5 | = | 9 | = | 8·3 | = | 9·0 |
| 10·1 | = | 9·5 | = | 8·9 | = | 9·4 |
| 10·4 | = | 10 | = | 9·3 | = | 9·4 |
| 11·3 | = | 11 | = | 10·0 | = | 10·0 |
| 11·7 | = | 12 | = | 10·4 | = | 10·6 |
| 12·5 | = | 13 | = | 10·7 | = | 11·2 |
| 13·3 | = | 14 | = | 10·9 | = | 11·8 |
| 14·5 | = | 15 | = | 10·9 | = | 12·4 |
| 15·9 | = | 16 | = | 10·9 | = | 13·0 |

It will be perceived that while the systems of Sir J. Herschel and Smyth are nearly enough alike to be practically interchangeable, the systems of Struve and Argelander are unlike for the fainter orders, and both differ markedly from the English system of indicating magnitudes. Unfortunately no system has been adopted uniformly by astronomers, or even by the astronomers of any given nation. Perhaps Argelander's is on the whole the best. Herschel's and Smyth's systems err in requiring that nicer distinctions should be drawn among very faint stars than ordinary observers can be expected to recognize. Struve's system appears to err in the opposite direction, by allowing too many stars to be included in the different orders of very faint stars.—The word "magnitude" as used in connection with stars refers only to apparent brightness; for the true magnitudes or volumes of stars are unknown. To determine a star's real magnitude, its distance must be determined and also its apparent diameter. But it is only in a few instances that the annual parallax of a star has been determined; and not a single star, however highly magnified, shows a true disk. Hence it is impossible to determine the volume of any star. In the few cases where the distance has been determined, it becomes possible to infer from the star's apparent brightness the total quantity of light emitted by it; and if we assume that equal portions of the star's surface and of our sun's emit equal amounts of light, we can compare the surface of such a star with our sun's surface, and so deduce its diameter and volume; but the assumption is not by any means safe. Very few stars have a measurable annual parallax. The following table includes all hitherto dealt with:

| STARS. | Magnitude. | Parallax. | Latest measures. |
|---|---|---|---|
| α Centauri | 1 | 0·976″ | 0·91″ |
| 61 Cygni | 6 | 0·348 | 0·55 |
| Lalande, 21258 | 8 | ..... | 0·26 |
| Oeltzen, 17415–6 | 9 | ..... | 0·25 |
| α Lyræ | 1 | ..... | 0·16 |
| Sirius | 1 | 0·150 | 0·27 |
| 70 Ophiuchi | 5 | ..... | 0·16 |
| 1 Ursæ Majoris | 3 | ..... | 0·13 |
| Arcturus | 1 | ..... | 0·13 |
| Polaris | 2 | 0·067 | 0·11 |
| Capella | 1 | ..... | 0·05 |
| Procyon | 1 | ..... | 0·12 |

Of the above measures, we owe the earliest, that of 61 Cygni, to Bessel; but it will be perceived that later measures differ appreciably from his. Henderson gave the earliest measures of α Centauri and Sirius, the corrected estimate for Sirius having been obtained by Mr. Cleveland Abbe, formerly of the observatory of Pulkova, now of Washington; most of the remaining measures are due to the labors of Krüger and Peters. When we observe that only α Centauri has given consistent results, we may well doubt whether as yet astronomers possess instruments competent to measure small parts of a second of arc. The distance of this star corresponds to the space traversed by light in about 3½ years, the distances of the other stars being greater according as the parallax is less; so that, for instance, if the parallax of Capella in the above list were strictly exact, Capella would be 19½ times further away than α Centauri, and light would not reach us from it in less than 63½ years. It would be a fair inference that the light of

many telescopic stars reaches us now only after the lapse of many thousands of years. To apply to $\alpha$ Centauri the method for inferring a star's volume, indicated above, we proceed as follows: The star's distance exceeds the sun's 230,000 times, so that the sun removed to that star's distance would shine with only $\frac{1}{52,900,000,000}$ part of his observed lustre. But it has been found by Zöllner that $\alpha$ Centauri shines with about $\frac{1}{16,950,000,000}$ part of the sun's brightness. Hence the star emits three times as much light as the sun, or (if our assumption as to equal intrinsic surface brightness be correct) $\alpha$ Centauri has a surface three times, a diameter $\sqrt{3}$ times, and a volume $3\sqrt{3}$ times (*i. e.*, more than five times) greater than the sun's. If we dealt with Sirius in like manner, we should deduce a volume exceeding the sun's about 2,700 times (taking the mean of the values above given for his annual parallax). But there is reason to believe that the real volume of Sirius, though far exceeding the sun's, is much less than that we have thus deduced; whence it is to be inferred that the larger stars shine with a greater intrinsic lustre than our sun, or in other words that a square mile of the surface of a large star like Sirius gives out much more light than a square mile of the sun's surface. It is not improbable that we may find hereafter in such considerations the means of distinguishing between the various orders of real star magnitudes, since stars of different intrinsic brightness might be expected to give different results under spectroscopic analysis. We have shown under SPECTRUM ANALYSIS that such differences unquestionably exist in stellar spectra; but as yet it has not been found possible to associate them satisfactorily with differences in the sizes of stars. In fact, when we observe that Capella, though a star not only of the leading order of apparent magnitude, but also, judging from its minute annual parallax, one of the largest in real volume, yet belongs to the second spectral class, that is, the class of stars resembling our sun, we can scarcely place much reliance on this method of discriminating large from small stars.—Closely connected with the question of the various orders of stars is the circumstance that many stars are colored. Of stars visible to the naked eye, only the brightest show recognizable color, at least as so viewed. Antares, Betelgeuse, and Aldebaran are ruddy; Arcturus, Pollux, and Procyon yellow; Vega and Altair bluish; Capella, Sirius, Canopus, and many others, brilliantly white. But among telescopic stars more marked instances of color occur, some stars being blood-red, garnet-colored, rich orange, golden yellow, and so on. It is noteworthy that few single stars show such colors as blue, green, violet, or indigo; but among double and multiple star systems not only are these colors recognized, but such colors as lilac, olive, gray, russet, and so on. A beautiful feature in many double stars remains to be noticed: it is often found that the components exhibit complementary colors. This is oftener seen among unequal doubles; and then the larger component shows a color from the red end of the spectrum, as red, orange, or yellow, while the smaller shows the corresponding color from the blue end, as green, blue, or purple. The colors are real, not merely the effect of contrast, for when the larger star is concealed the color of the smaller remains (in most cases) unchanged. Spectrum analysis shows that the colors of many double stars are due to absorptive vapors cutting off certain portions of the light.—The existence of double and multiple star systems is itself remarkable, and the theory of a real physical connection between the members of such systems was long opposed because of the strangeness of a conception which in our own day has become familiar to us. Of course, many stars apparently double are in reality far apart, and merely brought into accidental association because both lie nearly on the same visual line. But not only is the number of such pairs far greater than it should be to be thus explained, but also many pairs have been watched during long periods, and it has been found that the components are circling around each other, or rather around their common centre of gravity. Among the most remarkable instances of this kind are the double star 70 Ophiuchi, which completes a revolution in about 80 years; the stars of the pair $\xi$ Ursæ Majoris, which complete the circuit around their common centre of gravity in about 60 years; Castor, $\gamma$ Virginis, $\xi$ Boötis, $\zeta$ Cancri, and other doubles, which exhibit equally noteworthy motions. Many catalogues of double stars have been formed by astronomers since Sir W. Herschel first paid special attention to the work. He observed 2,400; W. Struve of Dorpat observed 3,063; Dembowski, Secchi, Webb, and others in Europe have observed many double stars, carefully measuring the distance between the components, the angle of position, color, and so on, thus forming a fund of materials from which future astronomers can determine what changes are taking place in these interesting systems. Among such catalogues, those recently formed by Mr. Burnham of Chicago will hold a distinguished place because of the "difficulty" of the double stars he has observed, arising chiefly from the nearness of the components, or from the smallness of one or both. It is remarkable that though every region of the heavens contains double stars, they are more abundant by far in some regions than in others; while again some regions of the heavens contain double stars of particular orders only or chiefly. This leads us to notice the circumstance that aggregations of stars of greater and greater extent are recognized as we extend our survey of the heavens. Of all such aggregations the most complex is the galaxy or milky way (see GALAXY), in which millions of stars shine with lustre so blended and softened by

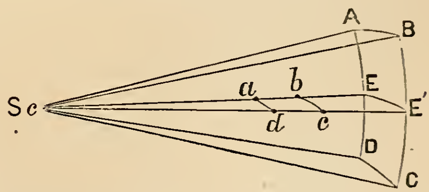
distance as to present a milky luminosity.—Many stars are variable in brilliancy. These may be divided into periodic variables, irregular variables, and temporary stars. Periodic variable stars are those which undergo increase and diminution of light at regular intervals. Thus the star Mira or *o* Ceti varies in lustre, in a period of 331⅓ days, from the second magnitude to a faintness such that the star can only be seen with a powerful telescope, and thence to the second magnitude again. It shines for about a fortnight as a star of the second magnitude, and then remains invisible for five months, the decrease of lustre occupying about three months, the increase about seven weeks. "Such," says Sir J. Herschel, "is the general course of its phases. It does not always, however, return to the same degree of brightness, nor increase and diminish by the same gradations; neither are the successive intervals of its maxima equal. From recent observations and inquiries into its history by Argelander, the mean period would appear to be subject to a cyclical fluctuation, embracing 88 such periods, and having the effect of gradually lengthening and shortening alternately those intervals to the extent of 25 days one way and the other. The irregularities in the degree of brightness attained at the maximum are probably also periodical." These irregularities are considerable. Thus between October, 1672, and December, 1676, Mira was never visible to the naked eye, while on Oct. 5, 1839, it was half a magnitude above its usual brightness, outshining *α* Ceti and *β* Aurigæ, which usually are brighter than Mira at its maximum. It suggests a probable explanation of these changes of brightness, that when the star is near its minimum its color changes from white to a full red, which, from what we know of the spectra of colored stars (see Spectrum Analysis), seems to indicate that the loss of brightness is due to the formation of many spots over the surface of this distant sun. Algol (or the Demon) is another remarkable variable, passing however much more rapidly through all its changes. It is ordinarily a second magnitude star, but during about seven hours in each period of 69 hours its lustre first diminishes until the star is reduced to the fourth magnitude, and after it has remained 20 minutes at its minimum, its lustre is gradually restored. Thus Algol remains a second magnitude star for about 62 hours in each period of 69 hours. These changes seem to correspond to what might be expected if a large opaque orb is circling around this distant sun in a period of 69 hours, transiting its disk at regular intervals. The star *β* Lyræ has a full period of 12d. 22h., divided into two periods of 6d. 11h., in each of which the star has a maximum brightness of about the 3½ magnitude, but in one period the minimum is about the 4½ magnitude, while in the other it is about the 4½ magnitude. This peculiarity points to an opaque orb with a satellite, the satellite being occulted by the primary in the alternate transits, and therefore the total loss of light less. The star *δ* Cephei varies in a period of 5d. 8h. 48m. from the fifth to the 3·5 magnitude, taking 1d. 14h. in passing from minimum to maximum of brightness, while it occupies 3d. 19h. in passing from maximum to minimum. Two or three hundred variable stars are already known. Among irregular variables the most remarkable is the star *η* Argûs. In 1677 Halley catalogued it as of the fourth magnitude; in 1751 Lacaille estimated it as of the second. Between 1811 and 1815 the star was of the fourth magnitude, and from 1822 to 1826 of the second; on Feb. 1, 1827, it had increased to the first magnitude; it fell again to the second magnitude, and remained so till 1837; in 1838 it increased in brightness, till it nearly equalled *α* Centauri; and it diminished again till 1843, when, however, it was still of the first magnitude. In April, 1843, it rapidly increased "until it nearly equalled Sirius in splendor." At present it is barely visible to the naked eye, and though it has lately been slightly increasing in brightness, it is still only of the sixth magnitude. The star *α* Orionis is another remarkably irregular variable, but amid all its changes it never descends below the first magnitude.—Temporary stars include the so-called new stars, as well as those which were formerly recorded in the catalogues of astronomers, but can no longer be seen, or have at least so changed in brightness as not to be recognized. The most remarkable instance of a new star is that which appeared in 1572 and was observed by Tycho Brahe. "It suddenly shone forth in the constellation Cassiopeia with a splendor exceeding that of stars of the first magnitude, or even Jupiter and Venus at their brightest, and could be seen with the naked eye on the meridian in full day. Its brilliancy gradually diminished from the time of its first appearance, and at the end of 16 months it entirely disappeared, and has never been seen since. During the whole time of its apparition, its place in the heavens remained unaltered, and it had no annual parallax; so that its distance was of the same order as that of the fixed stars. Its color, however, underwent considerable variations. Tycho described it as having been at first of a bright white; afterward of a reddish yellow, like Mars or Aldebaran; and lastly of a leaden white, like Saturn." A somewhat similar instance occurred in 1604, when a first magnitude star suddenly appeared in the right foot of Ophiuchus. It presented appearances resembling those shown by the former, and disappeared after a few months. In 1866 a star appeared in the Northern Crown, the observations of which threw great light on the subject of so-called new stars. In the first place, it was found that where this new star appeared there had been a tenth magnitude star; the new star then was in reality a star

long known which had suddenly acquired new brilliancy. When first observed by astronomers with this abnormal lustre it was shining as a star of the second magnitude. Examined by Huggins and Miller with the spectroscope, its light revealed a startling state of things in those remote depths of space. The usual stellar spectrum, rainbow-tinted and crossed by dark lines, was seen to be crossed also by four exceedingly bright lines, the spectrum of glowing hydrogen. Either the star was actually "in flames" at the time, that is, surrounded by burning hydrogen, or else some cause had raised the hydrogen around the star to a state of intense heat, but without actual combustion. The greater part of the star's light manifestly came from this glowing hydrogen, though it can scarcely be doubted that the rest of the spectrum was brighter than before the outburst, the materials of the star being raised to an intense heat. The maximum brightness of the star exceeded that of a tenth magnitude star nearly 800 times. After shining for a short time as a second magnitude star, T Coronæ (as the star was called thenceforth) diminished rapidly in lustre, and it is now between the ninth and tenth magnitudes.—The stars are not absolutely at rest, though many years pass before the motion of any star can be detected. Halley, comparing the observed places of Arcturus, Aldebaran, and Sirius with the places assigned by the Alexandrian astronomers, found reason to believe that these three stars are approaching the ecliptic. This surmise was confirmed by the elder Cassini, who observed that Arcturus had shifted southward 5′ in latitude since the time of Tycho Brahe. Bradley made observations to give means for detecting stellar motions, and before long astronomers began to recognize many instances of measurable motion. In 1783 Sir W. Herschel took up the idea that the stellar motions are in part due to a proper motion of the sun himself. Tobias Mayer had suggested this idea in 1771, but comparing Römer's observations with his own could find no evidence in its favor. Herschel was more successful. From the motions of seven stars, as estimated by Maskelyne, he deduced the inference that the sun is moving toward a point in the constellation Hercules in right ascension 257°. From a more exact inquiry, using Mayer's list of proper motions, he was led to place the point toward which the sun is moving (or, as it is called, the "apex of the solar way") near the star Herculis. In 1805, using Maskelyne's catalogue of the proper motions of 36 stars (published in 1790), he set the apex in right ascension 245° 52′ 30″ and N. declination 49° 38′. Bessel in 1818 expressed his agreement with Tobias Mayer, in regarding the evidence as insufficient for determining the direction of the sun's motion; but since then Mädler, Argelander, O. Struve, and Sir G. B. Airy have dealt with the problem, with results confirming the views of Sir W. Herschel in a very remarkable way, considering the imperfect evidence available in Herschel's time. Nevertheless it is noteworthy that, although the balance of the stellar motions indicates the real existence of a proper motion of our sun toward Hercules, yet on any of the usually accepted theories of stellar distribution, the stellar motions accounted for by the sun's motion do not form nearly so large a proportion of the observed stellar motions as they should do. The present writer has shown by a simple geometrical method that they should constitute one half of the total; or rather, that the sum of the squares of the observed displacements should be reduced one half on making the proper correction for the effects due to the sun's motion. The real reduction, instead of being one half, is between $\frac{1}{25}$ and $\frac{1}{26}$. This does not throw any doubt on the fact of the sun's motion, but it renders altogether untenable the commonly accepted theories as to stellar distribution.—The motions hitherto mentioned are apparent motions of the stars on the celestial sphere. Motions of recession or of approach would of course not be indicated in this way; nor would they produce any appreciable change in a star's brightness. This is easily perceived when we consider that motions of recession or of approach would be of the same average order as thwart motions. What thwart motions may be in actual amount we do not know, but we do know what proportion they bear to the distances of the stars they respectively appertain to. Thus if a star were displaced 10″ in a year (and no star has yet been observed to have so large a proper motion), the actual distance traversed in one year would be to the star's distance as sin. 10″ to 1, or as 20,626 to 1. A corresponding motion of recession or approach would therefore diminish or increase a star's brightness in one year by $\frac{1}{10323}$ part, and the brightness would be diminished or increased only by $\frac{1}{100}$ part in 103 years. Such a change would be quite inappreciable even if the observation of irregular variations of stellar brightness did not prevent us from placing any reliance on apparent changes of brightness as indications of distance. It might then appear hopeless to attempt to determine whether the stars have motions of recession or approach; but spectroscopic analysis affords a means of dealing with this problem which has been successfully applied by Huggins and Vogel, and may hereafter be widely extended. If a star is changing its distance from us, light waves of any given order proceeding from the star must reach the observer with their length increased if the star is receding, and decreased if the star is approaching. On comparing, then, any known line in a stellar spectrum with the corresponding line in the spectrum of the terrestrial element, any shift of the line which can be detected will indicate recession if toward the red end of the spectrum, and approach if toward the indigo end. Applying this method, Huggins has recognized motions

of recession and approach ranging from 10 m. to nearly 50 m. a second.—Some of the stars have proper motions in the same direction and at the same apparent rate. Mädler, noticing this peculiarity in the constellation Taurus, was led to surmise that the centre round which all the stars are moving lies in that constellation, and he assigned Alcyone, the principal star of the Pleiades, as the centre in question. Beyond the observed community of motion in Taurus there was not any direct evidence for this theory; and this observed phenomenon was held by astronomers to afford but weak evidence for a theory of importance. Yet Mädler's views were described in every text book of astronomy, in terms which would have been scarcely justified if there had been an overwhelming mass of evidence in their favor, and if astronomers had been practically unanimous in accepting them. In point of fact, even the one piece of direct evidence which seemed to support Mädler's theory is found on examination to have no weight whatever. It is true that if there is a centre around which all the stars are moving, the stars lying toward that centre should exhibit a community of proper motions, and the stars in Taurus do exhibit the peculiarity; but unfortunately for the theory, the same feature exists in other parts of the heavens. A map constructed by the present writer, showing all the stellar proper motions as yet satisfactorily determined, exhibits many such cases, and some of them are more remarkable than the case of the stars in Taurus. One singular instance of this "star drift" is observed in the constellation Ursa Major, in which the stars $\beta$, $\gamma$, $\delta$, $\varepsilon$, and $\zeta$ are all travelling in the same direction and at the same rate. As these are bright stars, it appeared to the writer that they would afford an instructive test of the theory of star drift, if their motions of recession or approach could be determined. This was effected by Huggins a year after the theory of star drift had been enunciated, and it was found that, as the theory required, the five stars had a common motion in the direction of the line of sight, and that they are all receding at the rate of about 17 m. a second from the solar system. The inference fairly deducible from this fact, that these stars form a single system or family travelling together through space, is interestingly confirmed by the fact that all five belong to the same order. (See Spectrum Analysis.)—Although many speculations were broached respecting the constitution of the sidereal heavens from the earliest ages of astronomy, the first to enter on the systematic study of the subject, combining observation with theory, was Sir W. Herschel. Mitchel, it is true, had theorized carefully and soundly, but his labors were not extended beyond a few points of detail; and though Wright of Durham made some observations for the purpose of determining the structure of the milky way, yet the telescope he used (only one foot in focal length) was far too small to give any really satisfactory results. At the beginning of his labors Sir W. Herschel took as the basis of his conceptions the belief that our sun is a member of a system of suns, scattered with a certain general uniformity throughout a region of space having a defined figure, possibly determinable if only a telescope could be constructed powerful enough to reach the limits of the system in all directions. To effect this, he devised his system of "star gauging by counting." It is clear that the further the sidereal system extends in any given direction, the greater will be the number of stars lying toward that direction, since the distribution is supposed (in a general sense) uniform; and therefore, if the same telescope, with unchanged power, were directed toward every part of the heavens in turn, then by counting the number of stars brought into view in these different directions the relative extension of the system along those visual lines could be determined—in other words, the shape of the star system. Let it be noticed that this plan of star gauging required that one and the same telescope should be applied to different parts of the heavens; it assumed a general uniformity of distribution within the limits of the system; and it required that the telescope should penetrate to those limits. Recognizing these points, we shall not fall into the mistake made by many (including Arago and the French astronomers generally, Smyth, and others, and repeated in almost all the text books) of confounding this method of star gauging with the method devised by Sir W. Herschel when a long experience had convinced him that the assumptions on which he had based the former method were unsound. While he still supposed these assumptions sound, however, he deduced as the result of applying his first method the inference that the sidereal system is shaped like a cloven flat disk. (See Galaxy.) But gradually his observations showed him that special laws of aggregation exist within the star depths. He saw, first, that the milky way is not produced by the combined lustre of stars scattered like those around us, but extending to enormous distances. Next he perceived that the stars forming the richer parts of the milky way are not arrayed along great ranges in distance, but really spread more richly within limited and roughly globular regions. In the same paper (all the passages we quote are from the "Philosophical Transactions") he wrote as follows: "On a very slight examination it will appear that this immense starry aggregation [the milky way] is by no means uniform. . . . By referring to some one of these clustering aggregations in the heavens, what will be said of them will be much better understood than if we were to treat of them in a general way." He selects the great double clustering aggregations in Cygnus, which form such conspicuous star clouds on clear summer nights. Here, he says, "the stars are clustering with a kind of

division between them, so that we may suppose them to be clustering toward two different regions. By a computation founded on observations which ascertain the number of stars in different fields of view, it appears that our space [*i. e.*, our selected region] in Cygnus, taking an average breadth of about five degrees of it, contains more than 331,000 stars; and admitting them to be clustering two different ways, we have 165,000 stars for each clustering collection. Now the above mentioned milky appearances deserve the name of clustering collections, as they are certainly much brighter about the middle, and fainter near their undefined borders. . . . We may indeed partly ascribe the increase both of brightness and of apparent compression to a greater depth of the space which contains the stars, but this will equally tend to show their clustering condition; for since the increase of brightness is gradual, the space containing the clustering stars must tend to a spherical form if the gradual increase of brightness is to be explained by the situation of the stars." That is to say, whether we consider the greater richness in the centre to be due to the clustering of stars toward the middle of these aggregations, or to the shape of the groups themselves, or partly take both causes of central richness into account, we are alike led to the conclusion that the groups are roughly spherical in shape. This conclusion, it need hardly be said, is utterly opposed to Herschel's old belief in a star system generally uniform throughout its whole extent; for here, and in all similar cases, we see rounded clouds of stars as distinct from the stars scattered around us as rounded clouds in the sky are distinct from a thin low-lying fog through which their shapes are seen. Accordingly, before long Sir W. Herschel saw the necessity of devising a new method of star gauging, based, not on the numerical richness of star fields, but on the telescopic power necessary to effect the resolution of the milky light of clustering aggregations into discrete stars. By this process he hoped to determine the relative distances of star groups. Supposing that a particular aggregation began to be resolved into discrete stars with a certain telescopic power, and was entirely resolved when a certain higher power was employed, there would be *prima facie* evidence as to the distance of the aggregation, if the stars forming different aggregations are similarly distributed. For, given a group of stars of certain sizes and set at certain distances from each other, it is clear that the further away the group is placed, the higher will be the telescopic powers required (1) to begin and (2) to complete the resolution of that group into separate stars. How perfectly unlike this method was, at once in principle and in practical details, to the former, will be seen from a comparison of the earlier method, above, with the following summary of the qualities of the later method. In the new method, the same part of the heavens was to be examined successively with different telescopes; the observer was not to count stars, but to note the extent to which resolution was effected; it was assumed that the stars within the clustering aggregations were distributed far more richly than elsewhere; and the telescope was required to effect resolution within a particular region of space, not to merely extend vision to particular distances. It is manifest that the new method and the assumptions on which it is based are open to exception. Herschel had found that the stars are not spread uniformly through the star system, as he had before surmised; and one would have supposed that having thus been misled by one assumption, he could not adopt others differing from it in degree only, not in kind. Yet his second method of star gauging could only give him, as he hoped, the means of "ascertaining a scale whereby the extent of the universe, so far as it is possible for us to penetrate into space, may be fathomed," if, first, the stars were spread uniformly within each clustering aggregation, and secondly, if different clustering aggregations were similarly constituted. For clearly, if one and the same aggregation included several orders of stars, each order distributed with a degree of richness peculiar to itself, and still more if there were not even any law of distribution for the several orders, then no reliance could be placed on the method; for a telescope might effect resolution with respect to some particular order of stars within the aggregation which would leave orders of smaller or more closely set stars within it quite unresolved. Nor again could any comparison be instituted between the distances of two aggregations resolved by particular telescopes, even though there were reason to believe that within each there was a general uniformity of distribution, unless we were certain that they were alike in constitution. If the more remote of two aggregations consisted of large stars sparsely strewn, and the nearer consisted of small stars closely set, the two aggregations might require exactly the same power for their resolution, notwithstanding the difference of distance. On the latter point Herschel's observations by the new method could throw little light, since there is no telescopic means of discriminating really large from really small stars. But on the former point he obtained evidence which should have been decisive against the new method of gauging, or rather against the assumptions on which it was based. For he observed several clusters which began to be resolved with very low telescopic powers, but were not entirely resolved even with the largest telescopes and highest powers Herschel employed. As these clusters were of small extent and round in figure, it followed that if the stars were spread uniformly within them, the extension of these clusters in the direction of the line of sight must enormously exceed their thwart diameter; in other words, that they

were all of them shaped like gigantic cylinders, of length vastly exceeding their breadth. This supposition being altogether untenable, it is certain that these clustering aggregations contain stars of many orders of real magnitude, distributed according to various laws of richness. . In fact the range of magnitude and of richness of distribution must be as great as in the case of the solar system, from the giant bulk of Jupiter and Saturn to the minute and (relatively) closely aggregated asteroids. And here in passing we may note that this legitimate inference from the observations of Sir W. Herschel is abundantly confirmed by Sir John Herschel's examination of the Magellanic clouds, in which all varieties of stellar magnitude and aggregation, from sparsely strewn stars of the eighth and ninth magnitudes to a nebulosity irresolvable by his 18-inch mirror (besides all orders of nebulæ), coexist within limits of distance not differing in proportion more than as 10 to 9. According to the assumptions on which Sir W. Herschel's second method of star gauging was based, the limits of distance to include such varieties of stellar distribution should differ in proportion more than as 300 to 1. Passing over the work of Sir J. Herschel, who, so far as stellar distribution is concerned, contented himself by extending his father's first method of star gauging to the southern heavens, we come to the work of W. Struve, whose researches are distinguished by a further extension of the theory of non-uniformity in stellar distribution. He, first of all astronomers since Herschel's papers were written, perceived their real purport, and the incorrectness of the description given by Arago, at least partially. He does not seem to have sufficiently weighed the significance of Herschel's remarks respecting the rounded figures of many clustering aggregations, and he quite misunderstood Herschel's observation that "when he could not resolve rich stellar regions, it was because they were unfathomable." (He appears to have read the word "when," in this sentence, as equivalent to the German *wenn*, since it is rendered by *si* in Struve's *Études d'astronomic stellaire.*) But he clearly perceived that Herschel had given up as early as 1802, if not earlier, the theory of a general uniformity of stellar distribution. Having found, indeed, that the stars down to the eighth magnitude are more richly spread over the milky way than elsewhere (whereas if stars were uniformly distributed within the system, these brighter orders, lying all far within even the nearer limits of the galaxy, should appear uniformly distributed over the heavens), he at first supposed that he had obtained a result opposed to the views of Sir W. Herschel; but having re-examined the whole series of Herschel's papers, he found that the result was quite accordant with Herschel's later views, and opposed only to views which Herschel had abandoned early in his career as an observer. But now Struve, having thus obtained evidence of a want of uniformity in the distribution of the stars, and having found that Sir W. Herschel had recognized an even wider range of irregularity, nevertheless proceeded (as Herschel had done, but in other directions) to assume laws of uniformity which, to say the least, should have been demonstrated before they were adopted as the basis of stellar theories. He assumed that stars gather more richly toward the medial plane of the galaxy, but that at equal distances from that plane the distribution is equally rich (on the average for that distance), and that stars in different regions have equal average dimensions. He counted all the stars down to the ninth magnitude in each hour of right ascension between 15° N. and 15° S. of the equator (or rather he took the numbers from Weisse's catalogue), and supposed them gathered on the equator, toward each "hour" of the equator its proper number, spread uniformly. Then he supposed the equatorial ring of stars thus formed spread over an equatorial disk, in horary sectors, and uniformly over each segment of such sectors limited by radii corresponding to star magnitudes. Thus, suppose E E′ to be a horary arc of the equator, and therefore 15° in length, A E D, B E′ C parts of hour circles, A B, D C parts of parallels having 15° N. and S. declination, S the sun; and let S *b*, S *c* represent



resent the greater limit, and S *a*, S *d* the lesser limit of stars of the seventh magnitude. Then Struve, having counted the stars of all magnitudes down to the ninth in the space A B C D, conceived them first distributed uniformly along the equatorial arc EE′, and next spread them over the sectorial area S E E′, distributing all of the seventh magnitude uniformly over the plane surface *a b c d*. Thus he obtained his equatorial section of the galaxy; and he persuaded himself that this artificial method of distributing the stars was based entirely upon observation, without any arbitrary hypothesis whatever. Prof. Forbes said justly, speaking of Struve's method: "I am persuaded that the popular writers and reviewers who have given additional publicity to the most striking and positive of M. Struve's conclusions, have (very naturally) done so on the strength of the author's well deserved reputation as an observer, and without attempting to analyze his reasoning, which it must be owned is sometimes obscure. My objections," he proceeds, "to M. Struve's argument were put in writing several years ago (1850), but not published except in my lectures. It was only in 1855 that I saw for the first time a memoir by Prof. Encke in the

*Astronomische Nachrichten*, vol. xxvi., No. 622 (published in 1848), maintaining the same view of the invalidity of M. Struve's reasoning, and questioning the hypotheses (of which M. Encke reckons five) tacitly assumed by him." The present writer, led independently to the same general views respecting Herschel's labors which Struve had formed, and afterward to the same general views respecting Struve's labors which Forbes and Encke formed, adopted the following as the principle on which fresh researches should be based: That as regards the laws of stellar distribution, the range of stellar magnitude, intrinsic brilliancy, and so on, we must assume nothing, all assumptions having been proved by the clearest possible evidence to be untrustworthy. We must be guided by the facts alone. Nor are we thus compelled to abandon as hopeless the great problem of the star depths. Even where Herschel's methods seemed to fail, they afford excellent promise of success. His first method, for example, had to be abandoned, so far as his original purpose was concerned, because he found reason to believe that the great rich regions of the milky way are situated like mighty clouds of stars in space, and are not mere ranges of stars extending continuously from our own neighborhood. But it was the method itself which taught this, which in fact effected this capital discovery. The second method, again, cannot be interpreted as Herschel hoped; it cannot tell us how far off, relatively, are different star groups. But this application of the method has to be abandoned simply because the use of the method itself has taught us that the architecture of the heavens is far too complex to be interpreted in so simple a manner. Here then is another great discovery effected by a method of star gauging which, so far as its original purpose was concerned, has had to be rejected. But so soon as we recognize these facts, a method of research is suggested which combines the trustworthy qualities of both methods, and is free from the faults of either. We must employ Herschel's first method of star gauging, counting the stars in equal fields with the same telescope; but we must not limit ourselves to the study of a star field here and there. The whole heavens must be surveyed, and this not with one telescopic power only, but with many, from the lowest powers to the highest available. The results obtained with each power must be compared together, after being carefully indicated in suitable charts; a method altogether more satisfactory than any processes of statistical enumeration. Differential charts, showing by how much each increase of power increases in each region the number of stars brought into view, ought also to be constructed. No preconceived opinions should be suffered to mar the teachings thus obtained; but the architecture of the heavens must be viewed precisely as it is presented to us by these results. Principles of interpretation, however, may legitimately be applied to the evidence, so long as they are founded on just considerations. It appears to the writer that the following principles are not open to question in this respect: 1. Where two surveys made with different telescopic powers indicate concordant laws of distribution over the heavens, the rich regions thus indicated are regions where the orders of objects dealt with by the two telescopes are intermingled. 2. Where instead of such accordance a law of contrast is indicated, regions rich in one order of objects being poor in another and *vice versa*, the two orders still belong to one system, but some peculiarity in the laws according to which they were formed causes them to occupy different parts of the system, segregating as it were from each other. 3. Where no connection whatever either of agreement or contrast can be recognized, it is probable, and in general presumable, that the two orders are altogether distinct and lie at different distances from each other. 4. Where partial or local agreement or contrast is indicated, the inference is that the true arrangement of the objects in space is affected both by laws of aggregation or segregation and by diversities of distance, and by one cause or the other to a degree corresponding to the extent of such agreement or contrast. What is here said of objects brought into view by different telescopic powers is true of different orders of objects, as nebulæ, double stars, colored stars, variables, and so on. These principles have been applied by the writer already to stars visible to the naked eye in both hemispheres, to stars down to the tenth magnitude of Argelander in the northern hemisphere only, and to the known nebulæ (5,500 in number) in both hemispheres. As an illustration of the fertility of the process, the following results may be indicated: First, the stars visible to the naked eye are not distributed uniformly through surrounding space, but are gathered markedly in two rich regions, one northern, the other (larger) southern, and are particularly rich in the region of the milky way; but the leading orders of these stars are gathered zonewise in a region somewhat inclined to the milky way; a circumstance first noted by Sir J. Herschel, but independently by the present writer and also by Prof. B. A. Gould. The northern stars, down to the tenth magnitude inclusive, are gathered in the most marked manner in the galactic zone, not increasing gradually in richness of distribution as they approach it, but being gathered richly in the nodules, clustering aggregations, streams, and whorls of stars of which the galaxy consists. This circumstance proves that the milky way is not only apparently but really so formed; and since Herschel's gauges show that wherever the milky way appears bright to the naked eye, there the fainter orders of stars, down to the least brought into view by his great telescope, are most richly strewn, it follows that these fainter

orders and the brighter stars of the first ten magnitudes are really intermingled in space, whence the fainter must be very much smaller than the brighter in these regions; though of course this does not prevent us from believing that a certain proportion of the fainter stars are really far more remote than the brighter stars. The nebulæ are found to be strewn in such a way that the second of the above laws is directly applicable to the relation between them and the fixed stars. For along the zone of the milky way few nebulæ are found, and those belonging only to two orders, the irregular (gaseous) nebulæ and star clusters. The further we proceed from the galactic zone, the more richly do we find the nebulæ scattered. This relation was first noticed by Sir W. Herschel, but not thoroughly established until Sir J. Herschel had completed the survey of the southern heavens. Mr. Cleveland Abbe made a more exact analysis, in which he dealt with all the nebulæ in Sir J. Herschel's latest list, classifying them according to their resolvability, and showing that the density of nebular distribution increased with the distance from the galactic zone for the irresolvable nebulæ, but diminished with that distance for the clusters. These researches were statistical. The present writer has employed Mr. Abbe's tables in the construction of an equal surface chart of the nebulæ, showing the law of their distribution to the eye. It is thus seen that there is not a gradual condensation of nebulæ toward two opposite regions, near the poles of the galactic zone, but that the nebulæ are gathered into streams, nodules, and irregular aggregations such as we find in the grouping of stars. We have said that law 2 characterizes the relation between stars and nebulæ; in other words, that their arrangement follows the law of contrast. There are two remarkable exceptions to this law, the Magellanic clouds. In these, where stars of all orders, from the ninth magnitude to irresolvable stellar aggregations, are as richly gathered as on the galactic zone, nebulæ of all orders are also gathered richly, even more so than anywhere else over the whole heavens.—It will be evident from what has here been shown, that the sidereal system is not the simple scheme imagined by the earlier astronomers and still described in most of the text books of astronomy. No law of uniformity of distribution can now be accepted, for one law after another has been disproved by the clearest possible evidence. Accidental numerical correspondences, found in the distribution of stars of various orders spread over large regions, cannot be admitted as evidence of uniform distribution of stars throughout surrounding space, or of any law of uniform condensation, when we find on analysis that these relations have to be otherwise interpreted. We know, for example, that the excess of stars of the fainter orders is not brought about by the mere extension of telescopic range, as Struve and Littrow have surmised, but has to be partly explained by the actually observed gathering of such stars in certain streams, clouds, sprays, and nodules of milky light. We must not allow any statistical rules (arbitrarily laid down in the first instance) to blind us to the facts thus disclosed. The future study of the sidereal system must in fine be based more exclusively on observation than heretofore; though even more laborious processes of deductive reasoning must be applied, since this, like all the greater problems of science, lies far beyond the range of mere induction. (See p. 891.)

**STARCH** (also called amylaceous matter and fecula), a proximate vegetable principle existing at certain periods of vegetable life in every plant that has been examined for it. It occurs especially in the seeds of cereals and other plants, in the tubers of potatoes, in tap roots, such as carrots and parsnips, in the pith of stems, as the sago palm, and sometimes in the bark. It is white, glistening, and pulverulent, composed of microscopic spheroids or granules of a firm consistency, varying according to their origin from $\frac{1}{200}$ to $\frac{1}{3000}$ of an inch in diameter, and contained in the cells of the cellular tissue of the plant, several being enclosed in one cell. (See fig. 1.) According to Payen, starch is found only when the nutriment is in excess, being consumed at the later stage of the vegetative process, when the nutriment becomes deficient. The young granules are exceedingly small, spherical, and homogeneous; but in developing they become ovoid, lenticular, or polygonal. They have a characteristic

Fig. 1.—Bean Starch lying in Cellular Tissue, magnified 200 diameters.

Fig. 2.—Starch Granules of *tous les mois*, magnified 150 diameters.

form and structure, being composed of a series of layers presenting the appearance of concentric markings, which, in connection with the size, are characteristic of the plant to which they belong. Each granule is marked by a peculiar spot called the *hilum*, at which point it is attached to the cell wall in its early state. When viewed by polarized light, each granule is seen to be marked by a dark cross having its point of intersection at the hilum, as in fig. 2, representing the granules of *tous les mois*, a starch obtained from the tubers of the *canna edulis*, a plant belonging to the order *marantaceæ*, which includes also the *maranta arundinacea* or West India arrow root, fig. 3. When a plate of mica or selenite is interposed, to produce interference of light, the cross becomes gorgeously colored. (See Light, vol.

x., p. 448.) The size of the granules in each plant is not uniform, but there is an average which is generally not much departed from, although sometimes, as in the potato, the dif-

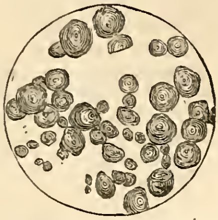

FIG. 4.—Starch Granules of *Manihot utilissima*, or Brazilian Arrowroot, magnified 225 diameters.

ference is great (see fig. 5), but then it is characteristic. It is now believed that each granule consists of two substances intimately mingled, which are alike in chemical composition, having the same proportion of elements as the cellulose ($C_6H_{10}O_5$) which forms the cellular structure of plants. These two substances are called granulose and cellulose, the former being soluble, the latter insoluble in boiling water. Starch is insoluble in cold water, and in alcohol and other liquids which do not decompose it; but when treated with about 20 parts of boiling water its granules swell, become gelatinous, and fuse into a thick opaline liquid; this on cooling solidifies into a homogeneous paste, or hydrated starch, which when dried becomes a hard horny substance like gum. If the starch is treated with 100 or 150 parts of boiling water, it forms an opaline liquid, which does not gelatinize, but on standing allows the cellulose constituent to form a turbid deposit, while the granulose, or soluble starch, remains in the transparent solution. Starch may be converted into dextrine and grape sugar by the action of diastase, or by boiling in a dilute acid. (See DEXTRINE, DIASTASE, and FERMENTATION.) It may be readily distinguished in the laboratory by the deep indigo-blue compound which it forms with iodine. The test is one of exceeding delicacy, but the iodine must be in a free state, for if it is combined with almost any other substance the affinity of the starch is not sufficient to abstract it. Starch may be obtained by rasping, bruising, or grinding the vegetable structure to pulp, and washing the mass upon a sieve, which retains the torn cellular tissue, or the gluten, while the starch passes through with the dissolved sugar and is precipitated, when it may be collected by decantation or elutriation, and washed and dried. The following table shows the percentage of starch in various kinds of food, according to Payen:

| | | | |
|---|---|---|---|
| Wheat | 57·88 | Potatoes | 20·00 |
| Rye | 64·65 | Sweet potatoes | 16·05 |
| Oats | 60·59 | Peas | 37·30 |
| Barley | 66·43 | Beans | 33·00 |
| Indian corn | 67·55 | Flaxseed | 23·40 |
| Rice | 88·65 | Cacao | 11·00 |

The size and appearance of the several different kinds of starch granules when examined by the microscope are given in the engravings. —Starch is extracted from grain by two principal processes, the old or fermenting, and the new or non-fermenting process. In employing the fermenting process the grain is steeped in water till it becomes soft enough to mash easily between the fingers. It is then passed through a malt mill or between rollers, and again mixed with water. Fermentation sets in, and lactic and acetic acids are formed, which disintegrate the cellular structure and liberate the starch granules. These are collected by repeated washings and precipitations, the process being continued for several days. The gluten undergoes putrefaction, emitting a most noisome odor. The sugar and a portion of the starch are converted into alcohol, and a part of this into lactic and acetic acids, which dissolve the gluten that has escaped putrefaction. Thorough washing and draining remove the soluble matters, and the starch left behind is next dried in blocks about 6 in. square; as the water escapes from them, the masses break up into the columnar fragments peculiar to starch. The other method, introduced by M. Émile Martin

FIG. 5.—Potato Starch, magnified 225 diameters.

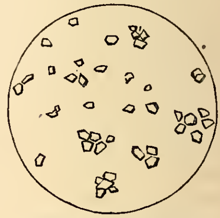

FIG. 6.—Rice Starch, magnified 300 diameters.

of Vervins, France, consists in kneading the flour into dough with water, and then washing on a sieve of No. 120 wire in a stream of water, as long as the water passes through milky. The starch in suspension and the sugary portion in solution are caught below the sieve, and the gluten nearly all remains behind in a sticky mass. What passes through is left to ferment 24 hours in an oven at 68° F., and a little leaven is added, or the skimmings of a former operation, to hasten the process. The portion of gluten carried through with the starch is thus separated and removed by skimming. The starch is then treated like that otherwise obtained. The product by this method is about 50 per cent. of the weight of the flour, while by the other process it is only from 35 to 40 per cent. Nearly the whole of the gluten also is saved in a condition suitable for food, either by mixing it with flour and making of it macaroni and similar pastes, or with boiled potatoes, and thus making a cheap and nutritious bread, by adding to the potatoes a nutritive element in which they are deficient. Potato starch is made from rasped or grated potatoes, by a process similar to that just described. This

variety does not assume the columnar form in drying, and is also peculiar in retaining a large amount of moisture, generally 20 per cent., or when saturated 23 per cent.—Rice is treated by a process patented in 1840 by Orlando

Fig. 7.—Wheat Starch, magnified 225 diameters.

Fig. 8.—Corn Starch, magnified 400 diameters.

Jones, which is also quite as applicable to the other grains. It is macerated in a weak alkaline solution, a gallon of water to every 2 lbs. of rice, and about 200 grains of caustic soda or potash to the gallon, which dissolves the gluten but leaves the starch. After standing about 24 hours, the alkaline liquid is drawn off, and the rice after being well washed is drained, and is then ground into flour. A fresh quantity of lye is added to it, and it is again digested for 24 hours, with frequent stirring. It is now left for 70 hours, in which time the dissolved gluten rises and is all found in a turbid, yellowish stratum at the top. This portion is carefully drawn off, leaving the fibrous portion of the grain at the bottom intermixed and covered with starch. The deposit is then stirred up and washed with abundance of cold water, and the mixture being left to repose, the fibrous portion is deposited with very little starch, and the remainder is drawn off by a siphon through a fine sieve into a cistern, when it is further washed and purified. The gluten is recovered by neutralizing its solution with sulphuric acid, by which means it is precipitated. The water is then drawn off and the gluten collected, dried, ground, and mixed with other flour. A patent was granted to James Colman of England in 1842 for making starch from maize and other grains by a process similar to that of Jones; but an application for a renewal of the patent of the latter in 1854 was refused because a similar one had been granted to Thomas Wickham in 1824. The manufacture of starch from Indian corn by an alkaline process was introduced in this country by Thomas Kingsford in 1842–'3, while foreman in the starch factory of William Colgate and co., in New Jersey. The two largest starch manufactories in the world are in the United States: one at Oswego, N. Y., established in 1848 by Thomas Kingsford and son, producing 21,500,000 lbs. annually; the other at Glen Cove, Long Island, established in 1858 by the Messrs. Duryea, and producing 19,000,000 lbs. annually. Their products, both laundry and edible corn starch, are largely sent to European and other foreign markets, and have taken the first prizes at international industrial exhibitions. Each establishment employs its own processes, and the recovery of the gluten is not practised, but this, with other parts of the grain separated from the starch, is sold as food for domestic animals.—The part taken by starch as a constituent of food is the most important of its numerous uses, being the principal element in the food of graminivorous and herbivorous animals, and an important one in that of man. It is used in the manufacture of dextrine or British gum, for stiffening linen and cotton goods, and for making size for paper and various other articles. It is employed in medicine for diluting and otherwise modifying the form of various articles of the materia medica; in surgery for preparing splints and bandages; and in the chemical laboratory for the detection of iodine.—Animal starch, called glycogen because it has the property of being transformed into glucose or starch sugar, exists in the livers of all healthy vertebrate animals, and in some of the tissues of other animals. It resembles vegetable starch, but yields a violet red instead of a violet blue color with iodine. (See Liver.)

**STAR CHAMBER, Court of the** (*curia cameræ stellatæ*, so called from the gilded stars on the ceiling of the old council chamber of the palace of Westminster, in which it sat), a tribunal famous in the political history of England, and mentioned as early as the reign of Edward III. It appears to have been then, and for upward of a century and a half afterward, identical with the ancient *concilium regis*, or king's ordinary council, which alone exercised jurisdiction, the *concilium secretum*, or privy council, being a deliberative body; and at the accession of Henry VII. its powers had become so greatly abridged by restraining statutes as to render it almost inoperative as a court of justice. The statute of 3 Henry VII. (1488) placed the jurisdiction on a permanent basis by establishing a court composed of three high officers of state, to whom a fourth was subsequently added, a bishop and temporal lord of the council, and two justices of the courts of Westminster, which took cognizance of riots, perjury, the misbehavior of sheriffs, and other offences against the administration of justice, without the assistance of a jury. This tribunal was distinct from the council itself, of which it may be considered a committee having delegated powers. It received an augmentation of its powers by act of 31 Henry VIII.; but during the minority of Edward VI. it was merged in the general body of the council, which thenceforth, as in earlier times, constituted the real court of the star chamber. The latter continued under the Tudors and their successors, in spite of numerous restraining statutes, to exercise a jurisdiction, particularly in criminal matters, unauthorized by the act of Henry VII. erecting a new court, and which gradually rendered it one of the

most odious instruments in overthrowing the liberties of the people. Every misdemeanor, and especially those of public importance for which the law had provided no sufficient punishment, seems to have come within the scope of its inquiry. Among these were corruption, breach of trust, and malfeasance in public affairs, attempts to commit felony, or breach of proclamations; and to such an extent was its authority stretched under the Stuarts, that, according to Clarendon, "any disrespect to any acts of state, or to the persons of statesmen, was in no time more penal, and the foundations of right never more in danger to be destroyed." The mode of process was generally by information filed at the suit of the attorney general, or, in certain cases, of a private relator, and in other respects resembled that familiar to the court of chancery. Although the court was held incompetent to pronounce sentence of death, fines, imprisonment, the pillory, whipping, branding, and various species of maiming were freely resorted to. After flourishing with constantly increasing power for upward of a century, as thus constituted, the court of the star chamber was finally abolished by act of parliament in 1641.

**STAR FISH**, the popular name of the radiated animals of the class of echinoderms and the order asterioids, well exemplified by the common species of the New England coasts, the five-fingered Jack of the sailors. The quinary arrangement prevails to a remarkable extent in the star fishes. The body is depressed, and divided into rays like a star; the upper surface is studded with rough knobs, varying in color with the species, but generally reddish or yellowish, between which are the openings of many very minute tubes for the passage of water in and out of the body; the skin is coriaceous, and contains the above named corpuscles, beneath which is a cutaneous skeleton of porous calcareous pieces, movably articulated, and extending on the lower surface from the mouth in the centre to the end of the rays. In the lacunæ between these pieces are the ambulacral pores, along the centre of the lower surface of each ray, through which are protruded the ambulacral tubes; these are the principal organs of locomotion, are arranged in a double or quadrangular row, and are provided with contractile sacs or vesicles on the inner surface of the envelope; the tubes are constantly in motion, each ending in a suctorial disk, and pull the animal along as by the successive action of so many little anchors. On the external edges of the rays are series of stiff spines, probably serving for protection, and at the end of each ray is a small reddish eye speck; there are also scattered over the upper surface small processes ending in calcareous hooks or pincers. The mouth opens into the stomachal cavity, from which branching cæcal tubes extend to the extremity of each arm; they have no long tentacles like the sea anemone (*actinia*), but the stomach can be everted over their food and then be turned back again; the mouth is very dilatable, and will admit large mollusks with the shell, the hard parts being ejected after the soft portions are digested. There is great variety in the spreading, division, and subdivision of the arms, and in the relative size of the central disk, but all are arranged after the radiated plan; the rays can be bent in any direction, according to the will of the animal, by the contractile skin and muscles. The slender ophiurans progress by the undulatory movements of the rays, which, when very slender, long, and branching, have no eyes at the tips; there is generally no anal aperture, and if any it is on the dorsal surface. By the action of cilia water flows through the body, through the aquiferous system, distending and protruding the ambulacral feet, filling the circular vessel around the mouth, and serving for respiration, which, according to Siebold, is performed partly by the vesicular appendages attached to the central ring; all the viscera are bathed in water, and respiration is also effected through the delicate blood vessels thereon distributed. The vascular system is very simple; the nervous ganglia are five, arranged around the mouth, each sending filaments to the arm at whose base it lies; the sense of touch is very acute. According to Sars, Steenstrup, and Lütken, there is not only in this class a great power of regeneration of lost parts, but a spontaneous division of the disk itself, with regeneration of the necessary portions, several times repeated up to a certain age, for the multiplication of the individual. While this may sometimes be a simple division, in many it is the normal mode of multiplication instead of gemmation. This form of agamic multiplication in ophiuroids and asterioids has been called schizogeny. On the upper surface, to one side of the centre and between two of the arms, is a round bright-colored spot, the madreporic plate or body, communicating with a canal leading to the water vessel around the mouth—a supposed filter for water passing into the aquiferous system and through the body. They propagate usually by eggs, and the sexes are in separate individuals; the larvæ are at first oval, ciliated bodies, from which the radiated perfect animal is developed, at various stages of its growth, by a process of internal gemmation. The crinoid *comatula*, or feather star, free when adult, has its young attached on a long slender stem; Sars has traced the growth of *echinaster* from a spheroidal free-moving mass to the perfect star fish. Some species secrete a reddish fluid on the surface, probably the coloring matter, often irritating to the skin of persons handling them; according to Deslongchamps, they can inject a fluid into the shells of their victims, which stupefies and renders them an easy prey. Rymer Jones says star fishes may be considered as mere walking stomachs, their office in the economy of nature being to

devour all kinds of garbage which would otherwise accumulate on the shores; they eat also living crustaceans, mollusks, and even small fish, and are believed to be very destructive to oysters; they are not used as food by man, but are in many places highly esteemed as manure.—For a popular account of the British species, see "History of British Starfishes," by Edward Forbes (London, 1841). For the New England species, see the recently published works of Agassiz. The common star fish of the North American coast (*asterias rubens*, Lam.), generally considered the same as the European species, is too well known to need description; the colors vary from reddish to yellowish, and the diameter from an

Common Star Fish (Asterias rubens).

inch to more than a foot.—The star fishes are found from the Trenton limestone of the lower Silurian epoch down to the present time.

**STARGARD. I.** A town of Prussia, in the province of Pomerania, on the Ihna, navigable by ships, 21 m. E. by S. of Stettin; pop. in 1871, 17,280. It has a Protestant Gothic church, built in the 14th century. It was formerly the capital of Further Pomerania. **II. Preussisch Stargard,** a town in the province of Prussia, on the Ferse, 25 m. S. by W. of Dantzic; pop. in 1871, 5,822. It is surrounded by walls and towers, and was frequently taken by the Poles in the 15th and 16th centuries, and in 1655 by the Swedes.

**STARGAZER,** a spiny-rayed percoid fish of the family *trachinidæ* or weevers, and genus *uranoscopus* (Linn.), so called from the position of the eyes, which look directly upward. The body is elongated, covered with smooth cycloid scales; head depressed, large and wide, bony and rough, with the gape ascending or vertically cleft, the upper jaw the shorter, and the teeth small and crowded on the jaws, palate, and vomer; branchiostegal rays six; dorsals two, of which the first is small and spinous, the second and the anal long; ventrals in front of the large pectorals and on the throat; anus very far forward; air bladder absent. In some of the family the dorsal and opercular spines are capable of inflicting painful wounds; they

Mediterranean Stargazer (Uranoscopus vulgaris).

have the power of raising the eyeballs from and retracting them within their sockets. There are more than a dozen species of the genus, mostly East Indian, of which the best known is the *U. vulgaris* of the Mediterranean, about a foot long, grayish brown above, with irregular series of whitish spots and grayish white below; ugly as it is, some people eat it. This was well known to the ancients, and Aristotle correctly describes the gall bladder as larger than in most other fishes; it is also called *callionymus* by the old authors, and is proverbially referred to by dramatic writers as the emblem of an angry man. On the coast of South Carolina has been found the *U. anoplos* (Cuv.), about 2 in. long, greenish above with minute black dots, and silvery below; the cheeks are unarmed. These fishes live on the bottom in deep water, burying all but the head in the sand or mud, and there lying in wait for prey; they are voracious, and like other ground fish some have sensitive barbels about the mouth; though the gills are widely open, they live a long time out of water; some have a slender fleshy filament in front of the tongue, which can be protruded.

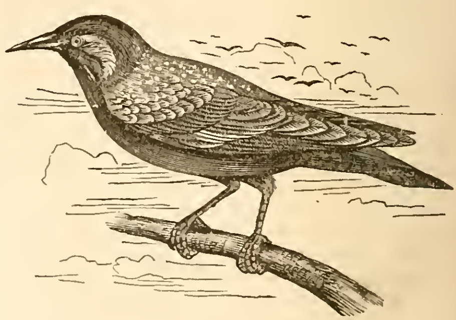
**STARK. I.** A N. E. county of Ohio, drained by the Tuscarawas river and its branches, and traversed by the Ohio canal and several railroads; area, 570 sq. m.; pop. in 1870, 52,508. The surface is undulating and the soil a rich sandy loam. Coal and limestone are abundant. The chief productions in 1873 were 686,418 bushels of wheat, 1,044,317 of Indian corn, 732,897 of oats, 42,376 of barley, 116,597 of potatoes, 44,507 tons of hay, 287,750 lbs. of flax, 246,893 of wool, 932,779 of butter, and 88,705 of cheese. Large quantities of coal and iron are produced. In 1874 there were 13,595 horses, 29,219 cattle, 69,387 sheep, and 25,421 hogs. In 1870 there were 22 manufactories of agricultural implements, 12 of brick, 22 of carriages and wagons, 12 of furniture, 1 of forged and rolled iron, 3 of pig iron, 20 of iron cast-

ings, 18 of tanned and 7 of curried leather, 4 of engines and boilers, 21 of tin, copper, and sheet-iron ware, 5 of woollen goods, 11 breweries, 19 flour mills, 30 saw mills, and 3 planing mills. Capital, Canton. **II.** A N. W. county of Illinois, intersected by Spoon river; area, about 325 sq. m.; pop. in 1870, 10,751. The surface is partly prairie, and the soil is fertile. It is traversed by the Peoria and Rock Island railroad and a branch of the Chicago, Burlington, and Quincy. The chief productions in 1870 were 124,639 bushels of wheat, 30,534 of rye, 1,149,878 of Indian corn, 316,726 of oats, 19,993 tons of hay, 20,789 lbs. of wool, 295,683 of butter, and 17,674 of honey. There were 7,080 horses, 11,558 cattle, 4,226 sheep, and 26,515 swine; 7 manufactories of carriages and wagons, 1 of woollen goods, and 6 flour mills. Capital, Toulon.

**STARK, John,** an American soldier, born at Londonderry, N. H., Aug. 28, 1728, died at Manchester, N. H., May 8, 1822. In 1752, while on a hunting expedition, he was captured by the St. Francis Indians, and remained with them several weeks until ransomed. In 1754 he joined the rangers under Major Rogers in the war against the French and Indians, and in 1757 was made a captain. He rendered efficient services in bringing off the troops after the expedition to Ticonderoga in 1758, and was actively employed in the subsequent campaign. In 1775, after the battle of Lexington, he received a colonel's commission, and enlisted a regiment which formed the left of the American line at Bunker Hill. He was in the expedition against Canada, and remonstrated against Gen. Schuyler's retreat to Ticonderoga. In December, 1776, he marched with his regiment under Gen. Gates to reënforce Gen. Washington. He led the van in the attack upon Trenton, and was in the battle at Princeton. In 1777, the time of his regiment having expired, he returned to New Hampshire and raised a new one; but considering himself unjustly neglected by congress in the list of promotions, he retired from its service. He received a vote of thanks from the New Hampshire legislature, and was placed in command of the troops raised there to oppose the British advance from Canada. Acting upon the authority of the state and his own judgment, he refused to obey the orders of Gen. Lincoln to march to the west of the Hudson, leaving Burgoyne's rear unmolested; and on Aug. 16, 1777, he fought the battle of Bennington, for which congress passed a vote of thanks to him and made him a brigadier general, notwithstanding they had just before censured him for his disobedience of the orders of Gen. Lincoln. He joined Gen. Gates at Bemis's heights, but the term of his militia having expired, he returned to New Hampshire and recruited a new force, with which he cut off Burgoyne's retreat from Saratoga. In 1778 he was placed in command of the northern department; in 1779 and 1780 he served in Rhode Island and New Jersey, and at West Point, and was a member of the court martial which condemned André; and in 1781 he again had command of the northern department, with his headquarters at Saratoga. He lived in retirement after the war, of which he was the last surviving general except Sumter.—See "Life of John Stark," by Edward Everett, in Sparks's "American Biography," 1st series, vol. i., and "Memoirs and Official Correspondence of General John Stark," by Caleb Stark (8vo, Concord, 1860).

**STARKE,** a N. W. county of Indiana, drained by the Yellow and Kankakee rivers, and traversed by several railroads; area, 432 sq. m.; pop. in 1870, 3,888. The surface is level and in many places marshy, with several small lakes, and the soil is fertile. The chief productions in 1870 were 12,449 bushels of wheat, 4,516 of rye, 26,104 of Indian corn, and 4,436 lbs. of wool. There were 1,017 milch cows, 2,403 other cattle, 1,482 sheep, and 2,187 Swine. Capital, Knox.

**STARLING,** or **Stare,** the common name of the conirostral birds of the family *sturnidæ*, and subfamily *sturninæ*, of which the genus *sturnus* (Linn.) is the type; the family also includes the straight-billed birds like the grakles, oxpecker, Baltimore bird, red-winged blackbird, and satin bower bird, separately described. In *sturnus* the bill is long, straight, and sharp, with flattened culmen and tip; wings long and pointed, first quill spurious and second and third nearly equal; tail short and nearly even; tarsi strong and broadly scaled; toes long, including the hind one, the outer united at the base; claws long, curved, and sharp. In habits the starlings resemble the smaller species of the crow family, and the food consists of worms, snails, insects, seeds, and fruits; they are docile in captivity, and may be taught to repeat a few words and to whistle short tunes. They are confined to the old world, migrating in large flocks, preferring swampy places; the flight is rapid and even, accompanied toward

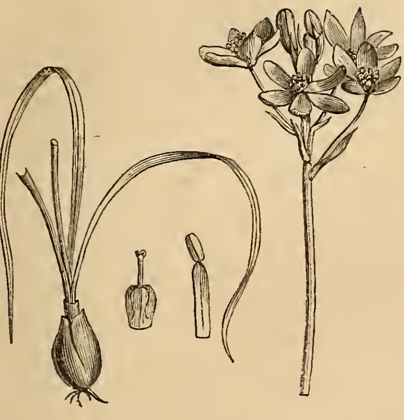


Common Starling (Sturnus vulgaris).

evening by singular circular evolutions; the note is a shrill whistle, with an occasional chatter or imitation of the cry of other birds and of animals; the nest is made of dried grass,

in holes of trees or old buildings, and the eggs are four to six. The best known species is the common starling (*S. vulgaris*, Linn.), about 8 in. long, black, with purple and greenish reflections, and spotted with buff; the female is much less brilliant, and the young males are brownish gray. This bird is found from N. Europe to S. Africa, and in E. Asia, occurring in as large flocks as the allied grakles (*quiscalus*) in North America; in England it often migrates south in October, returning in March; it is frequently kept in cages; the eggs are pale blue.—The American starling (*sturnella magna*, Swains.) has been described under MEADOW LARK. In the genus *pastor* (Temm.) the bill is shorter and more curved; it contains about a dozen species in the old world.

**STAR OF BETHLEHEM,** a name for the plant *ornithogalum umbellatum*, which is also called "eleven-o'clock-lady" (Fr. *dame d'onze heures*), as its flowers open about 11 o'clock; and as they close at 3 o'clock in the afternoon, it is in



Star of Bethlehem (Ornithogalum umbellatum).

some localities known as "Johnny-go-to-bed." It belongs to the lily family, and has a small bulb, from which arise narrow, grass-like leaves, with a white line in the middle, and a scape 6 to 8 in. high, bearing a corymb of a few bright white flowers, consisting of six sepals, which are green in the middle on the outside. A native of southern and central Europe, this was formerly a common garden plant, and has escaped and become naturalized in the older states. The genus *ornithogalum* (Gr. ὄρνις, a bird, and γάλα, milk, a whimsical name) includes several larger and more showy species, cultivated as hardy garden bulbs.

**STARR,** a S. county of Texas, bounded S. W. by the Rio Grande, which separates it from Mexico; area, 2,100 sq. m.; pop. in 1870, 4,154, including 18 colored persons and many Mexicans. There is considerable rich land in the valley of the Rio Grande, producing corn, sugar cane, &c. The rest of the county suffers from lack of water, and is suitable only for stock raising, which is the principal occupation. There are large herds of horses, mules, sheep, and cattle. Capital, Rio Grande City.

**STARVATION.** See ABSTINENCE.

**STASSFURT,** a town of Prussia, in the province of Saxony, on the Bode, 20 m. S. S. W. of Magdeburg; pop. in 1871, 10,327. It has one of the largest salt mines in the world, discovered about 1837, and worked with steam engines since 1856, and extensive manufactories of chemicals. The salt works have been described by Bischof (Halle, 1864), and by Rheinwarth (Dresden, 1871).

**STATEN ISLAND,** an island of New York, constituting with several adjacent islets the county of Richmond, 5 m. S. W. of New York city, from which it is separated by New York bay; length N. E. and S. W. 13 m., greatest breadth 8 m.; area, 58½ sq. m.; pop. in 1870, 33,029; in 1875, 35,241. It is separated from Long Island on the northeast by the Narrows, from New Jersey on the west by Staten Island sound, about ⅓ m. wide, and from the same state on the north by Newark bay and the Kill Von Kull, and is bounded S. E. and S. by the lower bay and Raritan bay. It is divided into five towns, viz.: Castleton, Middletown, Northfield, Southfield, and Westfield. New Brighton (pop. 7,495 in 1870), Port Richmond (3,028), and Tottenville (1,571) are incorporated villages. The surface is mostly level or gently undulating. A broad range of hills, reaching a maximum height of 310 ft., extends E. and W. across the N. portion. Iron ore is found. The island is the residence of a large number of persons engaged in business in New York, with which city it is connected by steam ferries. The Staten Island railroad extends from Clifton at the N. E. to Tottenville at the S. W. extremity. Fort Tompkins and Fort Wadsworth, with several batteries, command the Narrows. The New York quarantine establishment is situated on artificial islands off the E. shore. Staten Island is the seat of the "Sailors' Snug Harbor," a retreat for superannuated seamen, and of a hospital for seamen and an asylum for destitute, sick, and infirm families of seamen, supported by the "Seamen's Fund and Retreat." (See RICHMOND, vol. xiv., p. 319.)

**STATES GENERAL. I.** An assembly of the nation which existed in France previous to the revolution, and consisted of the representatives of the clergy, the nobility, and the third estate (*tiers état*). Before the reign of Philip the Fair, the people or unprivileged class had no voice in the general administration of the kingdom; but that monarch, being involved in his great struggle with the papacy, and desirous to have the whole nation on his side, determined to convene an assembly in which, in addition to the clergy and nobility, the principal inhabitants of the towns, or *bourgeoisie*, forming a third estate, should be represented. The mass of the people, however, never had a voice in these assemblies. The three orders forming the states general

met in Paris in 1302, and by their support induced the king to reassemble them in 1303 and again in 1308, when they voted for the condemnation of the knights templars. The example of Philip was imitated by his successors. During the wars with Edward III. of England the states general acted with such authority in the affairs of the revenue as to make the court dependent on their decisions. The disasters which befell the nobility at Crécy and Poitiers enabled the third estate to play an unusual part at this time. The people of Paris acquired an undue influence, while the provinces were imperfectly represented. In 1357 an ordinance of the dauphin Charles left the raising and disposition of the revenues to the states general, and declared the members inviolable. During the next 80 years they met frequently; but in 1439, by voting a fixed sum for the support of a standing army, they removed one of the principal reasons for their convocation. Henceforward they met at long intervals. A resolution to meet biennially, passed on the accession of Charles VIII. and approved by the court, remained without effect; and finally the kings came to feel that they could rule without the nation. The last meeting before the revolution, that of 1614–'15, was marked by disputes between the orders, in which the third estate was humiliated. In all, the body had assembled about 35 times in three centuries. In place of the states general the kings at times convened an assembly of the notables, or prominent men of all ranks, who, being nominated by the sovereign or the privy council, more readily complied with the royal demands. The notables assembled in 1626 for the last time previous to the reign of Louis XVI., when they were again convoked in 1787 and 1788. These assemblies having shown their inefficiency, the disorders of the kingdom induced Louis XVI. to revive the states general; and on May 5, 1789, their sessions were opened at Versailles. Under the old kings the states general were the only assembly in France which may be said in a measure to have formed a national legislature. Their sessions, however, were very brief, occasionally lasting only a few days, and they were generally called together to vote subsidies or deliberate on the measures of the court, not to devise laws for the state, though they were expected to present their lists of grievances (*cahiers de doléance*) to the sovereign. The assembly voted by orders, which made it easy for the clergy and nobles to thwart the measures of the third estate. Against this division the third estate rose in 1789. They insisted on a vote by members, and carried through their demand by constituting themselves the national assembly. (See CONSTITUTIONAL CONVENTION, and FRANCE, vol. vii., p. 385.)—Several of the provinces not originally included in the French crown, as Brittany, Burgundy, Navarre, Languedoc, and others, possessed special assemblies called *états provinciaux*, to whose approval the demands of the sovereign were submitted. The third estate early obtained a place in these bodies, and in the states of Languedoc they had a vote equal to that of the other orders combined. These assemblies gradually lost their importance, and disappeared with the revolution. **II.** The national assembly of the Dutch republic, consisting of the deputies of the provinces, who were chosen by the provincial assemblies or states. The deputies of each province had one collective vote. The term continues to be the official designation of the Dutch legislature.

**STATICS.** See MECHANICS.

**STATISTICS**, the systematic collection and classification of facts relating to the social and industrial conditions of the people. One of the first to systematize statistics and give to them a scientific character was Gottfried Achenwall, who lectured on that subject in the university of Göttingen about the middle of the 18th century, and gave the name (Ger. *Staat*, state) to the science. A. L. von Schlözer (died 1809), a pupil of Achenwall, developed the science more fully. During the present century marked progress has been made in statistical science. The chief countries of Europe have organized statistical bureaus, departments, or commissions, which collect and publish periodically facts relating to the condition of the people in every phase of life. France, Belgium, Sweden, Prussia, and Italy rank specially high in this respect. In London, Paris, and other European cities are statistical societies which publish periodicals. In 1862 a statistical seminary, for affording instruction in the theory and practice of the science, was established in Berlin, through the efforts of Dr. Engel, and a professorship of statistics was established in the university of that city in 1874. In England statistical reports on the various interests of the United Kingdom are published annually by parliament. In the United States statistics of commerce and navigation are published monthly and annually by the bureau of statistics; those relating to education are published annually by the commissioner of education, and those relating to agriculture by the bureau of agriculture.—Great importance is attached in all countries to the thorough and frequent collection of vital statistics, which are of the highest value in determining questions of health, duration of life, movement of population, &c. As early as 1686 the clergy in Sweden were required to keep registers of marriages, births, and deaths. In most if not all of the countries of Europe these statistics are carefully collected and published periodically. In England they are under the charge of the registrar general, who publishes an annual report. No provision has been made by the United States for the collection of vital statistics except when the decennial censuses are taken. In many of the states, however, records of births, marriages, and deaths are required

to be kept and published at intervals.—The first international statistical congress met in Brussels in 1853; sessions have since been held at Paris, 1855; Vienna, 1857; London, 1860; Berlin, 1863; Florence, 1867; the Hague, 1869; and St. Petersburg, 1872. (See CENSUS.)

**STATIUS, Cæcilius.** See CÆCILIUS STATIUS.

**STATIUS, Publius Papinius**, a Roman poet, born probably in A. D. 61, died probably in 96. His father was a preceptor of the emperor Domitian, by whom the son was patronized. In the Alban contests he three times gained the victory. It has been said that he was a Christian, and that the emperor stabbed him with a *stilus* in a moment of anger. Some details about his life and character have been compiled by Occioni (Padua, 1869). His extant works are: *Silvarum Libri V.*, a collection of 32 poems on passing events, divided into five books; *Thebaidos Libri XII.*, an epic founded upon the legendary account of the expedition of the seven against Thebes, of which the first book was translated into English by Pope; and *Achilleidos Libri II.*, an epic never finished. The best edition is Markland's (1728), revised by Queck (1854). A new critical edition has been published by O. Müller (1870). Five books of the "Thebaid" have been translated into English by Thomas Stephens (8vo, London, 1648), and the entire poem by W. L. Lewis (2 vols. 8vo, Oxford, 1767 and 1773). The "Achilleid" has been translated by Howard (8vo, London, 1660). There is a German translation by Bindewald (1868).

**STATUARY.** See SCULPTURE.

**STATUTE OF FRAUDS.** See FRAUDS, STATUTE OF.

**STATUTES OF LIMITATION.** See LIMITATION, STATUTES OF.

**STAUDENMAIER, Franz Anton**, a German theologian, born at Danzdorf, Würtemberg, Sept. 11, 1800, died in Freiburg, Baden, Jan. 19, 1856. He studied at Tübingen, was ordained a Roman Catholic priest in 1827, became professor of theology at Giessen in 1830 and at Freiburg in 1837, and a canon in 1843, and in 1851 was elected a member of the first chamber of the legislature of Baden. His chief works are: *Geschichte der Bischofswahlen* (Tübingen, 1830); *Encyklopädie der theologischen Wissenschaften* (Mentz, 1834; 2d ed., 1840); *Der Geist des Christenthums* (Mentz, 1835), many times reprinted and translated; and *Die christliche Dogmatik* (4 vols., 1844–'52, not complete), in which he attempts to harmonize the results of modern philosophy with the doctrines of the Catholic church. His other works include *Scotus Erigena und die Wissenschaft seiner Zeit* (vol. i., Frankfort, 1840, unfinished); *Die Philosophie des Christenthums* (vol. i., Mentz, 1840, unfinished); *Darstellung und Kritik des Hegel'schen Systems* (Mentz, 1844); and *Der Protestantismus in seinem Wesen und seiner Entwickelung* (Freiburg, 1846).

**STÄUDLIN, Karl Friedrich**, a German theologian, born in Stuttgart, July 25, 1761, died in Göttingen, July 5, 1826. He studied at Tübingen, and in 1790 became professor of theology at Göttingen. At first he was a rationalist, but he gradually inclined to supernaturalism. His works extend over nearly every department of theology; but those on church history are the most valued, and include *Kirchliche Geographie und Statistik* (2 vols., Tübingen, 1804), the first scientific work on this subject, and *Geschichte der theologischen Wissenschaften* (2 vols., Göttingen, 1810–'11).

**STAUNTON**, a river in the S. part of Virginia, which rises in Montgomery co., among the Alleghany mountains, flows E. and S. E. through a pass in the Blue Ridge, and with Dan river forms the Roanoke at Clarksville, Mecklenburg co. It is 200 m. long, and in the first 20 m. of its course has a fall of 1,000 ft.

**STAUNTON**, a city, county seat of Augusta co., Virginia, on Lewis creek, a tributary of the Shenandoah river, and on the Chesapeake and Ohio railroad at the junction of a branch of the Baltimore and Ohio line, 100 m. direct and 136 m. by rail W. N. W. of Richmond; pop. in 1870, 5,120, of whom 1,535 were colored; in 1875, about 7,000. It is surrounded by a highly productive country, abounding in fine scenery. Stages run to Weyer's and Madison's caves, 18 m., and to the Augusta springs, 12 m. distant. It is the seat of the western state lunatic asylum and of the state institution for the education of the deaf and dumb and the blind, each having fine buildings and grounds. The principal manufactories are two iron founderies, two tobacco factories, and two flour mills. There are three banks, with a capital of $500,000; free public schools, with an attendance of more than 600 white and 300 colored children; a Roman Catholic seminary; Lutheran, Methodist, and Presbyterian female seminaries, having more than 600 pupils; three weekly newspapers; and nine churches, viz.: 2 Baptist (1 colored), 1 Episcopal, 1 Lutheran, 3 Methodist (2 colored), 1 Presbyterian, and 1 Roman Catholic.

**STAUNTON, Sir George Thomas**, an English author, born in Salisbury, May 26, 1781, died in London, Aug. 10, 1859. He was the son of Sir George Leonard Staunton (1737–1801), confidential secretary of Lord Macartney at Madras, and a member of his embassy to China, of which he wrote an account (2 vols. 4to, 1797). George Thomas accompanied his father to China in 1792, afterward studied at Cambridge, and in 1799 went to Canton as secretary of the East India company's factory there, of which he afterward became president. In 1816 he was attached to Lord Amherst's embassy to China, and from 1818 to 1852, with a few intermissions, was a member of parliament. His principal works are: "The Penal Code of the Chinese Empire" (4to, London, 1810); "Narrative of the Chinese Embassy to the Tartar Khan Tourgouth during the Years 1812–'15" (1821); and "Miscellaneous Notices relative to China and the British Commercial Intercourse with that Country" (1822).

**STAUNTON, Howard,** an English author, born in 1810, died in London, June 26, 1874. He was educated at Oxford, but left without taking a degree, and went to London. In 1843 he won a match in Paris over St. Amand, the chess champion, and subsequently conducted the chess column in the "Illustrated London News," and published "The Chess Player's Hand Book" (London, 1847; with supplement, "Chess Praxis," 1860); "Chess Player's Companion" and "Chess Player's Text Book" (1849); and "Chess Tournament" (1852). From 1857 to 1860 he was engaged in editing an edition of Shakespeare; in 1864 he brought out a facsimile of the folio of 1623, and published "Memorials of Shakespeare;" and in 1872 he contributed to the "Athenæum" a series of papers on the "Unsuspected Corruptions of Shakespeare's Text." He also wrote "Great Schools of England" (8vo, 1865).

**STAUPITZ, Johann von,** a German theologian, born in Meissen, died in Salzburg, Dec. 28, 1524. He was an Augustinian monk, obtained from the pope in 1501 general privileges for the newly established university at Wittenberg, of which he was made dean on its opening in 1502, and in 1508 caused Luther to become a professor there. He approved of the theses of Luther against papal indulgences, but not publicly. In 1518 he demanded at Augsburg that Luther should not be condemned unheard and untried. He became court preacher at Salzburg, and in 1522 abbot of a Benedictine convent. He is the author of *De Amore Dei* (Leipsic, 1518), and several other writings of a mystical character.

**STAVANGER,** a town of Norway, capital of a district of the same name, in the province of Christiansand, on the Bukkefiord, 100 m. S. of Bergen; pop. in 1870, 17,058. It has three suburbs, a cathedral dating from the 11th century, a good harbor, about 500 registered vessels, and extensive fisheries. The population in 1801 was barely 2,500.

**STAVROPOL. I.** A government of Russia, in Ciscaucasia, bounded N. by the country of the Don Cossacks and Astrakhan, E. and S. by the Terek territory, and W. by the Kuban territory; area, 26,634 sq. m.; pop. in 1871, 437,118, embracing Russians, Cossacks, Nogai Tartars, Calmucks, Turkomans, Armenians, and others. The government is mostly level and unproductive, contains a number of shallow lakes and swamps, and is watered by the Kuma, Kalauz, and other rivers. **II.** A town, capital of the government, on the Atchla, 185 m. S. E. of Azov; pop. in 1871, 20,927. It is strongly fortified, has several churches and schools, a fine bazaar, manufactories of soap and leather, and an increasing trade with the Asiatic provinces of the empire. The neighboring warm sulphur springs are much frequented.

**STEAM,** the vapor of water. Water, and even ice, at all temperatures, when not confined within impermeable walls, continually give off vapor, the surface particles assuming the gaseous state with a rapidity determined by the temperature of the mass and the nature and density of the superincumbent atmosphere. When confined, this gasification goes on without regard to the character or density of the atmosphere present until the vapor produced, by gradual accumulation, acquires the maximum density and pressure attainable at that temperature; then the formation of vapor ceases. The minimum temperature at which the substance can exist as vapor under a given pressure, and the maximum at which the water can retain its liquid form under that pressure, are the same. This temperature is called the temperature of saturation under the given pressure. When the process just described is carried on in a vessel open to the atmosphere, the issuing vapor mingles with the molecules of that atmosphere as rapidly as formed, and separates only at the surface, until the boiling point is reached, at which temperature the pressure of the vapor becomes equal to that of the atmosphere; the formation of vapor (heat being supplied in sufficient quantity) becomes rapid, and takes place within the mass as well as at the surface; ebullition or boiling begins, the atmosphere is forced aside, and the ascending steam passes off *en masse.* (See Boiling Point.) The temperature of the boiling point varies with the tension of the atmosphere. Its mean temperature in open air at the sea level is 212° F., 100° on the centigrade scale, 80° on the Réaumur scale, and 673·2° on the absolute scale. The temperature of both water and steam in a steam boiler is the boiling point due to the pressure of steam carried. A table of such temperatures and pressures is given below. Superheated steam is that which has a temperature higher than that of saturation at the same pressure. If equal quantities of heat be supplied in equal times, an interval will elapse after the temperature has risen to the boiling point before the water will have become vaporized, which interval will be about 5¼ times that required to heat the liquid from the freezing to the boiling point. Careful experiment has shown that, in the transition from the liquid to the gaseous condition, 5¼ times as much heat is required as to heat the same weight of water from 32° to 212°. The exact ratio is as 180·5 to 966·1; it being necessary to supply 180·5 units of heat to each pound of water to raise it in temperature from the freezing to the boiling point, and 966·1 British thermal units to change it into steam. As no rise of temperature was perceived during this last change of state, this heat was called by Dr. Black latent heat, which name is still retained, although it is now well known that it is this heat which performs the work of vaporization. The quantity of heat required to change water at the boiling point to steam at the same temperature varies with the pressure. Under atmospheric pressure, Dr. Black and James Watt found its amount approximately, and Regnault, who discovered its variation with change of

pressure, determined it with great accuracy for a wide range of temperatures and pressures. At 212° it is 966·1 British thermal units per pound. At any other temperature it is $1091 \cdot 7 - 0 \cdot 695(T° - 32°) - 0 \cdot 000000103(T - 39 \cdot 1°)^3$(Rankine), or nearly 1113·94—0·695 T. The total amount of heat required to raise one pound of water from any given temperature to the temperature of evaporation, and to evaporate it at the latter temperature, or the total heat of evaporation, is often called the total heat of steam. This varies at different temperatures, and is equal to $1091 \cdot 7 + 0 \cdot 305 (T - 32°) - c_2(T_2 - 32°)$, or 1081·94+0·305 T, from 32°. It is nearly 1113·94+0·305 T where the initial temperature is hypothetically 0°. In these expressions, T is the temperature of vaporization, $c_2$ the mean specific heat of water between the freezing point and the temperature of the feed water, and $T_2$ the latter temperature. Reckoning from 212°, the values of latent and total heat become $l = 966 \cdot 1 - 0 \cdot 695(T - 212°)$, and with a given temperature $t$ of feed water, $h' = 1178 \cdot 6 - t + 0 \cdot 305(T - 212°)$, the total heat in the latter case being measured from the initial temperature of the feed water $t$ to that of the steam forming at T° F. For the centigrade scale, these values become $l = 606 \cdot 5 - 0 \cdot 695$ T°, and $h' = 606 \cdot 5 - t + 0 \cdot 305$ (T°—100°). The total heat of steam, expressed in foot pounds of energy, is H=835,000+235·5T. A pound of good coal, used under a good steam boiler, will evaporate 8½ lbs. of water at a temperature of 320° F., and a pressure of 75 lbs. per square inch above the atmosphere, the temperature of the water when entering the boiler being 40°. Here the total heat per pound of water is (1178·6—40)+0·305(320—212)= 1171·54; the heat per pound of fuel is 1171·54 ×8·5=9958·1; and the equivalent evaporation from and at 212° is 9958·1÷966·1=10·31 lbs. of water per pound of coal. The specific heat of steam under constant pressure is 0·480. At constant volume it is 0·365; *i. e.*, the quantity of heat per pound required to raise the temperature of steam, where its expansion is just sufficient to keep its pressure constant, is 0·480 British thermal units; and, when confined within an unchanging space, its pressure rising with its increase of temperature, the heat required per degree is 0·365 units. The thermal unit is the quantity of heat required to raise the temperature of one pound of water one degree at the temperature of maximum density. The value at other temperatures is practically the same.—Steam, when perfectly free from particles of water, is dry, invisible, and in its physical properties similar to other gases. Its density (air=1) is 0·622. In changing in temperature one degree under constant pressure, it absorbs heat equal to 85·77 foot pounds of work. The work of the evaporation of a cubic inch of water at 212° is nearly equal to that of raising a ton one foot. Its coefficient of expansion becomes equal to that of perfect gases at about 18° above the temperature due to its pressure, according to Fairbairn and Tate. Steam expanding while doing work, as in the steam cylinder of an engine, becomes partially condensed. When expanding without doing work it superheats, the difference of total heats at the temperatures of the extremes of pressure becoming observable as sensible heat in the production of this superheating. The elastic force of saturated steam being dependent only upon its temperature, the relation may be expressed by a mathematical formula. Many such formulas have been proposed, none of which are exact. The simplest is Tredgold's, $t = 175\sqrt[6]{A} - 75$, in which $t$ is the temperature F. and A the number of atmospheres of pressure. This is correct, within two degrees, from one up to above 25 atmospheres of pressure, and is much more nearly accurate at the extremes of that range. In Southern's formula, which has been much used by engineers, $P = \left(\frac{t + 51 \cdot 3}{135 \cdot 767}\right)^{5 \cdot 15} + 0 \cdot 1$, in which P is the pressure in inches of mercury. These formulas are now seldom employed, as every work upon this subject contains a table of pressures, temperatures, and volumes. Where great accuracy is required, and no table is at hand, Rankine's formulas, $\log. P = A - \frac{B}{\tau} - \frac{C}{\tau^2}$, and $\frac{1}{\tau} = \sqrt{\frac{A - \log. P}{C} + \frac{B^2}{4C^2}} - \frac{B}{2C}$, may be used. In these formulas, P is the pressure, $t$ absolute temperature (461·2+T° F.), and A, B, and C are constants: A=8·259; log. B=3·436; log. C=5·599; $\frac{B}{2C} = 0 \cdot 00344$; $\frac{B^2}{4C^2} = 0 \cdot 00001184$. The pressure increases with the temperature at a rate which itself also rapidly increases with rise of temperature. The relative volumes of steam and water can be calculated by Pole's formulas: $V = \frac{24250}{P} + 65$; $P = \frac{24250}{V - 65}$; and still more accurately by those of Fairbairn and Tate: $V = 25 \cdot 62 + \frac{49513}{P + 0 \cdot 72}$; $P = \frac{49513}{V - 25 \cdot 62} - 0 \cdot 72$. The relative volume or density of steam under varying pressure can be computed by the use of Rankine's formula, $\frac{V}{V'} = \left(\frac{P'}{P}\right)^{\frac{16}{17}}$, in which V and P are the volumes in cubic feet, and the pressure reckoned above a vacuum, in pounds per square inch, of one pound of steam at the given pressure, and V′ is the volume (26·36 cubic feet) of one pound of steam at P′, the atmospheric pressure. A cubic inch of water makes about a cubic foot of dry steam. Steam expanding in the cylinder of a steam engine does not follow the law of expansion of permanent gases, nor does the variation of the ratio of pressure to volume follow any law which has yet been exactly expressed mathematically. Rankine considers that pressure varies inversely as the $\frac{10}{9}$ power of the volume, where the steam neither gains nor loses heat, and as the reciprocal of the $\frac{11}{10}$ power where kept dry by a steam jacket. More exactly,

$PaV^{-1.0646}$, and log. $V = 2.516 - 0.939$ log. P. In the following table constant multipliers are given, the product of which into the initial pressure will give the mean or the terminal pressure for the grade of expansion selected:

MEAN AND TERMINAL PRESSURES (SALTER).

| POINT OF CUT-OFF. | CONSTANT. | | DRY AND SATURATED. | | CONDENSING BY WORKING. | |
|---|---|---|---|---|---|---|

—A mixture of steam and other gas has a tension which is equal to the sum of the tensions of the two components. Thus, if a cubic foot of air at atmospheric pressure be enclosed in a vessel of that capacity, and if a cubic foot of steam of the same tension be introduced with it, the pressure upon the walls of the vessel will be two atmospheres, the temperature of both gases being the same. Steam formed from sea water is liberated at a higher temperature than when formed from pure water. The boiling point of water is raised about 0·04° F. for each increment of 1 per cent. of its own weight of salt. Sea water, containing $\frac{1}{32}$ of its weight of salt, boils at 213·2° under atmospheric pressure. The maximum proportion of salt permitted in marine steam boilers is usually $\frac{2}{32}$, the boiling point being raised 2·4° F. Steam, as worked in the steam engine, if not dried by superheaters, is wet; *i. e.*, it carries in suspension fine particles of water. The amount of water so suspended has been found by Prof. Thurston to be from 0·03 to 0·20 of the weight of the mixture. Ten per cent. is a usual proportion with good boilers. The amount was determined by condensing in a calorimeter a determinable weight of the mixture, by the use of a known weight of water, and noting the rise in temperature of the latter. Knowing the temperature due to the steam pressure, the weights of steam and water can be determined. The principal advantage of superheating is an increase of economy due to the thorough expulsion of water from the vapor, and consequent reduction of loss by condensation and revaporization in the steam engine cylinder. A less degree of improvement is due to the simple increase of temperature, and to the consequent widening of the range of temperature within which it is worked. The most elaborate and most accurate experimental determination of the coincident temperatures, pressures, and volumes of saturated steam were made by Regnault, at the expense of the French government, and under the auspices of the academy of sciences, and published in the *Mémoires de l'académie* for 1847. The following table gives a summary of the properties of steam based upon Regnault's determinations. Pressures are given in pounds per square inch above a vacuum, and in inches of mercury measuring from the same point. Volumes are relative to water at its greatest density. Weights are given in pounds, and specific gravity is referred to air as unity at a temperature of 32° F. The distribution of heat in each pound of steam evaporated at 212° F. is given as follows:

| | Units of heat. | Mechanical equivalent, in foot pounds. |
|---|---|---|
| A. The sensible heat: | | |
| 1. To heat the water from 32°, or through 180° .................... | 180·9° = | 139,655 |
| B. The latent heat: | | |
| 2. To convert the water to vapor, irrespective of pressure on surface | 892·9° = | 689,242 |
| 3. To advance against and remove the incumbent atmosphere, whether air or previously generated steam, its pressure being 2,116·8 lbs. per square foot of surface.... | 72·3° = | 55,815 |
| Total latent heat.................. | 965·2° = | 745,057 |
| Total heat of steam............... | 1,146·1° = | 884,712 |

It is evident that the total latent heat of steam cannot be taken as in any way the measure of the energy or work in, or that can practically be obtained from, the steam. Much the larger part of such heat is expended in merely overcoming the cohesion of the liquid; and at all temperatures but a small fraction of the latent heat can be made available in performing work. Of the total, seven tenths is lost through the existence of natural conditions over which man can probably never expect to obtain control, two tenths through imperfections of mechanism, and but one tenth is utilized in even good engines.

PROPERTIES OF SATURATED STEAM.

| PRESSURE. Lbs. per sq. in. | PRESSURE. Inches of mercury. | Temperature in degrees. | Latent heat in degrees. | Total heat in degrees from zero. | Relative volume. | Weight of 1 cubic foot. | Specific gravity. |

V. Regnault* (Paris); and Porter, "Steam Engine Indicator," containing a valuable steam table (New York, 1875).

**STEAM BOILER.** The use of steam boilers dates from antiquity. Hero, who lived in the 3d century before the Christian era, described several forms of boilers which were used in generating steam for what seem to have been a variety of philosophical toys, one of which is generally referred to as the earliest known example of the steam engine. When steam began to be usefully applied, and considerable pressures became necessary, the forms given to boilers were approximately spherical, ellipsoidal, or cylindrical. Thus the boilers of De Caus (1615) and of the marquis of Worcester (1663) were spherical; those of Savery (1698) were ellipsoidal and cylindrical. After the invention of the steam engine of Newcomen, the pressures adopted were again very low, and steam boilers received irregular forms until, at the beginning of the present century, they were again of necessity given stronger shapes. The material was at first frequently copper; it is now usually wrought iron, and sometimes steel.—The present forms of steam boilers may be classified as plain, flue, and tubular boilers. The plain cylindrical or common cylinder boiler is the only representative of the first class in common use. It is perfectly cylindrical, with heads either flat or hemispherical. There is usually attached to the boiler a "steam drum" (a smaller cylindrical vessel), from which the steam is taken by the steam pipe. This enlargement of the steam space permits the mist, held in suspension by the steam when it first rises from the surface of the water, to separate more or less completely before the steam is taken from the boiler.—Flue boilers are frequently cylindrical, and contain one or more cylindrical flues which pass through from end to end, beneath the water line, conducting the furnace gases, and affording a greater area of heating surface than can be obtained in the plain boiler. A cylindrical boiler, having one flue traversing it longitudinally, is called a Cornish boiler, as it is generally supposed to have been first used in Cornwall. It was probably first invented by Oliver Evans in the United States, previous to 1786, at which time he had it in use. The flue has usually a diameter 0·5 or 0·6 the diameter of the boiler. A boiler containing two longitudinal flues is called the Lancashire boiler. This form was also introduced by Oliver Evans. The flues have one third the diameter of the boiler. Several flues of smaller diameter are often used, and when a still greater proportional area of heating surface is required, tubes of from 1¼ in. to 4 or 5 in. in diameter are substituted for flues. The flues are usually constructed by riveting sheets together as in making the shell or outer portion. They are sometimes welded by British manufacturers, but rarely if ever in the United States. Tubes are always "lap-welded" in the process of rolling them. Small tubes were first used in the United States, about 1785. In portable, locomotive, and marine steam boilers, the fire must be built within the boiler itself, instead of (as in the above described stationary boilers) in a furnace of brickwork exterior to the boiler. The flame and gases from the furnace or fire box in these kinds of boiler are never led through brick passages *en route* to the chimney, as often in the preceding case, but are invariably conducted through flues or tubes, or both, to the smoke stack. These boilers are also sometimes used as stationary boilers. Fig. 1 represents a steam fire engine boiler in section, as usually exhibited in working drawings. F is the furnace, W the water space, and S the steam space. This is the form of boiler adopted for the steam fire engine described in the article FIRE ENGINE. In these boilers the fire is usually urged by the blast produced by the exhaust from the engine cylinder, and is thus rendered very intense. The tubes are frequently made of brass or of copper, to secure rapid transmission of heat to the water, and thus to permit the use of a smaller area of heating surface and a smaller boiler. The steam space is made as large as possible, to secure immunity from "priming" or the "entrainment" of water with the steam. This type of steam boiler was the earliest of the tubular boilers. It was invented by Nathan Read of Salem, Mass., in 1791, and patented in April of that year. In the locomotive boiler, fig. 2, as in the preceding, the characteristics are a fire box at one end of the shell and a set of tubes through which the gases pass directly to the smoke stack. Strength, compactness, great steaming capacity, fair economy, moderate cost, and convenience of combination with the running parts are secured by the adoption of this form. It is frequently used also for portable and stationary engines. It was invented in France by M. Séguin, and in England by Booth, and

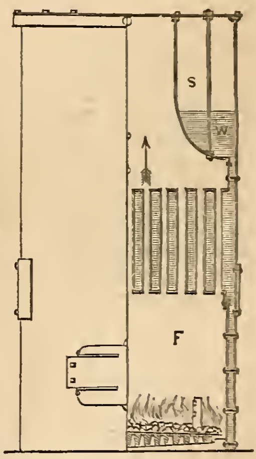

FIG. 1.—Steam Fire Engine Boiler.

used by George Stephenson contemporaneously, in 1828 or 1829. Fig. 3 is a common form of marine steam boiler. It is used very extensively in the United States when the steam pressure does not exceed 40 or 45 lbs. to the square inch. The gases, leaving the furnace F, pass to the "back connection" through large flues; there turning, as

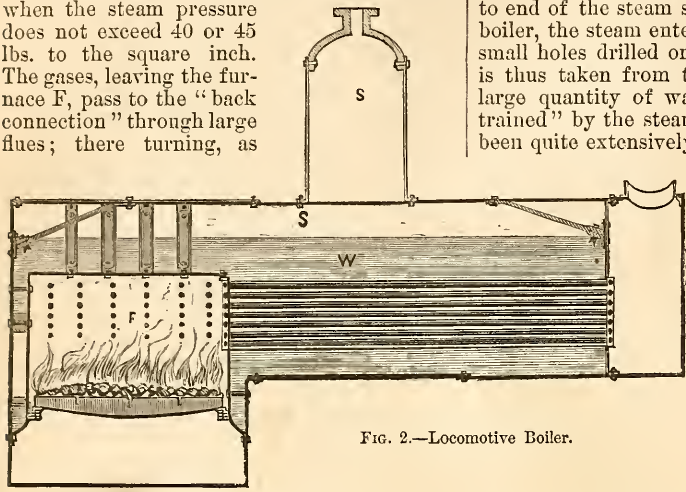

Fig. 2.—Locomotive Boiler.

shown by the arrow, they return to the front through the tubes, and from the "front connection" rise into the chimney. Large steam space is secured in this boiler by a steam drum, as in the locomotive boiler; but here the chimney passes through the steam drum, and thus this "steam chimney," as it is called, is made more useful in drying the steam and in economizing heat. The circular shell, the well stayed surfaces of the fire box and the ends, the convenient distribution of parts, and their excellent relative proportions, make this one of the most satisfactory of all types of boilers which are suitable for moderate pressure. Fig. 4 is a type of marine tubular boiler which is in most extensive use in seagoing steamers for moderate pressure, and particularly for naval vessels. Here the gases pass directly into the back connection from

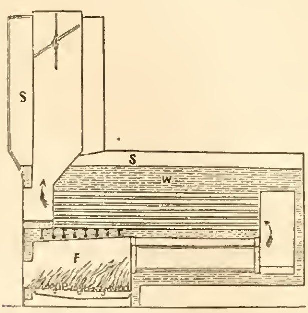

Fig. 3.—Marine Flue and Tube Boiler.

the fire, and thence forward again, through horizontal tubes, to the front connection and up the chimney. In naval vessels the steam chimney is omitted, as it is there necessary to keep all parts of the boiler as far below the water line as possible. Steam is taken from the boiler by pipes which are carried from end to end of the steam space, near the top of the boiler, the steam entering these pipes through small holes drilled on the upper side. Steam is thus taken from the boiler "wet," but no large quantity of water can usually be "entrained" by the steam. A marine boiler has been quite extensively introduced into the United States navy, in which the gases are led from the back connection through a tube box around and among a set of upright water tubes, which are filled with water, circulation taking place freely from the water space immediately above the crown sheet of the furnace up through these tubes into the water space above them. These "water-tubular" boilers have a slight advantage over the "fire-tubular" boilers already described in compactness, in steaming capacity, and in economical efficiency. They have a very marked advantage in the facility with which the tubes may be scraped, or freed from the deposit when a scale of sulphate of

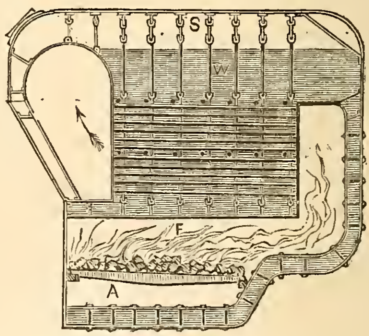

Fig. 4.—Marine Fire-tubular Boiler.

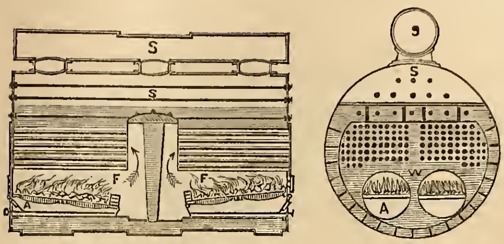
lime or other salt has formed within them by precipitation from the water. The fire-tubular boiler excels in convenience of access for plugging up leaking tubes, and is much less costly than the water-tubular. The water-tube class of boilers still remain in extensive use in the United States naval steamers. They have never been much used in the merchant service, although introduced by Montgomery in the United States and by Lord Dundonald in Great Britain twenty years ago. Opinion still remains divided among engineers in regard to their relative value. They are gradually reassuming prominence by their intro-

duction in the modified form of sectional boilers. The earliest water-tubular boilers were those of Voight, Rumsey, and Fitch, and were invented and known as "pipe boilers" as early as 1785. One of these, consisting of a "collection of long pipes bent so as to cross each



Longitudinal Section. Cross Section.

Figs. 5 and 6.—Marine High-Pressure Boiler.

other like the worm of a still," was used in one of John Fitch's boats in 1788; another form was adopted in the Babcock, built by John Babcock and R. L. Thurston in 1825. (See "American Journal of Science," March, 1827.) Where steam pressure exceeds about 30 lbs. to the square inch in marine boilers, they are now usually given the form shown in section in figs. 5 and 6. This form of boiler is adopted where steam pressures of 60 lbs. and upward are carried, as in steam vessels supplied with compound engines, cylindrical forms being considered the best with high pressures. The large cylindrical flues, therefore, form the furnaces as shown in the transverse sectional view. The gases rise, as shown in the longitudinal section, through the connection, and pass back to the end of the boiler through the tubes, and thence, instead of entering a steam chimney, they are conducted by a smoke connection, not shown in the sketch, to the smoke funnel or stack. In merchant steamers, a steam drum is often mounted horizontally above the boiler. In other cases a separater is attached to the steam pipe between boilers and engines. This usually consists of an iron tank, divided by a vertical partition extending from the top nearly to the bottom. The steam, entering the top at one side of this partition, passes underneath it, and up to the top on the opposite side, where it issues into a steam pipe leading directly to the engine. The sudden reversal of its course at the bottom causes it to leave the suspended water in the bottom of the separater, whence it is drained off by pipes.—Sectional steam boilers are a class of tubular boilers which differ from ordinary forms in their peculiar arrangement of water and steam space. These spaces are divided into a large number of small compartments, and it becomes thus comparatively easy to secure a large "factor of safety," the tubes of which such boilers are usually composed being capable of sustaining many times the pressure proposed to be carried within them.

The boilers are composed either of a series of water tubes, of such tubes attached to larger reservoirs containing water or steam or both, or of a collection of spherical vessels. The earliest real sectional steam boilers were probably that used by Col. John Stevens of Hoboken, on the Hudson river, in 1804, and another which was patented in Great Britain in June, 1805, by his son John Cox Stevens. The first boiler is shown in fig. 7. The inventor says in his specifications: "The principle of this invention consists of forming a boiler by means of a system or combination of small vessels, instead of using, as is the common mode, one large one; the relative strength of the materials of which these vessels are composed increasing in proportion to the diminution of capacity." The steamboat boiler of 1804 was built to bear a working pressure of over 50 lbs. to the square inch, at a time when the usual pressures were from 4 to 7 lbs. It consists of two sets of tubes, closed at one end by solid plugs, and at their opposite extremities screwed into a stayed water and steam reservoir, which was strengthened by hoops. The whole of the lower portion was enclosed in a jacket of iron lined with non-conducting material. The fire was built at one end, in a furnace enclosed in this jacket. The furnace

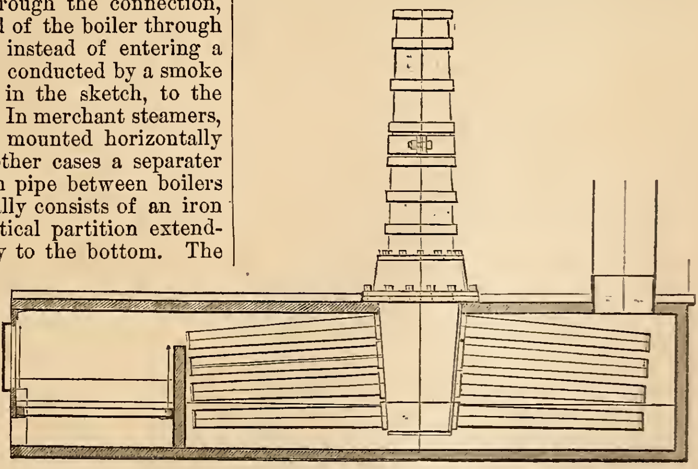


Fig. 7.—John Stevens's Sectional Boiler, 1804.

gases passed among the tubes, down under the body of the boiler, up among the opposite set of tubes, and thence to the smoke pipe. In the second form, as applied to a locomotive in 1825, the tubes were set vertically in a double circle surrounding the fire. These boilers are

preserved in the collections of the Stevens institute of technology, Hoboken. Walter Hancock constructed boilers for his steam carriage of flat plates connected by stay bolts, several such sections composing the boiler; and about the same time (1828) Sir Goldworthy Gurney constructed for a similar purpose boilers consisting of a steam and a water reservoir, placed one above the other, and connected by triangular water tubes exposed to the heat of the furnace gases. Jacob Perkins made many experiments looking to the employment of very high steam pressures, and in 1831 patented a boiler of this class, in which the heating surfaces nearest the fire were composed of iron tubes, which tubes also served as grate bars. The steam and water space was principally comprised within a comparatively large chamber, of which the walls were secured by closely distributed stay bolts. For extremely high pressures boilers composed only of tubes were used. Dr. Ernest Alban about 1843 reproduced the boiler described in the patent of John Stevens (1805), and published a work on "The High-Pressure Steam Engine," in which he described its construction and operation, and declared that he had experimented with pressures as high as 1,000 lbs. to the square inch (which pressure Perkins also attained), at which point the temperature of the steam was sufficiently high to char slightly the hemp packing of his engine. The Harrison steam boiler, which has been many years in use in the United States, consists of several sections, each of which is made up of hollow globes of cast iron communicating with each other by necks cast upon the spheres, and fitted together with faced joints. Long bolts, extending from end to end of each row, bind the spheres together. (See fig. 8.) An example of another modern type

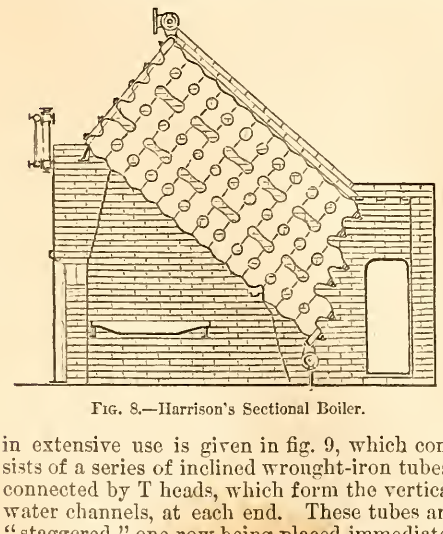

Fig. 8.—Harrison's Sectional Boiler.

in extensive use is given in fig. 9, which consists of a series of inclined wrought-iron tubes, connected by T heads, which form the vertical water channels, at each end. These tubes are "staggered," one row being placed immediately above the space between two rows below it. The joints are faced by milling them, and then ground so perfectly tight that a pressure of 500 lbs. to the square inch is insufficient to produce leakage. No packing is used. The fire is made under the front and higher end of the tubes, and the products of combustion pass

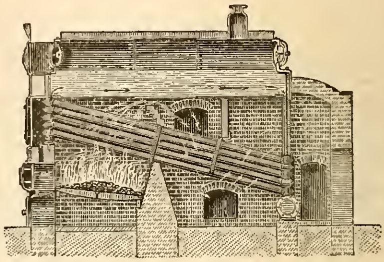

Fig. 9.—Babcock and Wilcox's Sectional Boiler.

up between the tubes into a combustion chamber under the steam and water drum; hence they pass down between the tubes, then once more up through the space between the tubes, and off to the chimney. The steam is taken out at the top of the steam drum near the back end of the boiler. The rapid circulation prevents to some extent the formation of deposits or incrustations upon the heating surfaces, sweeping them away and depositing them in the mud drum, whence they are blown out. Rapid circulation of water, as has been shown by Prof. Trowbridge, also assists in the extraction of the heat from the gases, by the presentation of fresh water continually as well as by the prevention of incrustation. A sectional steam boiler like that illustrated in fig. 8 is one of the best examples of this class of steam generator. It is immensely stronger, is fairly economical of fuel, and is durable when properly managed. The sudden introduction of a large volume of cold water, which is liable to produce leaks from some of its numerous joints, is the most serious injury to be apprehended. It is almost absolutely safe from explosion, and should a globe explode, the danger to its surroundings is comparatively slight. The disadvantages of this type are the small amount of water and of steam room, which causes a difficulty in securing regularity of steam supply, and makes necessary very careful and skilful management. In the boiler illustrated in fig. 9 the last objection is avoided by the use of the large steam and water drum. Some additional risk is thus incurred; but, as the flames are interrupted by the numerous tubes interposed between the drum and the fire, the liability of injury to the drum is too slight to be considered. Attempts have been made to adapt sectional boilers to marine engines; but very little progress has yet been made in their introduction. The Root sectional boiler, an American design, which is in extensive use in the United States and Europe, has been experimentally placed in service on shipboard. Its

heating surfaces consist wholly of tubes. They are connected by a peculiarly formed series of chambered caps, and the ends are made tight by packing with India-rubber grummets.—The proportions of steam boilers vary with the type, and are to some extent determined by special considerations. Efficiency is affected by the proportions of area of heating surface to fuel consumed, of area of grate surface to the same quantity, and by general arrangement of parts. The method of producing draught and the intensity of combustion are also influential in a great degree in determining efficiency. The efficiency of the boiler is to be studied in two parts: the efficiency of the furnace proper, or of the heat-generating apparatus, and that of the boiler proper, or of the heat-absorbing apparatus. In securing efficiency, the engineer first seeks to obtain the highest possible temperature of furnace by thorough combustion of the fuel with a minimum quantity of air. An excess of air, by diluting the products of combustion, diminishes the temperature of the furnace gases. As shown by Prof. Thurston, the abstract efficiency of the furnace in any ordinary case is represented by the formula, $E=\frac{\tau_1-\tau_2}{\tau_1-\tau_3}=\frac{T_1-T_2}{T_1-T_3}$, where E represents the efficiency and $\tau_1$ and $\tau_2$ are the absolute temperatures at which the heat is generated, and at which wasted heat is discharged, and $\tau_3$ that of the external air. $T_1$, $T_2$, $T_3$ are temperatures on the Fahrenheit scale. Suppose, in two instances, the temperatures of furnace gases, including excess of air, were 2118° F. and 919° F. respectively, and that the corresponding temperatures of chimney were 544° and 452°, while the temperature of external air was 74° and 86·5°. In these cases $E=\frac{2118^\circ-544^\circ}{2118^\circ-74^\circ}=0{\cdot}77$; and $E=\frac{919^\circ-452^\circ}{919^\circ-86{\cdot}5^\circ}=0{\cdot}56$; and the first is nearly 40 per cent. higher than the second. By increasing the temperature of the furnace in the first case to 2644°, which is not an unusual figure, the available heat becomes $E=\frac{2644^\circ-544^\circ}{2664^\circ-74^\circ}=0{\cdot}81$ of the whole amount generated. The remaining 19 per cent. passes up the chimney, producing or assisting in the production of draught. Where fuel is wet, a portion of the lost heat disappears in vaporizing the water contained in the fuel. The highest temperature attainable without dilution of gases by an excess of air is given by Prof. Rankine at 4580° F. with pure carbon, and 5050° with olefiant gas. With the more usual case, in which the air supplied is double that theoretically demanded, these temperatures are reduced to 2440° and 2710°. The rate of combustion of good coal, per square foot of grate per hour, depends upon the height of the chimney. This rate is stated by Prof. Thurston as equal to one pound less than twice the square root of the height of the chimney in feet; *i. e.*, $W=\sqrt{H}-1$. Rankine determines the height of chimney by the formula, $H=h\div\left(0{\cdot}96\frac{t_1}{t_2}-1\right)$, in which H is the height of chimney, $h$ the "head" required to produce the draught, as obtained from Peclet's formula, $h=\frac{V^2}{2g}\left(13+\frac{0{\cdot}012l}{m}\right)$, and $t_1$ and $t_2$ the absolute temperatures of the chimney and of the air. In Peclet's formula, V is the velocity of flow, $l$ is the length of chimney and flue, and $m$ is its "hydraulic mean depth." For ordinary practice, Isherwood found the proportion of chimney cross section to area of grate to be about one eighth. Probably a good rule for general practice would be: Make the area for draught one seventh at the bridge wall, one eighth through the flues, and one ninth in the chimney, of the area of grate. The area of heating surface determines the efficiency of the steam boiler as a heat-absorbing apparatus and reservoir. Rankine has given a formula ("Steam Engines and Prime Movers," p. 292, § iv.) for determining the efficiency of fuel in ordinary steam-boiler practice, where the ratio of the area of heating surface, and of fuel burned per hour, to the square foot of grate surface, is known: $\frac{E'}{E}=\frac{B\ S}{S+A\ F}$, in which $\frac{E'}{E}$ is the quantity called above E, A and B are constants, and F and S are the ratio of fuel burned per hour to the square foot of grate, and the ratio of area of heating surface of grate area. The effect of exceptionally low temperature of furnace is to equalize the value of heating surface; and the considerable velocity of the gaseous current, which is a consequence of the unusually great volume of air passing through the furnace, increases this effect. The nearer surface is inefficient, and the most distant portions of the heating surface are therefore proportionally much more efficient than in the preceding case. ("Transactions of the American Society of Civil Engineers," 1874–'5, pp. 290, 303.) With high temperature and slow movement of gases, a lower relative amount of heating surface is efficient; and with lower temperature of furnace and rapid movement of gases, the heating surface must be extended beyond the proportions upon which this estimate is based. The constants A and B have values varying from 1 and 0·5 respectively, in the best designed boilers, to 0·9 and 0·5 in ordinary cases, both having chimney draught, and to 0·95 and 0·3 for cases of ordinary practice with forced draught. These values are changed very slightly by wide ranges of proportions of heating and grate surfaces, or of the value of $\frac{F}{S}$. The value of F has already been given. The value of S is variable with the style of boiler used, and with the value of fuel. The ratio S of area of heating surface to grate area, in ordinary good practice, and under ordinary conditions, may be taken at 15 with plain cylindrical boilers, 20 with Cornish, 25 with flue, 28 with fire-tubular, and 30 with

water-tubular boilers having moderate draught. In locomotive and other boilers with forced draught, the ratio of heating to grate surface rises to from 50 to 100 to 1. For the sizes of the parts of steam boilers exposed to strain, see STRENGTH OF MATERIALS.—Burned in the furnace of good steam boilers, a cord of dry yellow pine, in the experiments of Prof. Walter R. Johnson, evaporated 12,618·3 lbs. of water. A cord of dry yellow pine is approximately equal in heating power to 0·6 of a ton of coal, and a ton of good coal is equal in calorific power to 1·66 cord of soft wood. As an average, a pound of dry wood is theoretically capable of evaporating 6·66 lbs. of water from and at 212° F. Similarly, a pound of good anthracite should evaporate 13·5 lbs. of water. (See FUEL.) Incomplete combustion is caused by an insufficient supply of air, by imperfect intermixture of air and combustible gases from the fuel, and by the falling of fuel through the grate into the ash pit. These losses are usually largely due to unskilful management, and they amount frequently to 15 per cent. They are sometimes due to defects of design. Loss of efficiency is also produced, as already shown, by excessive air supply, which, while insuring complete combustion, lowers the temperature of the furnace. Losses occur by conduction and radiation of heat from the boiler, the furnace, or the flues. This can usually be reduced to a very small amount by properly protecting the apparatus by non-conducting covering. Loss may occur by the passage of the gases to the chimney before their temperature has been reduced to that required for draught. This can be prevented by providing a sufficient extent of heating surface.—Incrustation and deposits are produced by the precipitation upon the interior of the boiler of substances held in solution or in suspension by the water. Sea water precipitates sulphate of lime, and, passing a concentration of $\frac{1}{3\frac{3}{3}}$, or when it contains 36·37 per cent. of salt, it precipitates the excess. River waters produce scales composed of lime carbonates and sulphates and various other mineral salts.—The horse power of a steam boiler is an indefinite and inappropriate term. It was formerly assumed that the evaporation of a cubic foot of water would yield sufficient steam to drive an engine of one horse power one hour. A moderately good modern engine should not use more than half this amount, and a good boiler should evaporate half a cubic foot an hour for each 12 sq. ft. of heating surface. A good engine of 100 horse power would therefore be supplied with steam by a good boiler of 1,200 sq. ft. area of heating surface. The most economical engines recently built use only about one fourth of a cubic foot or 16 lbs. of water per horse power per hour.—Steam boiler explosions occur as a consequence of ignorance or carelessness in design, in construction, or in management. Experimental explosions in Great Britain, and notably in the United States, have shown that even low pressures are sufficient to produce very violent explosions. The explosion experiments of Francis B. Stevens, in November, 1871 (reported by R. H. Thurston in "Journal of the Franklin Institute," 1872), were considered to indicate: 1, that a most violent explosion may occur in a boiler well supplied with water; 2, that what is generally considered a moderate steam pressure may produce a very violent explosion of a weak boiler containing a large body of water, and having all its flues well covered. The same writer estimated that one of the boilers exploded by Mr. Stevens contained 40,000 lbs. of water; and that when the steam pressure was, as at the time of explosion, 53 lbs. to the square inch, the heat stored in the boiler amounted to 2,674,080 British thermal units, equivalent in mechanical energy to about 2,064,389,760 foot pounds, or, if wholly so expended, sufficient to raise the whole boiler, weighing 70,000 lbs., to a height of 29,491 ft., or more than five miles. The conclusion reached was: "That it is very certain that the energy of this explosion, and all of its tremendous effects, were principally due to the simple expansion of a mass of steam suddenly liberated at a moderate pressure, by the general disrupture of a steam boiler of very uniform but feeble strength." When steam boilers are locally weak, explosion rarely occurs. The steam pressure produces rupture at the weakest point, and, the strength of surrounding parts being sufficient to prevent extension of the break, no explosion occurs. Where the weakest portions of the boiler are more extended and more uniformly weak, the extent of the rupture which finally occurs becomes greater, and the accident is attended with greater violence of disruption, and more serious results follow. Where considerable portions of the boiler are weak, or long lines of weakness exist uninterrupted by points much more defective, disastrous explosions are very likely to take place with old boilers and at moderate pressures. The most terrible explosions occur with good and uniformly strong boilers, in which, by accident or mismanagement, steam has been allowed to accumulate until a fatally high pressure produces rupture and drives the fragments of the boiler in all directions. It has been shown by compiling the statistics of explosions, that the gradual accumulation of steam until a pressure is reached under which the weakest portion of the boiler gives way, is by far the most usual cause. Prof. Trowbridge has shown that the time of accumulation may be calculated by a formula, $T=\frac{W(t_1-t)}{Q}$, in which T is the time of accumulation, in minutes, from the pressure corresponding to the temperature $t$ to that of the temperature $t_1$ F.; W is the weight of water in the boiler, and Q the quantity of heat in British units transferred to the boiler per minute. He shows that T=9·1 minutes in a large marine boiler, containing 79,000 lbs. of water,

and with the pressure rising from 2½ to 4 atmospheres. In a locomotive boiler, he estimates the time required to raise the pressure from 90 lbs., the working point, to 175 lbs., the assumed exploding point, at 3½ minutes. A safety valve, of sufficient size and of good design, is the safeguard against such accidents, being so weighted that it will never allow the steam to rise above a pressure at which a proper "factor of safety" is given. Steam boilers should be designed with a factor of safety of at least 6 or 8, but they are frequently, even when new, capable of sustaining without rupture no more than four times the regular working pressure. As they deteriorate with age, the factor of safety is too generally allowed to decrease, until it becomes as small as legal requirements permit. This has usually been far too low in the United States, and frequently boilers are legally passed by the inspectors when their factors of safety are less than 1½. The accumulation of steam to an excessively high pressure is found to be most commonly due to defective pressure gauges, to entire deficiency of pressure indicators, and to the absence of or defects in safety valves. Boilers fail in consequence of deficiency of water, which, causing exposure of heating surfaces to the heated gases without protection, permits them to become overheated and weakened. Braces and straps are weakened by corrosion, and even entirely severed. Plates are cracked by changes of temperature and irregular expansion and contraction, or even burned as just described, and are blistered in consequence of defective manufacture. Deposits cover the heating surfaces, and, interposing a non-conducting coating between the metal and the water, permit overheating to take place even when the boiler is amply supplied with water. Corrosion produces extended and uniform weakening of sheets, or, forming grooves along the lines of junction of the plates, creates long lines of weakness. The sudden evolution of steam, in such volumes that the pressure is increased too rapidly to be effectively relieved by the safety valve or by the supply pipe leading to the engine, is considered by many authorities to be an occasional cause of explosion. This may be caused by the overheating of a portion of heating surface not in contact with the water (as when a deficiency of water occurs, or when the surface is heavily coated with scale), and a subsequent sudden return of the water into contact with the metal. The occurrence of the "spheroidal state" may, it is supposed, sometimes produce this effect when the liquid is restored to contact with the plate. (See BOILING POINT.) A committee of the Franklin institute in 1833-'6 experimented upon the first of the above named conditions, and found that very considerable accessions of pressure might be caused by the sudden return of the water upon overheated surfaces. The superheating of the water, as in experiments of Donny, Dufour, and others, is also supposed to be a possible cause of explosions. The United States government has appointed a commission to investigate this subject. They have produced many explosions by over pressure, by injecting feed water upon overheated iron in boilers, but have not yet (1876) made their report. It is generally supposed by engineers that good design, good materials and workmanship, and skilful and intelligent management, will almost invariably insure perfect immunity from danger of explosion; but the phenomena of sudden evolution of steam in steam boilers have not yet been fully investigated by any thoroughly scientific series of experimental researches. Steam boilers are usually tested at regular intervals. Careful and skilful inspection will almost invariably detect all serious defects. Every sheet should be examined to discover blisters, lamination, fracture, or corrosion. The use of a light hammer, tapping its surface and following the seams, will generally in practised hands reveal such defects and indicate their extent. All stays and braces should be carefully examined, and the boiler fittings, valves, and gauges should be inspected, and the last should be tested. After such an inspection and the repair of injured parts, it is considered by many engineers to be advisable to subject the boiler to a hydrostatic test. This consists in filling it with water, and raising the pressure to a point exceeding by one half or more the regular working pressure. This form of test is prescribed by the laws of the United States regulating steam-boiler management on steam vessels. (See BOILING POINT, EVAPORATION, HEAT, and VAPORIZATION.)—See N. Burgh, "Steam Boilers" (London, 1871); E. B. Martin, "Steam Boiler Explosions" (London, 1871); L. Delvordre, *Traité pratique sur les chaudières à vapeur* (Paris, 1872); Trowbridge, "Heat as a Source of Power" (New York, 1874); R. Wilson, "Treatise on Steam Boilers" (London, 1874); and J. Laurent, *Chaudières à vapeur* (Paris, 1875).

**STEAM CARRIAGE.** Road locomotives and traction engines have been frequently constructed for the transportation of both freight and passengers, and for hauling wagons carrying heavy loads. The latter application only has been permanently successful, although repeated attempts have been made to perfect steam carriages of high speed. As early as 1759 Dr. Robinson called the attention of Watt to the possibility of constructing a carriage to be driven by a steam engine. The first actual experiment was made, as is supposed, by a French army officer, Nicolas Joseph Cugnot, in 1769. Encouraged by the partial success of the first locomotive, he constructed a second in 1770, which is still preserved in the *conservatoire des arts et métiers*, Paris. Watt patented a road engine in 1784. About the same time his assistant, Murdoch, completed and made a trial of a model locomotive, driven by a "grasshopper engine," having a steam cylinder ¾ in. in diameter and 2 in.

stroke. It is said to have run 6 to 8 m. an hour. In 1786–'7 Oliver Evans obtained from the Pennsylvania legislature the monopoly of his method of applying the steam engine in driving flour mills, and from Maryland a similar privilege in regard to propelling wag-

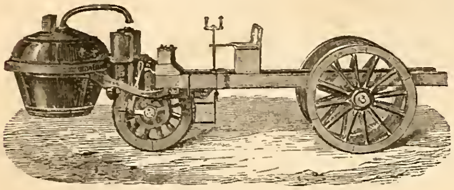

FIG. 1.—Cugnot's Steam Carriage, 1770.

ons. In the same or the following year William Symington constructed a working model of a steam carriage, which is now in the patent museum at South Kensington, London. In 1804 Oliver Evans completed a flat-bottomed boat to be used in dredging at the Philadelphia docks, and, mounting it on wheels, drove it by its own steam engine to the river bank. Launching the craft, he propelled it down the river, using its engine to drive its paddle wheels. Evans's "Oruktor Amphibolos," as he named the machine, was the first road locomotive that we find described after Cugnot's time. In 1821 Julius Griffiths of London made a steam carriage to carry passengers on common roads, which was probably the first ever constructed for that purpose only. During the succeeding 10 or 15 years, Messrs. Burstall and Hill and Bramah of London and Edinburgh, Sir Goldworthy Gurney, the Messrs. Seaward, Sir Charles Dance, W. H. James, Walter Hancock, Ogle and Summers, and others in Great Britain, and Harrison Dyar, Joseph Dixon, Rufus Porter, and Mr. James in the United States, attacked this problem with varying success. Sir Charles Dance made several hundred trips between London and Cheltenham in 1831. Hancock ran between London and Stratford, and Scott Russell from Glasgow to Paisley. From May to October, 1836, Han-

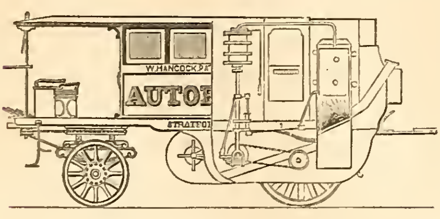

FIG. 2.—Hancock's Steam Carriage.

cock ran several carriages on the Paddington road. The general introduction of railroads, which took place immediately after the establishment of steam locomotion on the Liverpool and Manchester railway in 1829, put an end to what had promised to become an important and successful method of transportation of passengers and light merchandise. In December, 1833, more than 20 steam carriages were in use or under contract in and near London. It was proposed to substitute steam carriages, capable of travelling 12 or 15 m. an hour, for coaches drawn by horses on all mail routes. Hostile legislation procured by opposing interests, and the rapid progress of steam locomotion on railroads, caused an interruption of experiment, and almost nothing was done during the succeeding quarter of a century. It is only within a few years that any business has been founded upon the construction of road locomotives, although the scheme seems to have been at no time entirely given up. J. Scott Russell, Boydell, and a few others in England, and Messrs. Roper, Dudgeon, Fawkes, Latta, and J. K. Fisher, in the United States, have all labored in this direction. The last named engineer designed his first steam carriage in 1840, and was at work upon the problem till his death in 1873. A few firms have succeeded within a few years in making a business of constructing road locomotives for hauling heavy loads, and of building steam road roll-

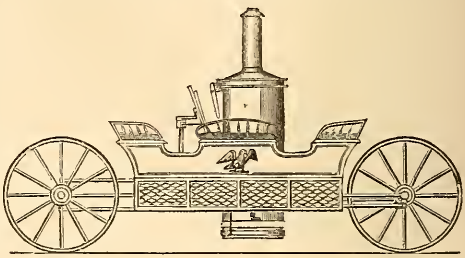

FIG. 3.—Fisher's Steam Carriage.

ers; but steam carriages of high speed, adapted to the transportation of passengers, have not yet been successfully introduced. The greatest impediments seem to be the roughness and bad construction of the ordinary highway, the frightening of horses, the engineering difficulties of construction, and the limited power of the machine as it has usually been built. The capabilities of the road locomotive are readily determined by experiment, and the following is an abstract of the results of several series of trials. A trial of a road engine was made by the well known French engineer H. Tresca, in presence of Prof. Fleeming Jenkin, and the report was submitted on Jan. 15, 1868. The results were as follows: 1. The coefficient of traction was about 0·25 on a good road with easy grades. 2. The consumption of coal was 4·4 lbs. per horse power per hour. 3. The consumption of water was 132·2 gallons an hour with the ten-horse engine. 4. The coefficient of adherence, or of friction between the wheels and the soil, was 0·3. 5. A speed of 7 m. an hour caused no special difficulty in managing either the locomotive or its load. About this

same time M. Servel conducted a series of experiments with a similar machine upon paved and upon macadamized roads, during what he described as the most trying of winter weather. He reports the following distribution of weight per cent.:

| | |
|---|---|
| Weight of locomotive | 41·4 |
| " of wagons | 18·2 |
| " of paying load | 40·4 |
| Total | 100 |

The average total weight of three loaded wagons, which was the usual load, was 22,575 kilogrammes, or about 22 tons. The experiment was made in 1867–'8 of applying these engines to the towage of boats on the French canals, with very encouraging results. In 1871 several traction engines were exhibited before the royal agricultural society of England at Wolverhampton, and the judges made a series of careful tests, reported in its "Journal" for that year. The coal used on special trial amounted to 3·2 lbs. per indicated horse power per hour, and the evaporation of water was 7·62 lbs. per pound of coal consumed, the average temperature of feed being 175° F. The load drawn up the maximum grade of 264 ft. to the mile on Tottenham hill, which is 1,900 ft. from top to bottom, was 26 tons, and including weight of engine 38 tons, giving a coefficient of traction of 0·35. On a country road 16 m. long it drew 15 tons at an average rate of 3½ m. an hour, using 2·85 lbs. of coal and 1·94 gallon of water per ton of useful load per mile. In October, 1871, Prof. R. H. Thurston conducted a public trial of road engines and steam road rollers, on a well macadamized road at South Orange, N. J. Two road steamers or traction engines and a steam road roller were tried. The following are the principal dimensions: weight of engine complete, 5 tons 4 cwt. (11,648 lbs.); diameter of steam cylinder, 7¾ in.; stroke of piston, 10 in.; revolutions of crank to one of driving wheel, 17; diameter of driving wheels, 60 in.; length of boiler over all, 8 ft.; diameter of boiler shell, 30 in.; load on driving wheels, 4 tons 10 cwt. (10,080 lbs.). The boiler was of the ordinary locomotive type, and the engine was mounted upon it, as is usual with portable engines. A representation of the engine is given in the article PLOUGH (fig. 10). The engine valve gear consisted of a three-ported valve and Stephenson link, with reversing lever, as generally used on locomotives. The connection between the gearing and the driving wheels was effected by the device called by builders of cotton machinery a Jack-in-the-box gear, or differential gear. By this combination, the effort exerted by the engine is made equal at both wheels at all times, even when the engine is turning a corner. The weight of the steam road roller was 15 tons. The engine and boiler were of the same general dimensions as in the road locomotives already described. The whole machine was carried on four large wheels, with broad tread, covering a total width of 6 ft. Its weight exerts a compressive force of 5,600 lbs. on each foot of width, or 467 lbs. on each inch. The following is a summary of the conclusions deduced from the trial, and published in the "Journal of the Franklin Institute:" A traction engine may be so constructed as to be easily and rapidly manœuvred on the common road; and an engine weighing over 5 tons may be turned continuously without difficulty on a circle of 18 ft. radius, or even on a road but little wider than the length of the engine. A locomotive of 5 tons 4 cwt. has been constructed, capable of drawing on a good road 23,000 lbs. up a grade of 533 ft. to the mile, at the rate of 4 m. an hour; and one might be constructed to draw more than 63,000 lbs. up a grade of 225 ft. to the mile, at the rate of 2 m. an hour. It was further shown that the coefficient of traction with heavily laden wagons on a good macadamized road is not far from $\frac{4}{100}$; the traction power of this engine is equal to that of 20 horses; the weight, exclusive of the weight of the engine, that could be drawn on a level road, was 163,452 lbs.; and the amount of fuel required is estimated at 500 lbs. a day. The advantages claimed for the traction engine over horse power are: no necessity for a limitation of working hours; a difference in first cost in favor of steam; and in heavy work on a common road the expense by steam is less than 25 per cent. of the average cost of horse power, a traction engine capable of doing the work of 25 horses being worked at as little expense as six or eight horses.—*Railroad Locomotives.* Steam carriages for use on railroads, or locomotives, came into public notice subsequently to the introduction of steam carriages on the common road, but they soon displaced the latter, and have now become the most usual means of transportation. In 1802 Trevithick, a Cornish miner, patented a high-pressure locomotive with a fly wheel on the crank shaft. Draught was secured by means of bellows. This little engine was so powerful that the inventor found the adhesion of the driving wheels to the rails insufficient, and proposed the use of gearing which should engage a rack laid down between the rails. Blenkinsop pursued Trevithick's plans, and made a locomotive which ran 10 m. an hour. Blackett in 1812 made a better distribution of weight, and obtained ample adhesion. John Stevens of Hoboken, N. J., in 1812 memorialized the legislature of the state of New York, urging the building of railways, and showing their advantages. He published a pamphlet in which he predicted that trains of carriages would be drawn on railways at 20 or 30 m. an hour, and that they might attain 40 or 50 m. an hour; and he further says: "I can see nothing to hinder a steam carriage from moving on these ways (rails) with a velocity of 100 m. an hour." Subsequently Stevens applied his steam boiler, patented in 1805, to a locomotive, which was

used however only experimentally. George Stephenson in 1814 introduced the locomotive in Great Britain. The steam blast of Hackworth, the tubular boiler of Séguin, and the link motion of Stephenson constitute the essential features of the modern locomotive. (See Railroad.) Locomotives have gradually and steadily increased in size and power from the date of their introduction. The Rocket, which first proved conclusively in 1829 the value of steam locomotion, weighed $4\frac{1}{4}$ tons. In 1835 Robert Stephenson, who had constructed it with his father, writing to Robert L. Stevens, said that he was making his engines heavier and heavier, and that the engine of which he enclosed a sketch weighed nine tons and could draw "100 tons at the rate of 16 m. an hour, on a level." Locomotives are now built weighing 70 tons, and powerful enough to draw more than 2,000 tons at a speed of 20 m. an hour. The modern locomotive consists of a boiler of the form shown in the article Steam Boiler, mounted upon a strong light frame of forged iron, by which it is connected with the wheels. The largest

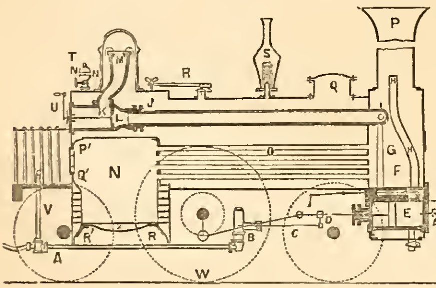

Fig. 4.—British Express Engine.

engine yet constructed in the United States is said to be one in use on the Philadelphia and Reading railroad, having a weight of about 100,000 lbs., which is carried on 12 driving wheels. A locomotive has two steam cylinders, either side by side within the frame, and immediately beneath the forward end of the boiler, or on each side and exterior to the frame. The engines are non-condensing and of the simplest possible construction. The whole machine is carried upon strong but flexible steel springs. The steam pressure is usually more than 100 lbs. The pulling power is generally about one fifth the weight under most favorable conditions, and becomes as low as one tenth on wet rails. The fuel employed is wood in new countries, coke in bituminous coal districts, and anthracite coal in the eastern part of the United States. The general arrangement and the proportions of locomotives differ somewhat in different localities. In fig. 4, a British express engine, O is the boiler, N the fire box, X the grate, G the smoke box, and P the chimney. S is a spring and R a lever safety valve, T is the whistle, L the throttle or regulator valve, E the steam cylinder, and W the driving wheel. The force pump, B C, is driven from the cross head, D. The frame is the base of the whole system, and all other parts are firmly secured to it. The boiler is made fast at one end, and provision is made for its expansion when heated. Adhesion is secured by throwing a proper proportion of the weight upon the driving wheel W. This is from about 6,000 lbs. on standard freight engines, having several pairs of drivers, to 10,000 lbs. on passenger engines, per axle. The peculiarities of the American type are the truck or bogie supporting the forward part of the engine, the system of equalizers, or beams which distribute the weight of the machine equally over the several axles, and minor differences of detail. The cab or house protecting the engine driver and fireman is an American device, which is gradually coming into use abroad also. The American locomotive is distinguished by its flexibility and ease of action upon even roughly laid roads. The cost of passenger locomotives of ordinary size is about \$12,000; heavier engines sometimes cost \$20,000. The locomotive is usually furnished with a tender, which carries its fuel and water. The standard passenger engine on the Pennsylvania railroad has four driving wheels, $5\frac{1}{2}$ ft. diameter; steam cylinders, 17 in. diameter and 2 ft. stroke; grate surface $15\frac{1}{2}$ sq. ft., and heating surface 1,058 sq. ft. It weighs 63,100 lbs., of which 39,000 lbs. are on the drivers and 24,100 on the truck. The shell of the boiler is $49\frac{1}{2}$ in. diameter and 20 ft. $2\frac{1}{2}$ in. long. The fire box is of steel, 6 ft. 2 in. long outside, $3\frac{1}{2}$ ft. wide, and 5 ft. 4 in. high. The tubes are of iron, 142 in number, $2\frac{1}{4}$ in. diameter, and 11 ft. 7 in. long. The steam dome is 30 in. outside diameter, the smoke stack $14\frac{1}{2}$ in. The feed water is supplied by one pump of 2 in. diameter and 2 ft. stroke, and by a No. 8 Giffard injector. The valves are $16\frac{1}{2}$ in. wide by $8\frac{1}{2}$ in. long, and have 5 in. travel. The steam ports are $15\frac{15}{16}$ in. wide and $1\frac{1}{4}$ in. long, and the exhaust port $15\frac{15}{16}$ by $2\frac{1}{2}$ in. The lap of the valve is, outside $\frac{3}{4}$ in., inside $\frac{1}{64}$ in. The eccentrics have a throw of $4\frac{1}{8}$ in. The freight engine has six driving wheels, $54\frac{5}{8}$ in. in diameter. The steam cylinders are 18 in. in diameter, stroke 22 in., grate surface 14.8 sq. ft., heating surface 1,096 ft. It weighs 68,500 lbs., of which 48,000 are on the drivers and 20,500 on the truck. The boiler is nearly of the same dimensions as that of the passenger engine, but the tubes are $2\frac{1}{2}$ in. in diameter, 12 ft. $9\frac{9}{16}$ in. long, and 119 in number. The stack is 18 in. in diameter. The pump is $2\frac{1}{4}$ in. in diameter, and has a stroke of 22 in. The valve has $\frac{3}{4}$ in. inside lap, $\frac{1}{16}$ in. outside. The former takes a train of five cars up an average grade of 90 ft. to the mile. The latter is attached to a train of 11 cars. On a grade of 50 ft. to the mile, the former takes 7 and the latter 17 cars. Tank engines for very heavy work, such as on grades of 320 ft. to the mile, which are found on some of the moun-

tain lines of road, are made with five pairs of driving wheels, and with no truck. The steam cylinders are 20½ in. in diameter, 2 ft. stroke; grate area, 15¾ ft.; heating surface, 1,380 ft.; weight with tank full, and full supply of wood, 112,000 lbs.; average weight, 108,000 lbs. Such an engine has hauled 110 tons up this grade at the speed of 5 m. an hour, the steam pressure being 145 lbs. The adhesion was about 23 per cent. of the weight. In checking a train in motion, the inertia of the engine itself absorbs a seriously large portion of the work of the brakes. This is sometimes reduced by reversing the engine and allowing the steam pressure to act in aid of the brakes. To avoid injury by abrasion of the surfaces of piston, cylinder, and the valves and valve seats, M. Le Chatelier introduces a jet of steam into the exhaust passages when reversing, and thus prevents the ingress of dust-laden air and the drying of the rubbing surfaces. The valve motion consists of the simplest forms of three-ported valve, moved by two eccentrics attached to a Stephenson link. In drawing a train weighing 150 tons at the rate of 60 m. an hour, about 800 effective horse power is required. A speed of 80 m. an hour has been attained several times. The locomotive engine has a maximum life which may be stated at about 30 years. The annual cost of repairs is from 10 to 15 per cent. of its first cost. On moderately level roads, the engine requires a pint of oil to each 25 m., and a ton of coal to each 40 or 50 m. run. (See RAILROAD.)—See Holley, "American and European Railway Practice" (New York, 1861); Weissenborn, "American Locomotive Engineering" (26 nos. 4to, plates 2 vols. fol., New York, 1861); Vose, "Manual for Railroad Engineers" (Boston, 1872); and Forney, "Catechism of the Locomotive" (New York, 1874).

**STEAM ENGINE.** Hero of Alexandria (about 250 B. C.) described, in his *Spiritalia* or *Pneumatica*, several insignificant contrivances illustrating the power of steam. The first modern reference to its actual or possible use is not definitely known. Blasco de Garay is believed by Spanish writers to have applied steam to the propulsion of a ship at Barcelona, A. D. 1543. Giambattista della Porta, in his *Spiritalia* (1601), described his apparatus for raising water by filling a vertical tube by condensing steam within it and then forcing the water upward by pressure. Salomon de Caus, engineer and architect to Louis XIII., in *Les raisons des forces mouvantes, avec diverses machines tant utiles que plaisantes* (1615), says that "water will, by the aid of fire, mount higher than its level," and describes a globe filled with water, and an attached vertical pipe through which the water was elevated by the expansion of steam generated by heating the vessel. Giovanni Branca published at Rome in 1629 an account of a mechanical application of a steam jet to the impulsion of a wheel against the vanes of which the jet impinged, and proposed its application to many useful purposes. The marquis of Worcester, in his "Century of Inventions" (1663), described an apparatus consisting of steam boilers worked alternately and of pipes conveying steam from them to a vessel in which its pressure operated to force water upward as suggested by De Caus. This was set up at Vauxhall, near London, and was the first instance of the application of steam to practical use. The separate boiler was the essential feature of this invention, and this is the basis of the claim that Worcester was one of the inventors of the steam engine. Sir Samuel Morland in 1683 constructed these engines commercially, and with an intelligent understanding of their principles and of the more important properties of steam. Denis Papin, of Blois, about 1690 invented an engine having a piston which separated the steam from the water in the cylinder, receiving steam from the boiler in Worcester's combination. He also invented the lever safety valve. Thomas Savery patented, July 25, 1698, a machine consisting of a duplicate set of boilers, steam reservoirs, and forcing tubes, which were worked alternately, and applied it extensively to the drainage of mines, and occasionally to raising water to turn mill wheels. Savery recharged his reservoirs by the use of surface condensation, and his apparatus was capable of working an indefinite period without stopping. Desaguliers in 1716 improved upon it by applying the Papin safety valve, and by using jet instead of surface condensation. This engine elevated 5,000,000 lbs. of water one foot with each hundred weight of coal consumed; it gave a "duty" therefore of 5,000,000. Thomas Newcomen, John Cawley, and Savery patented in 1705 the first steam engine really deserving the name. It consisted of a cylinder containing a piston driven upward by steam from a separate boiler, and forced downward by atmospheric pressure when the steam below the piston was removed by condensation. The engine was used only for pumping, the pump rod and piston rods being attached to opposite ends of a beam, as in modern engines. Steam was first condensed by the application of cold water to the exterior, as in the original Savery engine, but soon after a jet within the cylinder was used. The boiler was supplied with gauge cocks to indicate the height of water, and a safety valve. Humphrey Potter, an ingenious boy mechanic, in 1713 made the valve gear automatic by leading cords from the beam. Henry Beighton in 1718 substituted for the latter the plug rod and more substantial ap-

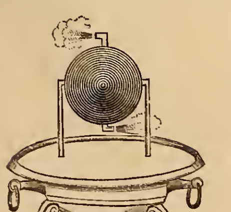

FIG. 1.—Hero's Steam Engine.

paratus still known to engineers. The improved Newcomen engine came into use during the 18th century throughout Europe. Brindley and John Smeaton devised some improvements in detail and proportion, and the latter built large engines of this type, attaining a duty of 9,500,000. Smeaton says that he had seen engines with cylinders 75 in. in diameter. His largest was 72 in., and its power that of 150 horses "acting together." James Watt, an instrument maker at the university of Glasgow, when repairing a model Newcomen engine (fig. 2) in 1763, began a series of improvements which finally rendered the steam engine universally applicable. To avoid losses of heat in the steam cylinder, which he estimated to amount to three fourths of all supplied, he attached (1765) the separate condenser, thus saving also three fourths of the injection water needed in the Newcomen engine. He first tried surface condensa-

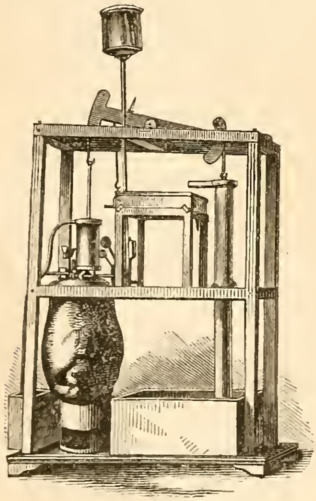

FIG. 2.—Newcomen Engine Model.

tion, but soon adopted the jet condenser and air pump. The piston had previously been kept from leaking by flooding it from above with water. Watt substituted oil and tallow. He closed the top with a cylinder head, passing the piston rod through a "stuffing box" to prevent leakage about it, and admitting steam above the piston, instead of air, during the down stroke, thus avoiding the cooling effect of the atmosphere. He then protected the cylinder by non-conducting coverings to intercept the heat previously lost by radiation from its exterior, and applied the "steam jacket," introducing a space intermediate between the cylinder and the external covering, in which space steam was retained. He thus converted the atmospheric steam engine of Newcomen into the type known as the engine of Watt. The firm of Boulton and Watt began building these engines at Soho, near Birmingham, in 1775. Watt proposed to secure economy of steam by its expansion in 1769, and in 1776 he adopted a form of cut-off which was patented in 1782. His later pumping engines attained a duty of 20,000,000. The crank and fly wheel were patented by Wasborough in 1781, and Watt adopted the "sun and planet wheels" as the next best expedient for obtaining rotary motion, and applied them in his double-acting engine patented July 4, 1782. This engine is shown in fig. 3, with the parallel motion, governor, and other details patented in 1784. Admitting steam and condensing on both sides of the piston, the power of the engine was doubled. Jonathan Hornblower in 1781 patented a compound or double cylinder engine, in which the steam used at high pressure in one cylinder was exhausted into a second, whence, after acting expansively and with reduced pressure, it was discharged. Woolf in 1804 patented the combination of this engine with the Watt condenser, and a few such engines were built. Oliver Evans devised in 1779 the high-pressure non-condensing steam engine. He introduced it into saw and grain mills, and applied it to the propulsion of vessels and locomotives. It still remains the most commonly used of all forms of the steam engine. Trevithick and Vivian introduced engines built on Evans's plan into Great Britain in 1802, which carried occasionally 60 to 80 lbs. of steam pressure. Col. John Stevens of Hoboken, N. J., built the direct-acting, high-pressure, and condensing engine, with a sectional steam boiler, in 1804. Joseph Dixon coupled two engines with cranks at right angles in 1823. The detachable, adjustable, or drop cut-off valve gear was patented by Frederick E. Sickels of New York in 1842, and the application of the governor to determine the point of cut-off was made by Zachariah Allen and George H. Corliss of Rhode Island, and patented by the latter in 1849. This completed the growth in general design of the now distinctive American expansive steam engine. Recently the revival of the double cylinder engine, with high steam, considerable expansion, and rapid motion of piston, which have proved economically successful, has been the only marked feature of this branch of engineering progress. It is estimated that the total steam power of the world is about 15,000,000 horse power, and that were horses actually employed to do the work which these engines would be capable of doing were they kept constantly in operation, the number required would exceed 60,000,000.—*Form of the Steam Engine.* In all engines the principal organs of the machine are present, but their forms and proportions, and their arrangement, differ greatly in different classes. In general, the piston, P, fig. 3, is accurately fitted into a steam cylinder, C, within which it moves from end to end with slight friction, and without permitting the escape of steam past its edges. The piston rod is attached at one end to this piston, and, passing through the cylinder head,

is attached at the other extremity to a cross head, which is so guided that it is compelled to move in a vertical line, and thus a side strain upon the rod which would produce friction and leakage, even were it not to cause actual bending and fracture, is prevented. In fig. 3 the

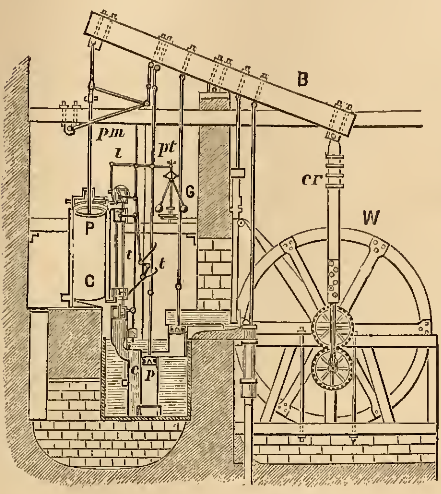

Fig. 3.—Watt's Engine, 1784.

cross head is guided by a parallel motion *p m*, an arrangement of rods of which one set vibrate about centres, thus displacing the centres of vibration of the other set just sufficiently to compensate the tendency of the latter to throw the cross head out of line by their sweep through their own curved path. This compensation permits the head of the piston rod to be securely guided in the vertical line. In later practice, a more common method of obtaining a rectilinear motion of the cross head is to place guides at each end of it, by which its extremities are kept in the desired line of motion. The sliding friction of the cross-head gibs upon these guides is slight, and is kept within proper limits by lubrication. The cross head is connected with the working beam, B, by links (usually a pair), and the beam, vibrating about the main centre, transfers the motion by means of the connecting rod, *c r*, to the crank attached to the main shaft or crank shaft, which carries the fly wheel or balance wheel, W. In this figure the crank is not shown, the sun and planet wheels taking its place. Steam is conveyed to the engine by the steam pipe, at some convenient point in which a stop valve is usually placed. Sometimes this valve is omitted, a throttle valve alone being used, adapted to adjust the supply of steam. The latter is either a disk valve, adjusted by a screw (in which form it is known as a screw stop valve), or it is some variety of slide valve, opening and closing by sliding transversely across the opening through which steam passes. Where the supply of steam is determined automatically, a governor, G, is attached, which when the speed of the engine tends to exceed the desired maximum closes the throttle valve, and when the speed falls too low opens it. In the figure, the governor consists of a pair of suspended balls caused to revolve by a belt, or by gearing connecting the spindle with the shaft, which when speed rises are given a high velocity of revolution about the spindle carrying them, and, separating under the action of centrifugal force, move the lever *l*, and thus close the throttle valve. There are many varieties of governors. The "fly-ball governor," just described, is most common, but, though simple and quite well adapted to general purposes, it is not perfectly isochronous; *i. e.*, it does not compel the engine to keep the precise speed at which it is set to work. As the governor and valve are rigidly connected, there is but one speed to which the position of the valve and of the governor can be perfectly adapted under any one set of conditions of steam pressure and of load. The valve gear is the system of valves and of actuating mechanism which distribute the steam as the engine passes through its cycles of motion. The steam valves admit steam alternately to each end of the steam cylinder, as the piston moves backward and forward, and the exhaust valves alternately open and close the passages or ports through which the steam escapes, after impelling the piston, into the condenser *c* in the condensing engine, or into the open air from a non-condensing engine. These valves are moved automatically by some part of the engine itself. In the kind of engine shown in fig. 3, and in pumping engines which have no crank and revolving shaft, the motion is obtained from a rod depending from the beam, projections on which rod strike the tappets *t* as they rise and fall. This rod is called the plug rod. In nearly all other engines, the valve gear is actuated by an eccentric, or disk attached to and revolving with the crank shaft. While the piston is moving upward, the steam valve below and the exhaust valve above are open, the steam entering below to drive the piston up, while the steam which had produced the downward stroke escapes through the open exhaust valve at the top into the condenser. During the descent of the piston these conditions are reversed. The condenser may be either a jet condenser, as shown in the figure, or a surface condenser. Its office is to condense the steam ejected from the cylinder, and thus to create a vacuum, so removing the resisting pressure of the atmosphere from before the piston. With the jet condenser, the steam issuing from the exhaust pipe of the engine is received in a closed vessel, where it is brought into contact with jets of cold water, and thus instantly condensed, and the vacuum so produced pervades the condenser, the exhaust pipe, and the exhausted end of the cylinder. The water of condensation, the re-

maining uncondensed vapor, and any air which may enter the condenser with the steam, are removed by the air pump *p*, and thrown into the hot well above the condenser whence they are taken by the hot water pump and discharged. Water is also taken from the hot well by the feed pump and fed to the steam boiler. —*Classification of Engines.* Steam engines are designated as condensing or non-condensing, according as they are furnished with a condenser or as that detail is omitted. They are high pressure or low pressure, the former term being applied to engines supplied with steam of 50 lbs. pressure to the square inch and upward, and the latter to engines working under 40 lbs. pressure. The latter are almost invariably condensing engines, and high-pressure engines are very generally non-condensing. Reciprocating engines have pistons moving backward and forward in the steam cylinder, as in Watt's engine. When they turn a shaft, they are sometimes called rotative. Rotary engines have a piston attached to a shaft and revolving with it within a cylinder of which the axis is parallel with the axis of rotation of the piston or vane. Engines are direct-acting where the piston rod acts directly upon the connecting rod, and through it upon the crank, without the intervention of a beam or lever. In back-acting or return connecting rod engines, the shaft lies between the cylinder and the cross head, the connecting rod returning from the cross head to the crank. Beam engines have the working beam already described. Side lever engines have two beams, one on each side of the steam cylinder, and below instead of above the cross head. Oscillating engines have their piston rods attached directly to the crank pin, and as the crank revolves the cylinder oscillates upon trunnions, one on each side of it, through which the steam enters and leaves the steam chest. The valves are within the steam chest, oscillating with the cylinder. In these engines the mechanism actuating the valves is seldom perfectly satisfactory in its operation. In compound or double-cylinder engines, the steam enters first a high-pressure cylinder, and there usually expands from its initial pressure of from 60 to 100 lbs. down to a much lower density; it is then exhausted into a second steam cylinder, in which it expands still further while completing its work.—Engines are also classified, according to the use for which they are intended, as stationary, pumping, portable, locomotive, or marine engines. The locomotive engine is the simplest form. In it the condenser and the governor are dispensed with, and the valve and its gearing are the simplest possible. The portable engine is usually very similar to the locomotive, and, like the latter, is attached to its steam boiler. It is sometimes provided with a heater to warm the feed water sent into the boiler, and is frequently provided with a governor. It is usually mounted on wheels. Both the locomotive and the portable engine employ high steam pressure without condensation. In both of these forms of engine are secured to the fullest extent lightness and simplicity, and, where properly constructed, cheapness, durability, compactness, and fair efficiency. Draft is usually secured in both by the blast of the exhaust steam. Engines of this class have attained the remarkable economical result of a horse power developed with the expenditure of less than three pounds of coal per hour.—The oldest form of pumping engine still retained in use is the Cornish. In it the crank shaft and balance wheel are dispensed with, the end of the pump rod being attached directly to the end of the beam opposite the steam cylinder. Steam is first admitted above the piston, driving it rapidly downward and raising the pump rod. At an early point in the stroke the admission of steam is checked by the sudden closing of the induction valve, and the stroke is completed under the action of expanding steam assisted by the inertia of the heavy parts already in motion. The necessary weight and inertia is afforded in many cases, where the engine is applied to the pumping of deep mines, by the immensely long and heavy pump rods. Where this weight is too great it is counterbalanced, and where too small, weights are added. When the stroke is completed, the "equilibrium valve" is opened, and the steam passes from above to the space below the piston, and an equilibrium of pressure being thus produced, the pump rods descend, forcing the water from the pumps and raising the steam piston. The absence of the crank or other device which might determine absolutely the length of stroke compels a very careful adjustment of steam admission to the amount of load. Should the stroke be allowed to exceed the proper length, and should danger thus arise of the piston striking the cylinder heads, the movement is checked by buffer beams. The valve motion is actuated by a plug rod, as in Watt's engine. The regulation is effected by a "cataract," a kind of hydraulic governor, consisting of a plunger pump with a reservoir attached. The plunger is raised by the engine, and then automatically detached. It falls with greater or less rapidity, its velocity being determined by the size of the eduction orifice, which is adjustable by hand. When the plunger reaches the bottom of the pump barrel, it disengages a catch, a weight is allowed to act upon the steam valve, opening it, and the engine is caused to make a stroke. When the outlet of the cataract is nearly closed, the engine stands still a considerable time while the plunger is descending, and the strokes succeed each other at long intervals. When the opening is greater, the cataract acts more rapidly, and the engine works faster. This has been regarded until recently as the most economical of pumping engines, and it is still generally used in freeing mines of water, and in situations where existing heavy pump rods may be utilized in con-

tinuing the motion of the piston during that portion of its stroke which is performed after expansion has begun. The direct-acting steam pump is sometimes used as a pumping engine. (See PUMP.) The compound pumping engine has been recently adopted with great success.

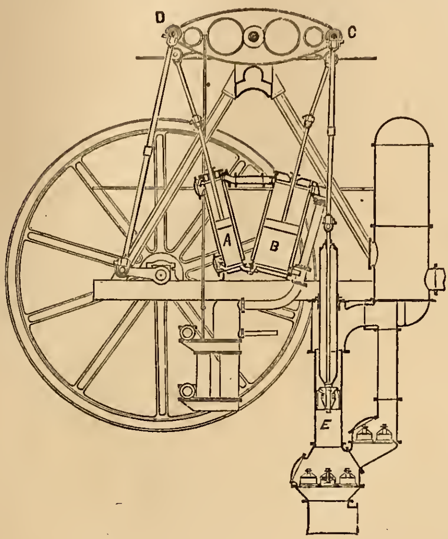

FIG. 4.—Leavitt's Pumping Engine.

One of the most efficient forms is that designed by E. D. Leavitt, jr., for the Lynn (Mass.) water works, and shown in fig. 4. The two cylinders, A and B, are placed one on each side the centre of the beam C D, and are so inclined that they may be coupled to opposite ends of it, while their lower ends are placed close together. At their upper ends a valve is placed at each end of the connecting steam pipe. At their lower ends a single valve serves as exhaust valve to the high-pressure and as steam valve to the low-pressure cylinder. The pistons move in opposite directions, and steam is exhausted from the high-pressure cylinder A directly into the nearer end of the low-pressure cylinder B. The pump, E, of the "Thames-Ditton" or "bucket and plunger" variety, takes a full supply of water on the down stroke, and discharges half when rising and half when descending again. The duty of this engine is reported by a board of engineers as 103,923,215 foot pounds for every 100 lbs. of coal burned. The duty of a moderately good engine is usually considered to be from 60 to 70 millions. This engine has steam cylinders of $17\frac{1}{2}$ and 36 in. diameter respectively, with a stroke of 7 ft. The pump had a capacity of about 195 gallons, and delivered 96 per cent. Steam was carried at a pressure of 75 lbs. above the atmosphere, and was expanded about ten times. Plain horizontal tubular boilers were used, evaporating 8·58 lbs. of water from 98° F. per pound of coal.—The stationary steam engine has a great variety of forms. Since compactness and lightness are not as essential as in portable, locomotive, and marine engines, the parts are arranged with a view simply to securing efficiency, and the design is determined by circumstances. It was formerly usual to adopt the condensing engine in mills and wherever a stationary engine was required. In Europe generally, and to some extent in the United States, where a supply of condensing water is obtainable, condensing engines and moderate steam pressures are still employed. But this engine is gradually becoming superseded by the high-pressure condensing engine, with considerable expansion, and with an expansion gear in which the point of cut-off is determined by the governor. The best known engine of this class is the Corliss engine, which is very extensively used in the United States, and which has been copied very generally by European builders. Fig. 5 represents the Corliss engine as built in the United States by Harris. The horizontal steam cylinder is bolted firmly to the end of the frame, which is so formed as to transmit the strain to the main journal with the greatest directness. The frame carries the guides for the cross head, which are both in the same vertical plane. The valves are four in number, a steam and an exhaust valve being placed at each end of the steam cylinder. Short steam passages are thus secured, and this diminution of clearance is a source of some economy. Both sets of valves are driven by an eccentric operating a disk or wrist plate, which vibrates on a pin projecting from the cylinder. Short links reaching from this wrist plate to the several valves move them with a peculiarly varying motion, opening and closing them rapidly, and moving them quite slowly when the port is either nearly open or almost closed. This effect is ingeniously secured by so placing the pins on the wrist plate that their

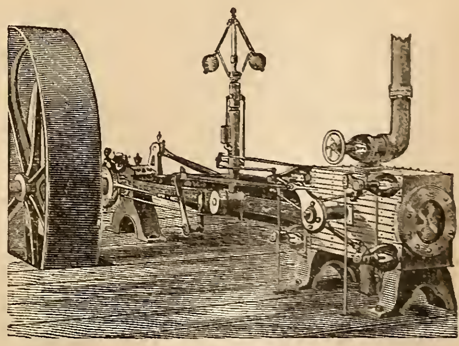

FIG. 5.—Corliss Engine.

line of motion becomes nearly transverse to the direction of the valve links when the limit of movement is approached. The links connecting the wrist plate with the arms moving the steam valves have catches at their extremities, which are disengaged by coming in con-

tact, as the arm swings around with the valve stem, with a cam adjusted by the governor. This adjustment permits the steam to follow the piston further when the engine is caused to "slow down," and thus tends to restore the proper speed. It disengages the steam valve earlier, and expands the steam to a greater extent, when the engine tends to run above the proper speed. When the catch is thrown out, the valve is closed by a weight or a strong spring. To prevent jar when the motion of the valve is checked, a "dash pot" is used, invented by F. E. Sickels. It is a vessel having a nicely fitted piston, which is received by a "cushion" of water or air when the piston suddenly enters the cylinder at the end of the valve movement. In the original water dash pot of Sickels, the cylinder is vertical, and the plunger or piston descends upon a small body of water confined in the base of the dash pot. In the Greene steam engine, fig. 6, the valves are four in number, as in the Corliss. The cut-off gear consists of a bar, A, moved by the steam eccentric in a direction parallel with the centre line of the cylinder and nearly coincident as to time with the piston. On this bar are tappets, C C, supported by springs and adjustable in height by the governor, G. These

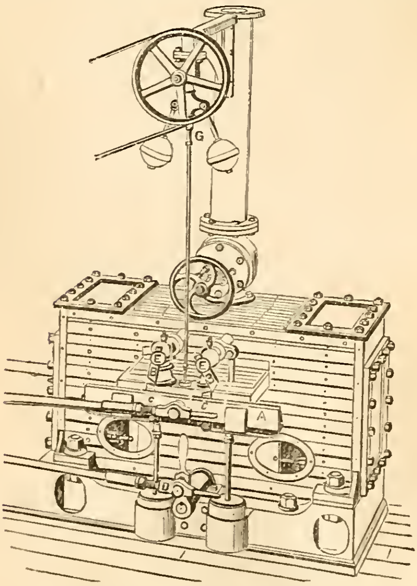

Fig. 6.—Greene Engine.

tappets engage the arms B B, on the ends of rock shafts E E, which move the steam valves and remain in contact with them a longer or shorter time, and opening the valve during a greater or less part of the piston stroke, as the governor permits the tappets to rise with diminishing engine speed, or forces them down as speed increases. The exhaust valves are moved by an independent eccentric rod, moved by an eccentric set, as is usual with the Corliss and with other engines generally, at right angles with the crank. This engine, in consequence of the independence of the steam eccentric, and of the contemporary movement of steam valve motion and steam piston, is capable of cutting off at any point from beginning to nearly the end of the stroke. The usual arrangement, by which steam and exhaust valves are moved by the same eccentric, only permits expansion with the range from the beginning to half stroke. The Wright engine has an adjustable expansion valve gear also, and the point of cut-off is determined by the governor. In this machine the steam valves are opened by a cam of such form that when the cam shaft is moved longitudinally, the valve is held open a longer or a shorter time. The position of the cam shaft is adjusted by the governor. Its motion is obtained by gearing it to the main shaft. The Babcock and Wilcox engine has a cut-off valve on the back of the main valve, which is moved by a small steam cylinder. The point of cut-off is determined by the governor also, by varying the time of admission of steam into the auxiliary cylinder. This engine has the same latitude of expansion as the Greene engine.—The characteristics of the American stationary engine are high steam pressure without condensation, an expansion valve gear with drop cut-off adjustable by the governor, high piston speed, and lightness combined with strength of construction. In other countries this engine is now rapidly coming into general use, but abroad the valve most generally adopted is the form usual in other styles of engine, expansion being obtained by a cut-off valve on the back of the main valve, and regulation secured by attaching the governor to a throttle valve.—*The Marine Steam Engine.* Marine engines have a great variety of forms, but general practice has now indicated a few which are preferred. They are almost invariably fitted with condensers. Until recently they were usually driven by steam of moderate pressure, but within a few years the pressure of steam, which in the time of Watt was usually from 5 to 10 lbs. above the atmosphere, has risen to 60 lbs. In the earlier days of steam navigation, the paddle wheel was exclusively used. Recently the screw has become the sole instrument of propulsion, where deep water permits its use. In shallow water the paddle wheel is still employed. Marine engines are therefore divided into paddle engines and screw engines. —The most common forms of paddle engines in the United States are the overhead beam engine, driven by steam of from 20 to 50 lbs. pressure, and fitted with a jet condenser, and the high-pressure and non-condensing direct-acting engine, used principally on the western rivers. The latter is driven by steam of from 100 to 150 lbs. pressure, and exhausts its steam into the atmosphere. It is the simplest possible form of direct-acting engine. The valves

are of the disk or poppet variety, rising and falling vertically. They are four in number, two steam and two exhaust valves being placed at each end of the steam cylinder. The beam engine is a peculiarly American type, seldom if ever seen abroad. Fig. 7 is an outline sketch of this engine as built for a steamer plying on the Hudson river. This class of engine is usually adopted in vessels of great length, light draught, and high speed. But one steam cylinder is commonly used. The cross head is coupled to one end of the beam by means of a pair of links, and the motion of the opposite end of the beam is transmitted to the crank by a connecting rod of moderate length. The beam has a cast-iron centre surrounded by a wrought-iron strap of lozenge shape, in which are forged the bosses for the end centres, or for the pins to which the connecting rod and the links are attached. The main centre of the beam is supported by a "gallows frame" of timbers so arranged as to receive all stresses longitudinally. The crank and shaft are of wrought iron. The valve gear is usually of

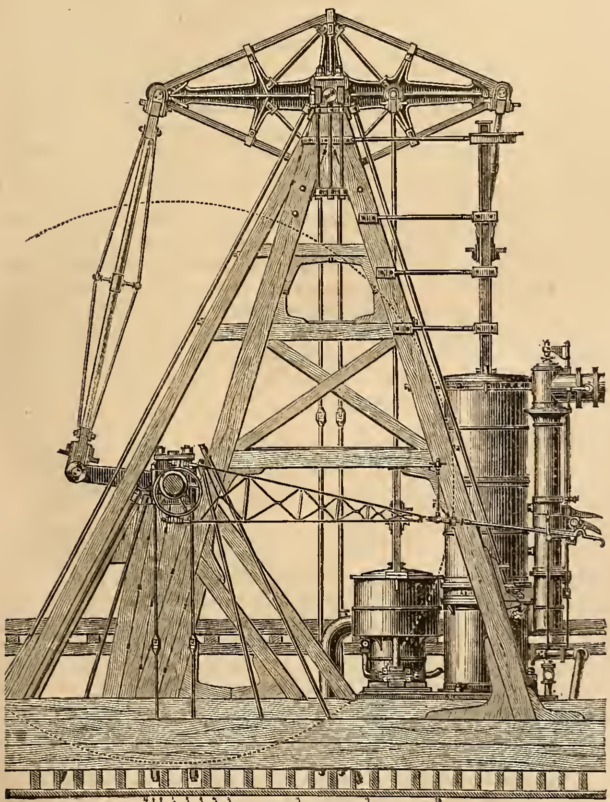

Fig. 7.—Beam Engine.

the form known as the Stevens valve gear an invention of Robert L. and Francis B. Stevens. The steam and exhaust valves are worked by independent eccentrics, the latter being set in the usual manner, opening and closing the exhaust passages just before the crank passes its centre. The steam eccentric is so placed that the steam valve is opened as usual, but closed when but about one half the stroke has been made. This result is accomplished by giving the eccentric a greater throw than is required by the motion of the valve, and permitting it to move through a portion of its path without moving the valve. Thus in fig. 8, if A B be the direction of motion of

Fig. 8.

the eccentric rod, the valve would ordinarily open the steam port when the eccentric assumes the position O C, closing when the eccentric has passed around to O D. With the Stevens valve gear, the valve is opened when the eccentric reaches O E, and closes when it arrives at O F. The steam valve of the opposite end of the cylinder is open while the eccentric is moving from O M to O K. Between K and E, and between F and M, both valves are seated. H B is proportional to the lift of the valve, and O H to the motion of the valve gear when out of contact with the valve lifters. While the crank is moving through an arc E F, steam is entering the cylinder; from F to M the steam is expanding. At M the stroke is completed and the other steam valve opens. The ratio $\frac{EO}{EM}$ is the ratio of expansion. The condenser is placed immediately beneath the steam cylinder. The air pump is placed close beside it, and worked by a rod attached to the beam. Steam vessels on the Hudson river have been driven by such engines at the rate of 23 m. an hour. This form of engine is remarkable for its smoothness of operation, its economy and durability, its compactness, and the latitude which it permits in the change of shape of the long flexible vessels in which it is generally used, without injury by "getting out of line." For paddle engines of large vessels, the favorite type has been the side lever engine, which is now rarely built. For smaller vessels, the oscillating engine with feathering paddle wheels is still largely employed in Europe. This style

of engine is shown in fig. 9. It is very compact, light, and moderately economical, and excels in simplicity. The feathering paddle wheel is made with floats or buckets variable in position, and so adjusted by the feathering mechanism that less power is expended in ob-

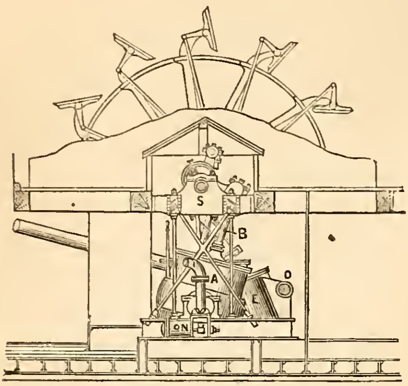

FIG. 9.—Oscillating Engine and feathering Paddle Wheel.

lique action, raising or pushing downward the water impinged upon, than with the ordinary radial wheel, in which the floats are rigidly attached to the arms. The usual arrangement is such that the feathering wheel has the same action upon the water as a radial wheel of double diameter. This reduction of the diameter of the wheel, while retaining maximum effectiveness, permits a high speed of engine, and therefore less weight, volume, and cost. The smaller wheel boxes, by offering less resistance to the wind, retard the progress of the vessel less than those of radial wheels. The feathering of the paddle is produced by the use of a rod, E D, fig. 10, which connects an eccentric strap, E F, secured to the vessel, with the short arm A D, by which the paddle is turned upon the pin A. C is the centre of the paddle wheel, and C B is one of the arms. Circular hoops, or bands, connect all of the arms, each of which carries a float. They are all thus tied together, forming a very firm and powerful combination to resist external forces. Inclined engines are sometimes used for driving paddle wheels. In these the steam cylinder lies in an inclined position, and its connecting rod directly connects the crank with the cross head. The condenser and air pump usually lie beneath the cross-head guides, and are worked by a bell crank driven by links on each side the connecting rod, attached to the cross head. Such engines are used to some extent in Europe, and they have been adopted in the United States navy for side-wheel gunboats. They are also used on the ferry boats plying between New York and Brooklyn. Paddle wheels should be immersed usually not more than one third the radius of the wheel for sea-going vessels, and on rivers they are frequently not immersed more than one sixth or one eighth. In the first case the loss by oblique action is about 5 per cent., in the last case about 10 per cent. A loss of 20 or 25 per cent. of the total power applied to the wheel is frequently caused by slip.—Many forms of engines have been used for driving the screw, but they are now almost invariably of one type. The ordinary screw engine is direct-acting. Two engines are placed side by side, with cranks on the shaft at an angle of 90 degrees with each other. In merchant steamers the steam cylinders are usually vertical and directly over the crank pins, to which the cross heads are coupled. The condenser is placed behind the engine frame, or, where a jet condenser is used, the frame itself is sometimes made hollow and serves as a condenser. The air pump is worked by a beam connected by links with the cross head. The general arrangement is like that shown in figs. 13 and 14. For naval purposes such a form is objectionable, since its height is so great that it would be exposed to injury by shot. In naval engineering the cylinder is placed horizontally, as in fig. 11, which is a sectional view, representing a horizontal, direct-acting naval screw engine, with jet condenser and double-acting air and circulating pumps. A is the steam cylinder, B the piston, which is connected to the crank pin by the piston rod D and connecting rod E. F is the cross-head guide. The eccentrics G operate the valve, which is of the "three-ported variety," by a Stephenson link.

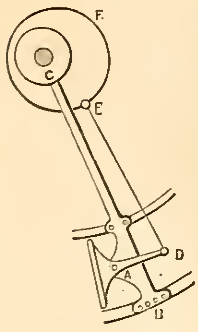

FIG. 10.

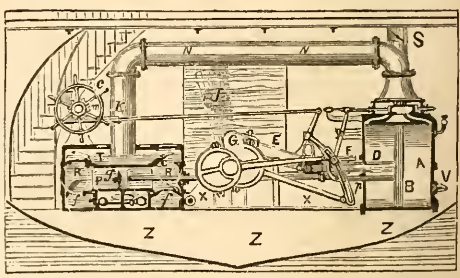

FIG. 11.—Horizontal direct-acting Naval Screw Engine.

Reversing is effected by the hand wheel C, which by means of a gear $m$ and a rack $k$ elevates and depresses the link, and thus reverses the valve. As shown in the sketch, this valve is so constructed that, when in precisely the middle of its path, it covers both steam ports as well as the exhaust port. When it is moved to the right, the forward steam port is opened

and the engine takes steam at the end D, while the steam from the opposite side of the piston, A, is allowed to pass out under the valve and off through the exhaust port. The valve is shown in this position in the figure. When the eccentric has turned with the shaft, or when the link is shifted so as to bring the end *p* into action and thus communicate the motion of the other eccentric to the valve, steam enters at the end A and is exhausted from D. Each eccentric produces this change in such a manner that when the piston reaches the end of its stroke this reversal occurs, and the steam and exhaust ports are opened and closed in the manner required to produce the proper distribution of steam. One eccentric is adjusted to give the correct distribution when the engine is moving ahead, the other when worked backward. When it is desired to produce a limited amount of expansion of steam, the exterior edges of the face of the valve are carried further apart, and the valve when in mid-position overlaps the steam ports. The throw of the eccentrics is then correspondingly increased, and they are moved upon the shaft until they can be secured in new positions in which they bring the edge of the valve to the edge of the port opening as before, admitting steam at the beginning of the stroke. By this process, which is termed giving lead to the valve, the exhaust port is also both opened and closed earlier than before. To remedy this fault, the edges of the interior of the valve are sometimes changed also, and they are given "lap" in either position, as on the steam side or negative. In the latter case they are moved further apart. Zeuner's valve diagram, fig. 12, is a useful graphic representation of the action of this valve. Let A B represent the path of the piston, A O, B O being the positions of the crank at each end of the stroke. Then E O, F O will be the positions of the crank when the

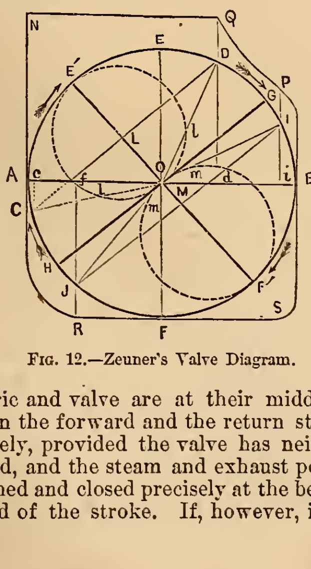

Fig. 12.—Zeuner's Valve Diagram.

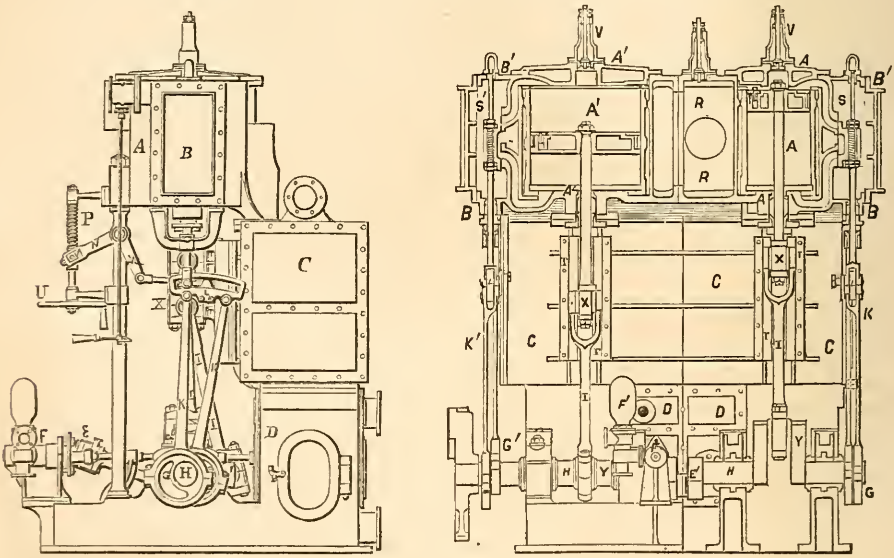
eccentric and valve are at their middle positions on the forward and the return stroke respectively, provided the valve has neither lap nor lead, and the steam and exhaust ports will be opened and closed precisely at the beginning and end of the stroke. If, however, it is desired to open the steam port when the crank is at C and the piston at *c*, approaching A, and if the steam is to be cut off and expansion to begin when the crank is at D and the piston at *d*, on the forward stroke, the valve must be at "half throw" when the crank is at E′ midway between A and D. E′ O, F′ O will then be the positions of the crank when the valve is at mid throw on the forward and return stroke respectively. While the crank is moving from D to G the valve must continually cover the port which has remained open from A to D. The distances E′ L, L O are thus proportional to the motion of the valve while the port is opened and closed respectively, and $\frac{\mathrm{L\,O}}{\mathrm{E'\,O}}$ measures the lap. H O A is the "angular advance," or the distance by which the eccentric must precede its normal position E to insure the desired distribution of steam. A circle E *l* O being inscribed, the distance O *l* also measures the lap. Similarly, if the exhaust port is to be opened at I, it must close at J, and the steam is confined and "cushioned" behind the piston as the crank moves from J to A. O M or O *m* measures the "exhaust lap." The figure N Q P S R A N is the indicator diagram corresponding to such a distribution of steam, the steam pressure being maintained from N to Q, expansion occurring from Q to P, exhaust taking place at P, and S R being the line of back pressure on the return stroke. Cushioning takes place at R, and the steam being admitted immediately afterward, the pressure rises again to its maximum at N. This valve and gear only permits a very limited range of expansion in consequence of the seriously objectionable effect of the accompanying alteration of the exhaust. A separate expansion valve, moved by an independent eccentric, is usually placed between the steam pipe, S, fig. 11, and the main valve. The piston of the air pump, P, and the circulating pump, where a surface condenser is used, are driven by a rod *p* R from the main piston. The valves *f f* admit the water, and *c c* are the delivery valves. The pump is represented as just making a stroke from left to right. Steam is exhausted from the cylinder A through the exhaust pipe N N to the condenser, and when condensed falls to the bottom, whence the water of condensation is raised by the air pump and forced overboard through a delivery pipe and valve not shown. A portion of the stern of the vessel is represented as torn away to show the screw J. A strong and stiff main frame, X X, unites the cylinders with the condenser and also supports the main shaft journal at G. The whole is firmly secured by bolts to the cross floors of the vessel, Z Z, if of iron, or to engine keelsons if of wood. A spring water valve, V, is placed on the cylinder head to allow water which may enter the cylinder with the steam to be forced out without endangering the cylinder or the heads, as it might were

it caught there on the return of the piston. The trunk engine, in which the connecting rod is attached directly to the piston and vibrates within a trunk or cylinder secured to the piston, moving with it, and extending outside the cylinder, like an immense hollow piston rod, is frequently used in the British navy. It has rarely been adopted in the United States. —In nearly all steam vessels which have been built for the merchant service recently, and in some naval vessels, the compound engine has been adopted. Figs. 13 and 14 represent the usual form of this engine. Here A A, A′ A′ are the small and the large, or the high-pressure and the low-pressure cylinders respectively. B B′ are the valve chests. C C C is the condenser, which is invariably a surface condenser. The condensing water is sometimes directed around the tubes contained within the casing C C C, while the steam is exhausted around them and among them, and sometimes the steam is condensed within the tubes, while the injection water which is sent into the condenser to produce condensation passes around the exterior of the tubes. In either case, the tubes are usually of small diameter, varying from five eighths to half an inch, and in length from four to seven feet. The extent of heating surface is usually from one half to three fourths that of the heating surface of the boilers. The air and circulating pumps, D D, are placed on the lower part of the condenser casting, and are operated by a crank on the main shaft at E′; or they are sometimes placed as in the style of engine last described, and driven by a beam worked by the cross



Side Elevation. Front Elevation.

Figs. 13 and 14.—Compound Marine Engine.

head. The piston rods are guided by the cross heads X X working in slipper guides T T, and to these cross heads are attached the connecting rods I I, driving the cranks Y Y. The cranks are now usually set at right angles; in some engines this angle is increased to 120°, or even 180°. Where it is arranged as here shown, an intermediate reservoir, R R, is placed between the two cylinders to prevent the excessive variations of pressure that would otherwise accompany the varying relative motions of the pistons, as the steam passes from the high-pressure to the low-pressure cylinder. Steam from the boilers enters the high-pressure steam chest S, and is admitted by the steam valve alternately above and below the piston as usual. The exhaust steam is conducted through the exhaust passage around into the reservoir R, whence it is taken by the low-pressure cylinder, precisely as the smaller cylinder drew its steam from the boiler. From the large or low-pressure cylinder the steam is exhausted into the condenser. The valve gear is usually a Stephenson link, L, the position of which is determined, and the reversal of which is accomplished, by a hand wheel U and screw P, which, by the bell crank N M, are attached to the link L L.—*The Screw.* Screw steamers are far more efficient than paddle-wheel vessels, not only because the screw is a better instrument of propulsion, but because it permits the use of more efficient machinery, and especially because it utilizes a large amount of energy entirely wasted with the paddle wheel in putting in motion the water, which latter, coming into contact with the hull of the vessel, is set in motion by friction, and the following current is left behind to expend its *vis viva* by

contact with the surrounding mass of water. The currents so produced, in the case of screw vessels, impinge upon the screw, which works immediately astern of the vessel, and communicate to it a portion of that energy which would otherwise be lost in the creation of such currents. Screws work far below the surface of the water, and lose less by slip than the paddle wheel. Screw engines are quick-working, compact, and light. Their higher piston speed, their smaller size, and especially their more uniform action upon the propeller and the water, produce greater economy in the use of steam and a more effective application of power than is obtained with the paddle wheel. Incidentally, by permitting the replacing of a considerable weight of machinery and fuel by paying freight, they add greatly to the commercial value of the steam vessel. The forms of screws are exceedingly diverse, but those in common use are not numerous. In naval vessels it is common to apply screws of two blades, that they may be hoisted above water into a "well" when the vessel is under sail, or set with the two blades directly behind the stern post, when their resistance to the forward motion of the vessel will be comparatively small. In other vessels, and in the greater number of full-powered naval vessels, screws of three or four blades are used. The usual form of screw has blades of nearly equal breadth from the hub to the periphery, or slightly widening toward their extremities, as is seen in an exaggerated degree in fig. 15, representing the form adopted for tug-boats, where large surface near the extremity is more generally used than in vessels of high speed running free. In the Griffith screw, which has been much used, the hub is globular and very large. The blades are secured to the hub by flanges, and are bolted on in such a manner that their position may be

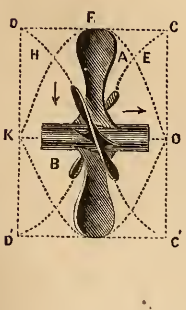


Fig. 15.—Tug-boat Screw.

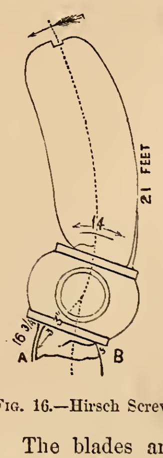

Fig. 16.—Hirsch Screw.

changed slightly if desired. The blades are shaped like the section of a pear, the wider part being nearest the hub, and the blades tapering rapidly toward their extremities. A usual form is intermediate between the last and that shown in fig. 15, the hub being sufficiently enlarged to permit the blades to be attached as in the Griffith screw, but more nearly cylindrical, and the blades having nearly uniform width from end to end. The Hirsch screw, fig. 16, is used on the steamship City of Peking. The pitch of a screw is the distance which would be traversed by the screw in one revolution were it to move through the water without slip; *i. e.*, it is double the distance C′ D, fig. 15. C D′ represents the helical path of the extremity of the blade B, and O E F H K is that of the blade A. The proportion of diameter C C′ to the pitch of the screw is determined by the speed of the vessel. For low speed the pitch may be as small as one and one fourth the diameter. For vessels of high speed the pitch is frequently double the diameter. The diameter of the screw is made as great as possible, since the slip decreases with the increase of the area of screw disk. Its length is usually about one sixth the diameter. A greater length produces loss by increase of surface causing too great friction, while a shorter screw does not fully utilize the resisting power of the cylinder of water within which it works, and increased slip causes waste of power. Negative slip occurs when the vessel moves at a higher speed than it would attain were the screw to work in a solid nut; it is sometimes observed in badly formed vessels. The slip is decreased by increasing the diameter, and also by increasing the length of the screw. The increased friction above referred to prevents the latter process from being economically carried beyond the maximum given. An empirical value for the probable slip in vessels of good shape, which is closely approximate usually, is given by Prof. Thurston as $S=4\frac{M}{A}$, in which S is the slip per cent., and M and A are the areas of the midship section and of the screw disk in square feet. The most effective screws have slightly greater pitch at the periphery than at the hub, and an increasing pitch from the forward to the rear part of the screw. The latter method of increasing pitch is more generally adopted alone. The thrust of the screw is the pressure which it exerts in driving the vessel forward. In well formed vessels, with good screws, about two thirds of the power applied to the screw is utilized in propulsion, the remainder being wasted in slip and other useless work. Its efficiency is in such a case, therefore, 66 per cent. Twin screws, one on each side of the stern post, are sometimes used in vessels of light draught and considerable breadth, whereby decreased slip is secured. The following are the dimensions of some of the largest marine screw engines of the well known types. The engines of the British iron-clad Monarch, a vessel of over 8,000 tons displacement, have given an "indicated power" of 8,528 horses at 65 revolutions a minute, when making a speed

of about 15 knots or $17\frac{1}{2}$ statute miles an hour. The steam pressure was 25 lbs. These engines are horizontal, and have steam cylinders 120 in. in diameter, and $4\frac{1}{2}$ ft. stroke of piston; the pistons weigh 8 tons each. The surface condensers contain 16,500 sq. ft. of condensing surface, the tubes being $\frac{5}{8}$ in. diameter, and 6 ft. long. The propelling power is a two-bladed Griffith screw, $23\frac{1}{3}$ ft. diameter, $26\frac{1}{3}$ ft. mean pitch, expanding 5 ft. The valves are moved by a link motion, of which the reversing gear is worked by a small steam reversing engine, which weighs about 350 tons; the boiler weighs nearly as much more. The cost of engines and boiler was £66,500. The City of Peking, a screw steamer built for the Pacific mail company, is a vessel of 5,000 tons. There are two pairs of compound engines, having cylinders of 51 and 88 in. diameter, and $4\frac{1}{2}$ ft. stroke of piston. The crank shafts are 18 in. in diameter. Steam is carried at 60 lbs., and is expanded nine times. The boilers are ten in number, cylindrical in form and with cylindrical flues; they are 13 ft. in diameter, $10\frac{1}{2}$ ft. long, with shells of iron $\frac{13}{16}$ in. thick, and have 520 ft. of grate surface, 16,500 sq. ft. of heating surface, and 1,600 sq. ft. of superheating surface. The smoke funnels, or stacks, are $8\frac{1}{2}$ ft. in diameter and 70 ft. high.—*Steam Pressure and Engine Power.* The steam in the engine exerts a varying pressure from the beginning to the end of the stroke, and these pressures may be determined experimentally by the use of the steam engine indicator. The best form now in general use is the Richards indicator, fig. 17. A miniature steam cylinder, A, has within it a closely fitted piston, which by exceedingly nice construction is made to work perfectly steam-tight without friction or leakage. Its rod B is attached to the parallel motion C D E F, which carries a pencil at the middle of F in a perfectly vertical line. To the upper side of this piston and to the cap V of the cylinder is screwed a helical steel spring, of such strength that, resisting the steam pressure beneath the piston, it causes the pencil to rise and fall, as pressures vary, through distances which are proportional to the changes of pressure. A scale, G, on the barrel H H, indicates the pressures per square inch which correspond with the position of the pencil at any instant. The barrel H H is connected by means of the string I with some part of the engine having a motion coincident in time with that of the steam piston, but of such extent that at each stroke of the engine the barrel H will be turned about three fourths of a revolution only. A piece of paper or thin card is wrapped upon this barrel, its end being secured by the springs W, and upon this paper the indicator card or diagram is automatically made by the pencil. The instrument is attached to the steam cylinder by the cock N, which is screwed at O into the cylinder in such a position that steam can at all times enter it, and so that the pressure in the engine and in the indicator shall be the same. The instrument is secured to the cock by the use of the nut with its double screw threads R S, one of which being finer than the other, the cone T may be forced into U very firmly, and perfectly steam-tight. An indicator should be attached to each end of the cylinder, and diagrams taken simultaneously if possible. The instrument being thus attached and steam admitted, after a few moments' working has thoroughly heated the cylinder, the steam is shut off from the indicator, and the pencil is, with its support J K, swung around, until it touches the paper. As the barrel revolves, the pencil makes a horizontal line, which is called the atmospheric line or line of atmospheric pressure. The reading of the barometer will then give the distance of the vacuum line, or the line of absolutely no pressure, below this line of reference. Steam is again admitted, and the pencil, rising and falling as the steam pressure changes in the cylinder, while the paper is moved laterally with a motion precisely similar to that of the piston, a diagram is made, usually resembling *b c d e f a* in fig. 18, taken from the work of Mr. Charles T. Porter on the indicator. Steam from the boiler is supplied to the engine at the commencement of the stroke nearly at boiler pressure, and follows the piston at that pressure until at *c* the steam passage is gradually contracted, and finally closed by the steam valve. The steam thus confined within the cylinder expands as the piston moves forward, diminishing in pressure until it arrives at *d*, where the exhaust valve gradually opens communication with the

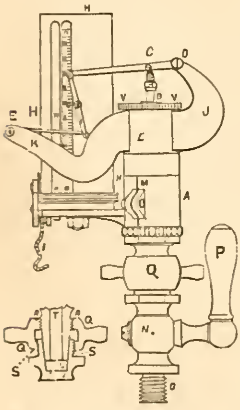

Fig. 17.—Richards Indicator.

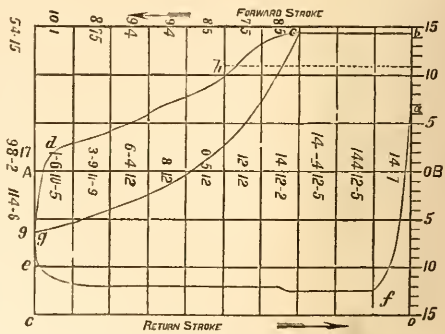

Fig. 18.—Diagram of Indicator.

condenser; the pressure drops to $e$ at the end of the stroke, and as condensation becomes completed during the return stroke, the minimum pressure is soon reached and retained until at $f$ the closing of the exhaust valve shuts up a small portion remaining in the cylinder, and it is compressed by the returning piston and its pressure thus increased to $a$, where the end of the return stroke is reached, the steam valve again opens, and a new cycle of operations begins. A B is the atmospheric line, and C D that of absolute vacuum. In consequence of the slow closing of the steam or cut-off valve in this case, the steam is not completely cut off until the point $h$ is reached, where the change in the character of the curve shows that only from $h$ to $d$ does the steam expansion line truly represent the law of change of volume with pressure. From $c$ to $h$ the steam "wire-draws" through the steam port, and the benefit of expansion is not fully secured. Were the steam port closed instantaneously at $c$, the line $c\,g$ would be the expansion line, and would closely correspond with that described already (see STEAM) for the special conditions under which it may have been formed. It is to secure this sudden closing and this full benefit of expansion that the drop cut-offs of Sickels, Corliss, Greene, and others have been adopted. Referring again to the diagram, should the "lead" be increased, and steam thus admitted earlier in the stroke, the line $a\,b$ would be formed parallel with but in advance of its present position. With less lead, the point $b$ would be moved also, the line $a\,b$ becoming inclined to the left. With a greater or less expansion, the point $e$ moves to the right or the left. With a rapidly closing cut-off valve, the curve $c\,h$ becomes shorter, and the curve $c\,h\,g$ more nearly like $c\,g$. A better vacuum would bring the line $e\,f$ nearer C D. In a non-condensing engine $e\,f$ would be above A B. The distance of $e\,f$ above A B or above C D indicates the back pressure produced by resistances in the exhaust passages, or the degree of imperfection of the vacuum which is due to the presence of both vapor and air in small quantity. With a three-ported valve, such as is used on locomotives, a shorter cut-off would cause an earlier closing of the exhaust on the return stroke, and the point $f$ would fall at the left of its present position. —The mean value of the steam pressure in the cylinder, as determined by measuring the altitude of the diagram at several points, or by obtaining its area with a planimeter and dividing by its length, is termed the mean pressure. The horse power is determined by multiplying the mean pressure by the area of piston and the speed of piston, and dividing by the value of a horse power. That is, HP $= \frac{P \times A \times V}{33000}$, where P is the mean pressure per square inch, A the area of piston in square inches, V the speed of piston or the product of the length of stroke in feet by twice the number of revolutions per minute. The horse power was assumed by James Watt as equivalent to 33,000 lbs. raised one foot high in a minute, 550 foot pounds a second, or 1,980,000 foot pounds of work an hour. This is about the maximum which the best London draught horses were then considered capable of performing. An average actual horse power is about 25,000 lbs. a minute, but Watt's figure is retained by engineers. With engines of ordinary proportions, the mean pressure may be determined with considerable accuracy also by the formula $p = P\,\frac{1 + A \log . E}{E} - B - CP$, the assumption being very nearly correct that steam expands in such cases according to Mariotte's law, the curve of pressure being a hyperbola and the product of pressure and volume constant. The values of the constants A, B, and C, as determined by Francis B. Stevens, are $A = 2{\cdot}3$, $B = 5$, and $C = 0{\cdot}06$. P is the initial pressure and $p$ the mean pressure. With engines working at moderate pressure, with unjacketed cylinders and medium speed of piston, the point of cut-off giving maximum economy is at about 0·4 or 0·5 the stroke. With high steam and rapid motion, and with steam-jacketed cylinders, economy is gained until the steam is expanded four to six times. In compound engines it is not unusual to expand from eight to twelve times, but experiment has not indicated that such great expansion is attended with economy. The losses which accompany great expansion are due to internal condensation of steam and its reëvaporation on the opening of the exhaust valve, when it carries away a large proportion of unutilized heat into the condenser. This loss sometimes exceeds the amount of heat actually utilized. In recent experiments the steam jacket has been found to save 20 per cent. by checking this condensation, which is the principal source of loss of economy in such engines. Superheating the steam sufficiently to cause it to pass through the cylinder "dry" diminishes it also. The minimum expenditure of steam in the best engines is about 16 or 18 lbs. per horse power per hour. The amount used in the single cylinder engine with moderate expansion and comparatively low pressure is seldom less than 30 lbs., and in old styles of engines worked with a pressure of 20 lbs. per square inch and cutting off at three fourths stroke, the consumption of fuel is often 6 lbs. and of steam 40 to 50 lbs. per horse power per hour. The expenditure of coal has been reduced by successive improvements, as the increase of steam pressure, greater expansion, surface condensation, high piston speed, the use of the steam jacket, and minor changes in both engine and boiler, until the best steam engines of the present day consume but about 2 lbs. of coal per horse power per hour, in ordinary work, and in some instances as little as 1½ lb. Even the latter, however, is but about one eighth the efficiency which would be given by a per-

fect heat engine.—See Tredgold, "Treatise on Steam Engines" (3 vols. 4to, London, 1852); Bourne, "Treatise on the Screw Propeller" (new ed., London, 1873), "Treatise on the Steam Engine" (new ed., 1873), "Handbook of the Steam Engine" (new ed., 1873), and "Examples of Modern Steam, Air, and Gas Engines" (4to, 1868 *et seq.*); Rankine, "Manual of the Steam Engine and other Prime Movers" (7th ed., London, 1874); and Clark, "Steam and Steam Engines" (London, 1875).

**STEAM HEATING.** See p. 894.

**STEAM NAVIGATION.** The origin of the paddle wheel for propelling vessels antedates the Christian era. The earliest application of steam to turn the paddle wheel was anticipated by Roger Bacon. The attempt of Blasco de Garay in 1543, if it was made as asserted, is the earliest on record. Papin is said to have experimented with his engine in a model boat in 1707, on the Fulda at Cassel. Jonathan Hulls patented a marine steam engine Dec. 21, 1736, proposing to employ his vessel in towing. He published a descriptive pamphlet in 1737, containing a sketch (fig. 1) of a Newcomen engine, with a system of counterpoises, ropes, ratchets, and grooved wheels, giving a continuous motion. William Henry of Chester co., Pa.,

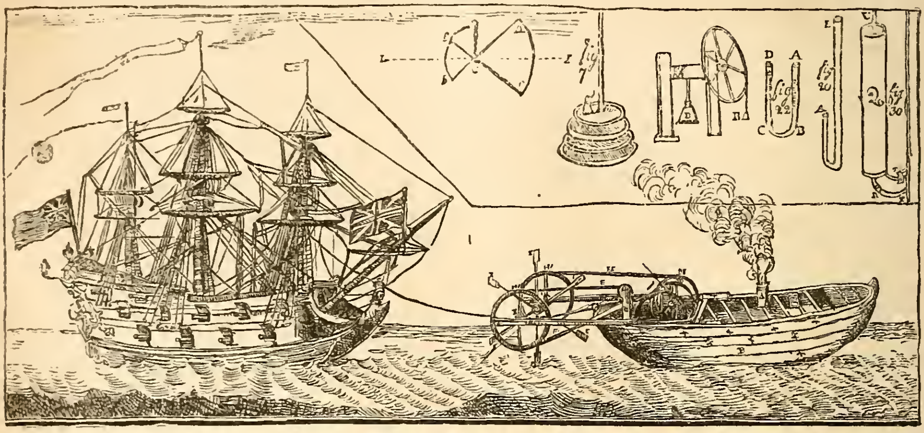

Fig. 1.—Hulls's Steamer, 1736.

tried a model steamboat on the Conestoga river in 1763. The count d'Auxiron, a French nobleman, assisted by M. Périer, made a similar attempt in 1774, and Périer repeated the experiment in 1775. The marquis de Jouffroy was engaged in the same work from 1776 to 1783, using a larger vessel and meeting with encouraging success. James Rumsey was engaged in experiments in the United States as early as 1784, and in 1786 drove a boat on the Potomac near Shepherdstown at the rate of 4 m. an hour by means of a water jet forced out at the stern. Rumsey subsequently went to England and continued his experiments on the Thames. (See Rumsey, James.) John Fitch worked at this problem at the same time with Rumsey, and had an experimental steamer on the Delaware in 1786. His propelling instruments were paddles suspended by the upper ends of their shafts and moved by a series of cranks. This boat (fig. 2) was 60 ft. long. Another vessel in 1790 made many trips on the Delaware, reaching an average speed of 7½ m. an hour. It was laid up in 1792. In 1796 Fitch resumed his experiments at New York, using a screw. (See Fitch, John.) In 1788 three Scotch gentlemen, Miller, Taylor, and Symington, obtained a speed of 5 m. an hour with a steamboat on Dalswinton loch. In this vessel two connected hulls were driven by a single paddle wheel placed between them and turned by a small engine. In 1789 a larger vessel, propelled by an engine of 12 horse power, attained a speed of 7 m. an hour. In 1801 Symington constructed for Lord Dundas a steamboat for towing on the canal, named the Charlotte Dundas, which was used successfully in 1802. It had a stern wheel driven by an engine, 22 in. in diameter of cylinder and of 4 ft. stroke. It drew vessels of 140 tons burden 3½ m. an hour, but was laid up soon afterward in consequence of a fear that the banks of the canal might be seriously injured

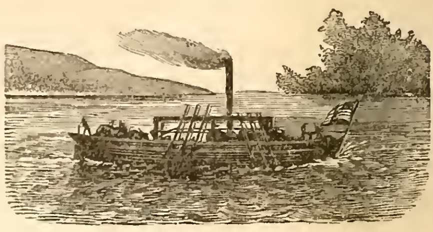

Fig. 2.—Fitch's Steamboat, 1786.

by the waves. Robert Fulton, an American artist, and subsequently a civil engineer, built a steamboat on the Seine in 1803, assisted by

Chancellor R. Livingston. (See FULTON, ROBERT.) Fulton had known William Henry in the United States, and seems to have been familiar with the work of contemporary in-

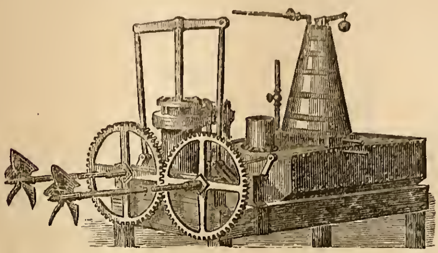

FIG. 3.—Col. John Stevens's Steam Engine, Boiler, and Screws, 1804.

ventors, and he had visited England, where he found others at work upon the same problem. In 1804 Col. John Stevens experimented with encouraging success with a small vessel driven by a high-pressure engine, a sectional boiler, and a single screw. He also tried twin screws, the steamboat having a length of 68 ft. and a breadth of 14 ft. This machinery (fig. 3) is retained in a good state of preservation at the Stevens institute of technology, Hoboken, N. J. Placed in a new hull on the Hudson in 1844, this engine produced a speed of 8 m. an hour. The experiments of Oliver Evans have been mentioned under STEAM CARRIAGE. Fulton, after studying the subject abroad, returned to the United States in 1806, and with Livingston had a boat built in which he placed machinery made by Boulton and Watt in England. The craft was 130 ft. long, of 18 ft. beam, 7 ft. depth, and 160 tons burden. The hull was built by Charles Brown of New York. The engine had

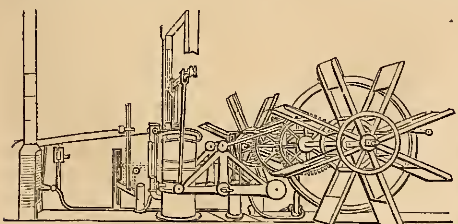

FIG. 4.—Engine of the Clermont, 1807.

a steam cylinder 24 in. in diameter and a stroke of 4 ft. The boiler was 20 ft. long, 7 ft. deep, and 8 ft. wide. The wheels were 15 ft. in diameter, with floats of 4 ft. length and 2 ft. dip. This steamboat, the Clermont, made a successful trip to Albany in 1807, leaving New York at 1 o'clock P. M. on Monday, Aug. 7, stopping at Livingston Manor (Clermont) from 1 o'clock Tuesday until 9 A. M. Wednesday, and reaching Albany at 5 P. M. on that day. The average speed was nearly 5 m. an hour. The return trip, on Thursday and Friday, occupied 30 hours, the rate of speed being 5 m. an hour. The Clermont, lengthened 10 ft., and with machinery slightly altered, made regular trips to Albany in 1808, and was the first steamboat ever made commercially successful. Almost simultaneously with Fulton's Clermont, Stevens brought out the Phœnix, a side-wheel steamer having hollow water lines; in the following year it was provided with feathering paddle wheels. This steamer could not ply on the Hudson, as Fulton and Livingston held a monopoly of the navigation of that river, and the Phœnix was taken by sea around to the Delaware river. This was the first sea voyage ever made by a steam vessel. From this time the steamboat was rapidly introduced. Fulton with his coadjutors placed a fleet upon the Hudson river and Long Island sound, and Stevens worked with his sons upon the Delaware and the Connecticut, and finally in the waters of New York also. In 1811 Fulton and Livingston began building steamers at Pittsburgh. In 1812 the Comet, built by Henry Bell, inaugurated regular steam navigation on the river Clyde in Scotland. This steamboat was 40 ft. long, 10½ ft. wide, and of 25 tons burden. The engines, of three horse power, drove two pairs of paddle wheels. The speed attained was about 5 m. an hour. In 1825 James P. Allaire of New York built compound engines for the Henry Eckford, and subsequently constructed similar engines for several other steamers, of which the Sun made the trip from New York to Albany in 12 hours 18 minutes. Soon afterward Erastus W. Smith introduced this form of engine on the great lakes, and still later they were introduced into British steamers. The machinery of the steamer Buckeye State was constructed at the Allaire works, New York, in 1850, from the designs of John Baird and Erastus W. Smith, the latter being the designing and constructing engineer. The steamer was placed on the route between Buffalo, Cleveland, and Detroit in 1851, and gave most satisfactory results, consuming less than two thirds the fuel required by a similar vessel of the same line fitted with the single-cylinder engine. The steam cylinders of this engine were placed one within the other, the low-pressure exterior cylinder being annular. They were 37 and 80 in. in diameter respectively, and the stroke was 11 ft. Both pistons were connected to one cross head, and the general arrangement of the engine was similar to that of the common form of beam engine. The steam pressure was from 70 to 75 lbs., about the maximum pressure adopted a quarter of a century later on transatlantic lines. This steamer was of high speed as well as economical of fuel.—Ocean navigation by steam, begun by Stevens in 1808, was made an assured success by the voyage of the Savannah in 1819, from Savannah, Ga., to Russia *via* England. In this vessel both sails and steam were used. She returned to New York, direct from St. Petersburg, in 26 days. Between 1821 and 1825 John Babcock, Robert L. Thurston, and Capt. Northup

ran steamers from Newport, R. I., to Providence and to New York. In 1825 the steamer Enterprise went to Calcutta from England, and in 1836 it was proposed to establish lines of steam vessels between New York and Liverpool. In 1838 the Sirius, a ship of 700 tons and 250 horse power, sailed from Cork, April 4; and the Great Western, a comparatively powerful steamer of 1,340 tons, 236 ft. in length, with engines of 450 horse power, paddle wheels 28 ft. diameter and 10 ft. length of floats, sailed from Bristol April 8. Both vessels arrived at New York April 23, the Sirius in the morning and the Great Western in the afternoon. At this time Ericsson, Smith, and others were again experimenting with the screw, and Ericsson soon brought it into general use in the United States. His first boat was successful as a tugboat on the Thames in 1837. (See STEAM ENGINE.) The first naval screw vessel, the Archimedes, built for the British navy in 1840, was so perfectly successful that comparatively few paddle steamers were subsequently built. The earliest regular transatlantic line of steamers, the Cunard line, sent its first vessel, the Britannia, of 1,350 tons, from Liverpool, July 4, 1840. In 1847 Capt. R. B. Forbes took out the first transatlantic screw steamer, the Massachusetts, and introduced steam vessels into Chinese waters, sending out hulls and machinery from the United States in sailing vessels.—Attempts have been made within a few years to revive the system of hydraulic propulsion first tried a century ago by Rumsey. Chain propulsion has in some instances proved very satisfactory. A chain or wire rope is laid in the bed of the river, or along the proposed route of the steamer, and passes over a drum worked by steam engines on the vessel, which is hauled along, taking in the chain at the bow and passing it out astern. In this arrangement loss by slip or oblique action is avoided, and a very satisfactory degree of economy is attained. Here, however, but little lateral movement of the vessel is permitted, and only one vessel can make use of the chain.—The most successful steam vessels in general use are the screw steamers of transoceanic lines. These are from 350 to 450 ft. long, usually propelled from 12 to 15 knots (14 to 17½ m.) an hour, by engines of from 3,000 to 4,000 horse power, consuming from 70 to 100 tons of coal a day, and crossing the Atlantic in from 8 to 10 days. These vessels are now invariably fitted with the compound engine and surface condensers. The largest vessel yet constructed is the Great Eastern, fig. 5, begun in 1854 and completed in 1859, by J. Scott Russell, on the Thames, England. This ship is 680 ft. long, 83 ft. wide, 58 ft. deep, 28 ft. draught, and of 24,000 tons measurement. There are four paddle and four screw engines, the former having steam cylinders 74 in. in diameter with 14 ft. stroke, the latter 84 in. in diameter and 4 ft. stroke. They are collectively of 10,000 actual horse power. The paddle wheels are 56 ft. in diameter, the screw 24 ft. The steam boilers supplying the paddle engines have 44,000 sq. ft. (more than an acre) of heating surface. The boilers supplying the screw engines are still larger. At 30 ft. draught this great vessel displaces 27,000 tons. The engines were designed to develop 10,000 horse power, driving the ship at the rate of 16½ statute miles an hour.

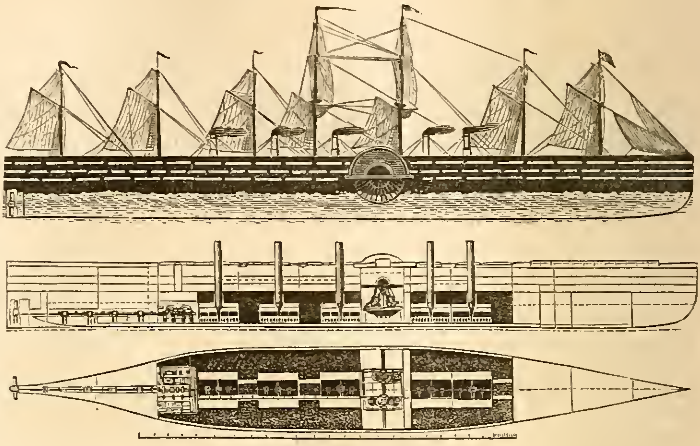

FIG. 5.—Great Eastern.

**STEARIC ACID** (Gr. *στέαρ*, tallow), a fatty acid obtained from mutton suet, and other fats that contain stearine, by saponifying suet and decomposing the hot solution of the soap with hydrochloric, or still better with tartaric acid. The oily acids are next submitted to pressure between hot plates, by which means a large portion of the oleic acid is separated; the solid residue is then to be purified by recrystallization from alcohol three or four times. Its formula is $HC_{18}H_{35}O_2$. When recrystallized from ether, until the fusing point becomes constant at 159°, and slowly cooled, the acid forms beautiful colorless, transparent, rhombic plates; these melt into a colorless oil, tasteless and without odor, and when quickly cooled the substance concretes in a white crystalline mass, which is insoluble in water, but readily forms with hot alcohol a solution having acid reaction. It is the material of the so-called stearine candles. Stearic acid exists in fats in combination with glycerine, forming stearine,

from which it is separated by saponification. (See GLYCERINE.) It combines with numerous bases, and forms with them both normal and acid salts, called stearates. Stearate of soda is the basis of ordinary hard soap; stearate of lead is a constituent of lead plaster.

**STEARNS,** a central co. of Minnesota, bounded E. by the Mississippi, and drained by Sauk river and lake; area, 1,379 sq. m.; pop. in 1870, 14,206. A portion of the county is prairie, but the W. part is hilly. There are numerous lakes and streams. It is traversed by the St. Paul and Pacific railroad. The chief productions in 1870 were 305,114 bushels of wheat, 78,627 of Indian corn, 447,193 of oats, 23,856 of barley, 120,865 of potatoes, 28,939 tons of hay, 17,701 lbs. of wool, and 323,085 of butter. There were 2,313 horses, 4,399 milch cows, 8,571 other cattle, 6,174 sheep, and 6,237 swine; 9 manufactories of carriages and wagons, 1 of agricultural implements, 4 of furniture, 7 breweries, 6 flour mills, and 5 saw mills. Capital, St. Cloud.

**STEATITE.** See TALC.

**STEDMAN, Edmund Clarence,** an American poet, born in Hartford, Conn., Oct. 8, 1833. He entered Yale college in 1849, was suspended in 1852, and did not return; but in 1871 the trustees restored him to his class and gave him the degree of A. M. After editing the "Norwich Tribune" and the "Winsted Herald," he settled in New York in 1855, and in 1859 became a writer for the "Tribune." In 1861–'2 he served as an army correspondent for the "World," and in 1863 he was private secretary to Attorney General Bates at Washington. In 1864 he became a stock broker in New York. He has published "Poems, Lyric and Idyllic" (1860); "Alice of Monmouth, an Idyl of the Great War, and other Poems" (1864); "The Blameless Prince, and other Poems" (1869); "Complete Poems" (1873); and "Victorian Poets," a volume of critical studies (1875).

**STEEL,** a malleable compound of iron and carbon, which may be hardened and tempered. Considerable confusion in the use of the word has arisen in late years, owing to the introduction of improved metallurgical processes, whereby wrought or malleable iron may be melted and cast into ingots. These ingots, having the appearance of ordinary cast steel and some of its properties, have likewise received the name of steel, although they lack the capacity of hardening which hitherto was regarded as the essential characteristic of steel. Pure or wrought iron possesses a high degree of malleability and ductility, is difficultly fusible, may be welded at high temperature, but below fusion, and is soft enough when cold to be readily wrought with tools. By the gradual addition of carbon to iron we notice an increase in fusibility, hardness, and resiliency, while malleability and ductility decrease. The smallest proportion of carbon which will distinctly produce these effects is about 0·25 per cent., and the largest amount of carbon which can exist in iron without destroying its malleability is about 2 per cent. Within these limits the compounds of iron and carbon possess the property of becoming soft when heated to redness and slowly cooled, and of becoming hard again when heated and quickly cooled. These processes of hardening and annealing may be repeated indefinitely, or until the carbon is burned out by the successive heatings. Iron with more carbon than 2 per cent. (say 2 to 5) is known as cast iron. It is more fusible than steel, but is not at all malleable, and while it may be hardened by sudden cooling, it is brittle and does not possess the resiliency or "spring" of steel. Soft or wrought iron has been until within the last 20 years worked by rolling or hammering when in a plastic condition at a red or white heat, owing to the impracticability of fusing pure iron. Steel was worked in the same manner as wrought iron until Huntsman succeeded in melting it in crucibles during the latter half of the last century, since when cast steel has replaced welded steel for most purposes, on account of its greater homogeneity, since all welded products consist of layers or fibres of metal separated by cinder, which, though it may be largely extruded by rolling or hammering, yet is always present to a sufficient extent to prevent the absolute contact of all the particles of metal. Since the idea of perfect homogeneity combined with malleability has so long been associated with our notions of steel, it was natural that when malleable iron, or iron low in carbon, was melted and cast in moulds, it should receive the name of steel without regard to the amount of carbon or the capacity for hardening. It is thus that the products of the Bessemer converter and the Siemens furnace have all been classed as steel, although the content of carbon may vary from 1·50 to 0·10 per cent.; and owing to the very large production of metal by these processes, far exceeding in amount ordinary cast steel, this classification has become well established in iron metallurgy. The uncertainty and confusion that has arisen from classing together products of widely different physical and chemical properties, has led to an active discussion of the definition and classification of steel. The classification of Greiner of Seraing is as follows:

| AMOUNT OF CARBON PER CENT. | Series of irons (welded). | Series of steels (melted). |
|---|---|---|
| 0 to 0·15 | Ordinary iron. | Extra soft steel. |
| 0·15 to 0·45 | Granular iron. | Soft steel. |
| 0·45 to 0·55 | Steely iron or puddled steel. | Semi-soft steel. |
| 0·55 to 1·50 | Cemented iron or steel. | Hard steel. |

While the simplicity and convenience of this classification from a manufacturing point of view must be admitted, its adoption is opposed by Gruner and others on the ground that it takes no account of the capacity for hardening.

—Among the elements other than carbon met with in steel are phosphorus, silicon, sulphur, and oxygen among the non-metals, and manganese, copper, tungsten, titanium, and chromium among the metals. Some of these are invariably present in the materials used for steel making, and are usually regarded as impurities in the steel, while others are added to produce certain specific effects. The modifications of the properties of steel by the above named elements have been already treated partially under IRON. Steel is more susceptible to the action of impurities than is wrought iron. This is especially true with regard to phosphorus and silicon, and is readily accounted for by the similarity of action of these substances with carbon. Recent experiments have shown that an amount of phosphorus which would be highly detrimental to steel containing say 0·50 per cent. of carbon, may be present with safety when the carbon is as low as 0·10 or 0·20 per cent., or in other words when the steel passes into soft iron. The effect of this formerly much dreaded enemy of iron and steel has been so thoroughly studied that "phosphorus steels," so called, are manufactured and sold. Phosphorus makes iron hard, brittle, and cold-short (see IRON), and this is also true in a modified degree of carbon and silicon; hence, when two or all three are present together in iron, the effect is cumulative. The contradictory statements as to the maximum percentage of phosphorus that Bessemer metal will bear find here their explanation. It was formerly said that Bessemer steel with more than 0·05 per cent. of phosphorus was unfit for rails, but later experience has shown that if the amount of carbon does not exceed 0·15 per cent., phosphorus to the extent of 0·35 per cent. may exist without seriously impairing the strength and ductility of the metal. This fact, recently brought into prominence by the manufacture in France of phosphorus steel on a large scale, was recognized in this country as early as 1870. Samples of boiler plate and tough steel made at Trenton, N. J., by the Martin process, showed on analysis the following composition:

| ELEMENTS. | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|
| Carbon | 0·160 | 0·120 | 0·120 | 0·125 | 0·120 |
| Sulphur | 0·003 | 0·008 | 0·007 | .... | ..... |
| Phosphorus | 0·530 | 0·113 | 0·275 | 0·314 | 0·272 |
| Manganese | 0·144 | 0·580 | 0·072 | .... | ..... |
| Silicon | 0·174 | 0·015 | 0·025 | .... | 0.052 |

While it appears from the above that phosphorus may in a measure replace carbon in steel, the effect of these two substances is not identical, and the limit of rigidity is much sooner reached with the former than with the latter. The use of phosphorus steel is solely a question of economic advantage, since its manufacture permits the use of impure and consequently cheaper materials; but as far as is at present known, the compounds of iron and phosphorus possess no properties that give them a superiority over the carbon compounds for industrial applications. The effect of silicon on steel appears to be similar to that of carbon, as the general analogy of the two elements would suggest; but to produce a given degree of hardness, the amount of silicon necessary is very much greater than that of carbon—the reverse of the case with phosphorus. The most contradictory statements exist regarding the effect of silicon on steel. The best established data are summarized by Turner as follows: A small amount of silicon is not necessarily injurious to steel, and may be an advantage in those varieties which are to be used without hardening, and where there is no special demand for tenacity and strength. On the other hand, where steel must be hardened for use, as for tools, silicon can only be injurious, and that in proportion to the quantity present. This is one reason why Bessemer steel cannot generally be used for purposes requiring a fine, hard steel; for it is usually made from highly silicious pig iron. But some of the Swedish Bessemer steel, made from pure manganiferous pig iron low in silicon, approximates in quality to ordinary cast steel. A puddled steel made with the addition of a highly silicious iron ore has been brought into prominence under the name of "silicon steel;" but there is no evidence that it derives any of its properties from silicon, or indeed that there is any more silicon in it than in ordinary puddled steel. The effect of sulphur on steel is entirely different from that of the elements already mentioned. It makes it "red-short," that is, brittle when hot; but unlike phosphorus, it does not sensibly affect its malleability when cold. The largest amount of sulphur that steel will bear without serious impairment of its malleability is said to be about 0·10 per cent. Oxygen produces the same effect on homogeneous iron as sulphur, as might be inferred from the close chemical relations of the two elements. It can never exist in the harder steels prepared by fusion, for it would then combine with the carbon; but it is frequently met with in the Bessemer low steels and iron, and makes them red-short. Red-shortness, formerly ascribed exclusively to sulphur, has been found in very many instances to be due to oxygen. Considerable importance has been attached to the presence of nitrogen in steel, and Frémy considers it an essential ingredient. Numerous analyses do not support this view, and it is probable that its presence in steel is entirely accidental and due to the property which many metals possess of absorbing or occluding gases. —The compounds of iron with the metals, or the true alloys of iron, have not been as closely studied as its compounds with the non-metals, and but little can be said with precision of the physical characters of these alloys as such, or as modified by the presence of the non-metallic elements. The properties of iron are not as radically modified by the addition of small quantities of metals as is the case with the

non-metals. Manganese is closely allied to iron in its chemical properties; and it plays a very important part, and one in many cases not well understood, in the preparation of steel. Ores containing considerable manganese are often known as steel ores. The beneficial effect of the addition of this metal or its compounds in the manufacture of crucible steel was discovered by Heath in England (patented in 1839), but the nature of its action is still somewhat obscure. Recent experiments by Caron show that sulphur is at least in part removed by manganese, and it is also probable that the presence of this metal in the steel prevents the injurious action of sulphur, although as a rule manganese added as oxide in the crucible does not enter into the composition of the steel. The part that it plays in the Bessemer and Martin processes is well understood, viz.: it removes the oxygen that the molten metal has absorbed, and thus corrects red-shortness, and it is probable that its favorable effect may be in many other instances referred to this action. The affinity of manganese for oxygen is much greater than that of iron, and therefore the reduction of metallic manganese from its oxide is accomplished with more difficulty; consequently a manganese cinder, unlike an iron cinder, protects the carbon of steel from oxidation. Further, when manganese is present in molten metal, the oxidation of the iron is prevented until all or nearly all the manganese is oxidized. Below a certain amount, say 1 per cent., manganese has been shown, contrary to former opinions, to exert no disturbing effect on the properties of steel. Greiner says that manganese possesses the property of rendering steel very malleable and weldable, and that hard steels containing sulphur, phosphorus, and carbon (as high as 1·50 per cent.) can be forged with ease if they contain sufficient manganese. Nearly all observers agree that it is a corrective of red-shortness. Manganese steel, so called, was for some time made in Leoben, Austria, but its manufacture was abandoned, owing to the uncertainty of the product. The combinations of steel with chromium, tungsten, and titanium have attracted much interest from the fact that they appear to have peculiar and valuable properties. They are often represented to be steels in which the metals named replace carbon. This view is inadmissible from a chemical standpoint, and it is probable that these compounds are carbon steels modified in their properties by the presence of other metals. An analysis of Mushet's "special" steel, generally supposed to be made from titaniferous ores, showed the presence of tungsten and no titanium, viz.: tungsten, 7·98 per cent.; carbon, 1·40; silicon, 0·24. This compound is excessively hard under ordinary conditions; on sudden cooling it breaks, and it can only be worked at a very low red heat. Tungsten has also been added in the Bessemer converter, and the resulting steel, containing as high as 0·558 per cent. of tungsten, was found to combine a high degree of toughness and capacity for hardening. Tungsten likewise increases the power of steel to retain magnetism. Titanium seems to produce effects similar to those of tungsten. Chromium also appears to confer valuable properties on steel, somewhat resembling those produced by tungsten. The "chrome steel" manufactured in Brooklyn, N. Y., combines in a high degree tenacity and ductility, and is capable of bearing a high heat for rolling, hammering, and welding. It is highly carburized, one sample giving 0·98 per cent. of carbon, and another 1·23. The amount of chromium found in one analysis was 1·66, and in another it did not exist in appreciable quantity. Determinations of the tensile strength of this steel by Kirkaldy of London, on bars 5 in. in length, varied from 115,780 lbs. to 167,320 lbs. per square inch, with an elongation in the first instance of 11·6 per cent., and in the second of 7 per cent. Determinations made at the West Point foundery ranged from 173,770 lbs. to 198,910 lbs. per square inch. When hardened at a very low heat, it acquires great hardness; a high heat renders it brittle, as might be expected from its large percentage of carbon. Copper is sometimes an accidental ingredient in steel. It seems to make it red-short, and its presence even in small amount is believed to be highly deleterious. Faraday and Stoddart have experimented on alloys of steel with the noble metals. They found the compound of steel with a small amount of silver to have valuable properties, but its expense would be a barrier to its introduction. Many analyses of fine steel have shown the presence of aluminum; and it is not improbable that this metal exerts a favorable action on steel, but the subject has not been investigated.—Classification and Manufacture of Steels. For the purposes of description of steels and the processes of their manufacture, a classification based on the mode of production may be found convenient. When iron ore is used, the process is one of deoxidation and subsequent carburization; with pig iron it is one of decarburization; and with wrought iron it is one of carburization. The following outline of processes is arranged on this plan:

1. Steel from the ore direct, by reduction and carburization. Ore steel, direct steel. Example, bloomary steel.
2. From pig iron by decarburization.
   - *a.* By solid oxidizing agents, as iron ore, saltpetre, &c., without fusion. Examples, puddled steel, Heaton steel.
   - *b.* By solid oxidizing agents with fusion. Example, Uchatius steel.
   - *c.* By the oxidizing agency of air, with fusion. Example, Bessemer steel.
   - *d.* By oxidizing and reducing gases. Example, the Bérard process.
3. From wrought iron by carburization.
   - *a.* By fusion with pig iron. Example. Martin steel.
   - *b.* By fusion with coal or carbonaceous substances. Example, Indian steel or wootz.
   - *c.* By heating in charcoal without fusion. Example, cement steel.
   - *d.* By heating in carburetted hydrogen, without fusion. Example, Mackintosh or Baron steel.

The distinction between crude and fine steel is not now so sharply defined as formerly, but in

general the term fine steel is reserved for those products made by fusion of the purest materials in a crucible, and particularly for the cast steel made by fusion of cement steel. Shear steel, produced by welding and rolling cement steel, may also be classed here. In many instances two or more reactions or processes for steel making are combined, but in following the above classification the principal feature only of the process is considered.—1. *Steel direct from the Ore.* The process for obtaining wrought or soft iron direct from the ore (see BLOOMARY, and IRON) affords, with some slight modifications of charging and manipulation, a product containing sufficient carbon to entitle it to rank among the steels; but the steel thus produced is always low in carbon, and may be classed with puddled steel. In the Catalan or bloomary forge the circumstances favoring the production of a steely product are: a slow process, that the reduced iron may have time to absorb carbon; the protection as far as possible of the mass of plastic metal from the direct action of the blast and from the action of rich iron cinder; and also the use of manganiferous ores, since the oxide of manganese, as already explained, does not oxidize carbon readily. The character of the steel produced by the bloomary depends on the nature of the ores and the skill of the workmen. The impurities of the ores are more completely eliminated in the direct processes than in the blast furnace process, a gain obtained at the expense of a considerable loss of iron. Titaniferous ores can be successfully worked in the bloomary, and are said to give a superior steel. The product of the bloomary generally lacks uniformity, a defect which can be remedied by repeated heatings and hammering. The bloomary process is rarely used now for the direct production of steel, but the iron made by this process is, on account of its purity, advantageously employed for conversion into steel by the cementation process.—2. *Steel from Pig Iron.* 2*a. Puddled Steel.* The process of puddling for steel does not differ essentially from that for iron. (See IRON MANUFACTURE.) The operation is stopped before complete decarburization, or when the desired hardness is attained. The conditions favoring the production of steel in the puddling furnace are as follows: 1. Pure pig iron is necessary, since the refining is not carried as far as with wrought iron, and also because a less basic cinder is employed. 2. The pig iron should be highly carburized, that it may not come to nature too quickly. 3. It should not contain too little silicon, or the cinder will be too basic or "rich." 4. The presence of manganese is favorable, as it produces a fluid and non-oxidizing cinder. 5. The cinder should be "poor" or highly silicious, since rich cinder decarburizes the metal. 6. The process should go on slowly, that it may be the more under control. 7. During the balling the temperature must be reduced as much as possible, and a smoky flame produced, to prevent oxidation. The nature of puddled steel has already been considered in the foregoing. It possesses a degree of hardness proportional to the amount of carbon (which rarely exceeds 0·5 per cent.), and a fibrous or welded structure. It has been largely used for the heads of rails, being much more readily welded to iron than ordinary cast steel. Puddled steel made from pure pig irons is also much used for melting in crucibles for the production of fine cast steel. Saltpetre (potassium nitrate) has been used for the conversion of pig iron into wrought iron and steel. Its action is both oxidizing and purifying, the former through the large amount of oxygen of the salt which is readily given off, and the latter through the strong base, potassa, which combines with the silicic and phosphoric acids produced. The apparatus devised by Heaton for the reaction between molten cast iron and saltpetre, for the conversion of poor pig iron into good steel, has been abandoned on account of the expense and uncertainty of the process. 2*b. Uchatius Steel.* Steel produced by the reaction of pig iron and iron ore may be obtained in the molten condition, if the temperature of production is high enough. This is effected either in a crucible or in a Siemens regenerative furnace. Uchatius steel, named from its inventor, is made by fusing a mixture of granulated pig iron, iron ore, and oxide of manganese in crucibles. Its manufacture is now confined to Sweden (though originally introduced in Austria), where the pure irons and ores are admirably adapted to the process. At the Siemens works in Landore, Wales, the manufacture in the open hearth is regularly carried on by mixture of pig iron and iron ore. The process differs from that of Uchatiüs in that the ore is added in successive portions, and that to the decarburized metal spiegeleisen is added, as is usual in the open-hearth processes. Scrap iron is also sometimes added, but its use is not essential to the process. The charge consists of 5 to 6 tons of Bessemer pig iron and 30 cwt. of pure ore. The product is used principally for rails, and averages 0·40 per cent of carbon. 2*c. Bessemer Steel.* The Bessemer or pneumatic process consists in the removal of the carbon, silicon, &c., from pig iron by means of a blast of air forced through the molten metal. The reactions involved are in many respects the same as those in the puddling process; that is to say, the silicon is first oxidized, and the silica thus formed combines with the oxides of iron and manganese (if present) to form a cinder, and the carbon is subsequently oxidized to carbonic oxide. Owing, however, to the rapidity of the process and the large amount of pig iron employed, the heat developed in the oxidation of the silicon, carbon, &c., is sufficient to retain the resulting steel or iron in a fluid condition, so that it can be cast directly into moulds. The history of this remarkable

process is briefly as follows: On Oct. 17, 1855, Henry Bessemer patented a process of blowing air or steam through molten pig iron in crucibles, until the metal was decarburized to any desired extent. At this time he recognized the fact that while steam cooled the metal, air increased the heat from red to white. A patent in December of the same year specified a circular or elliptical vessel provided with a refractory lining and hung on trunnions, which could be filled and emptied by means of a lipped opening. In this patent the essential features of the process were fully developed. A patent of Feb. 12, 1856, indicated that the heat developed in the process was sufficient without the additional use of fuel, and that, according to the duration of the blowing, steel or soft iron might be produced. In July, 1856, Bessemer read a paper before the British association at Cheltenham on the "Manufacture of Iron and Steel without Fuel," which created an intense interest. But the subsequent trials did not yield uniformly satisfactory results, and except by the inventor the process was practically abandoned. Patient and careful experiments showed that not all pig irons were adapted to the process; that sulphur and phosphorus were not eliminated, and consequently pig irons containing a notable proportion of these substances could not be used. Again, the interruption of the process at the precise point of decarburization desired was found to be impracticable, owing to lack of trustworthy indications. Further, it was found that the process was not adapted to making the finer and harder steels, but had its chief application in the production of low steels or soft iron. The absorption of oxygen, and the consequent red-shortness of the metal when the pig iron was blown to nearly complete decarburization, was overcome by the addition of spiegeleisen, a white pig iron containing from 7 to 12 per cent. of manganese. This was a suggestion of Robert Mushet, and to it the practical success of the Bessemer process is largely due. After conquering all the obstacles to success, Bessemer did not find a ready acceptance of his process owing to the distrust caused by his previous failures. He therefore started in 1859 a small establishment of his own in Sheffield for the regular manufacture of his steel. His commercial success soon led to the general adoption of his process throughout the civilized world, more particularly at first in Sweden, where the pure ores and fuels furnished a pig iron admirably adapted to the process. In 1867 there were in England 52 Bessemer converters, in Prussia 22, in France 12, in Austria 14, in Sweden 15, and in Belgium 2. In 1873 Germany alone had 70 converters, and the number had risen in England to 105. The production in England has increased from 6,000 tons in 1867 to 540,000 tons in 1874.—The Bessemer process consists, first, in melting the pig iron; second, transferring the molten metal to the converter, where it is subjected to the action of the blast of air; third, pouring the finished product into a ladle; and fourth, pouring from the ladle into the mould. The metal when solid, but while still hot, is taken from the moulds and worked by rolling or hammering into the desired form. Pig iron is in some cases used direct from the blast furnace, but remelting is generally found advantageous. The furnaces now used for this purpose are generally cupolas, which melt quicker and are more economical, although the direct contact of the iron with the fuel may cause a deterioration of the metal if the fuel is impure. The reverberatory furnace is not open to this objection, but the pig iron may here suffer a loss of silicon and manganese, owing to the oxidizing atmosphere. The molten metal is either run in troughs directly from the furnace to the converter, or is first run into ladles where it can be weighed, and thence carried to the converter. The latter is a pear-shaped vessel, sometimes called the retort or simply the vessel, consisting of an iron mantle lined with a refractory silicious material. It is usually made in two parts, upper and lower, for convenience of lining. The bottom, which contains the tuyeres, is made in a separate conical piece, and inserted from below. The size of the converter is usually calculated for a charge of five to six tons of pig iron. This amount of metal occupies but a small part of the vessel, as is indicated in the accompanying figures. The greatest external diameter is about 8 ft., with a total height of from 12 to 15 ft. The silicious material of the lining usually contains a little alumina. The so-called "ganister" used in England for this purpose is a ground sandstone found in the coal formation, containing 93 per cent. of silica, 4 per cent. of alumina, and 1 to 2 per cent. of oxide of iron. The lining is made by ramming the material in a moist condition around a form placed in the converter. It is usually about 12 in. thick. The greatest attention must be paid to the selection of the material for the

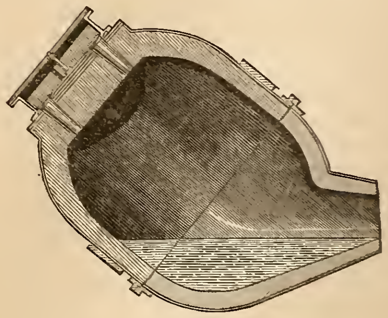

Fig. 1.

lining and to its thorough consolidation, for upon the lining the success of the process largely depends. The tuyeres, from 7 to 12

in number, are made of fine clay in the form of truncated cones, each perforated with 7 to 12 holes about three eighths of an inch in diameter. They are arranged on the bottom plate, and ganister or other material stamped around them; and the finished bottom, after drying, is inserted in the converter. The bottom lasts generally for 6 to 10 heats, while a carefully made lining may endure 1,000 or more heats. The converter is mounted on trunnions, one of which is hollow and conveys the blast to the tuyere box below the tuyeres, and to the other is attached the mechanism by which the converter is revolved. Figs. 1 and 2 give sectional views of the converter in two positions. Fig. 3 is a plan of the converter with the rotating machinery. The ladle into which the steel is poured from the converter is shown in figs. 4, 5, and 6. Fig. 4 is a vertical section of the ladle crane and elevation of the ladle. Fig. 5 shows the platform on which the ladle moves, and fig. 6 is a partial section through the ladle, showing the loam-coated rod which acts as a stopper in pouring. By this latter arrangement the fluid steel is discharged in a thick stream, and the cinder remains on top. The steel is usually cast in long ingots about 12 to 14 in. square at the base and tapering from 1 to $1\frac{1}{4}$ in., each ingot being rolled into two or three rail blooms. When the steel is intended for other purposes than rails, moulds of special forms are used. To obviate the occurrence of air bubbles in the steel, caused by the falling of the stream from the top to the bottom of the mould and spattering against the sides, bottom casting is employed; that is, pouring the steel down a central sprue and causing it to enter the bottom of several moulds at a time through fire-clay distributors. The blowing engine for supplying the blast is usually double, and should be able to deliver 8,000 to 11,000 cubic feet of air a minute at a pressure of 25 lbs. to the square inch. Probably no other invention of the magnitude

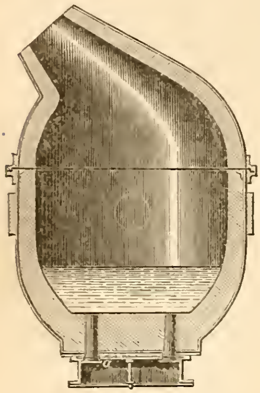

Fig. 2.

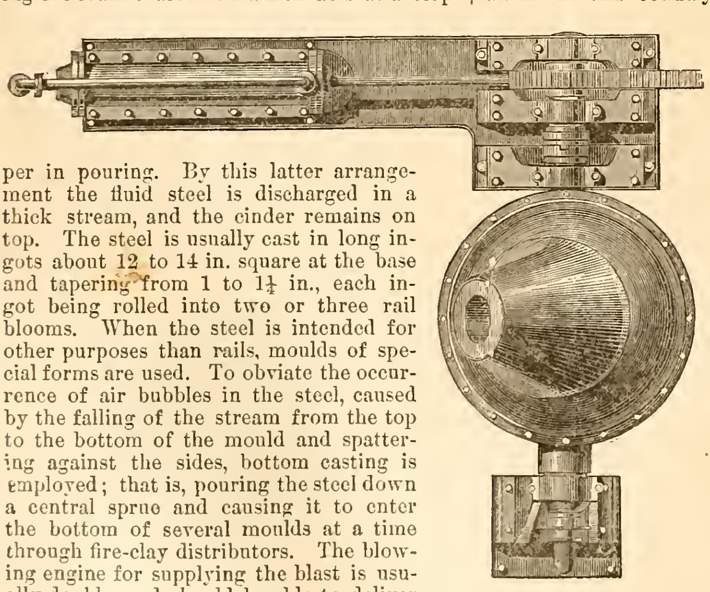

Fig. 3.

of the Bessemer process ever came from the hands of its inventor in as complete a form. But while the accumulated experience of 15 years has added nothing to the essential features of the apparatus and machinery, yet in the minor details of construction improvements have been made which have increased the capacity of the process four fold. The highest perfection of apparatus and working has been attained in the United States, where there are now (1876) ten works with two converters each, of five to six tons capacity. The improvements in American practice have been largely due to Mr. A. L. Holley, who has superintended the construction of most of the works in this country. In 1868 an output of 500 tons a month from two five-ton converters was barely reached. The production had gradually increased to 4,200 tons of ingots a month in the best works, in others to 3,800 tons, and in one instance to 5,000 tons. In the nominally five-ton vessels $5\frac{1}{2}$ to $5\frac{3}{4}$ tons are sometimes produced at a heat. The improvements which have rendered this large and regular production possible in this country, far exceeding that of European works, have been summed up by Mr. Holley as follows: 1, improved cupola furnaces and method of working; 2, the means used for quickly and soundly renewing the vessel bottoms, and the use of fire brick around the tuyeres;

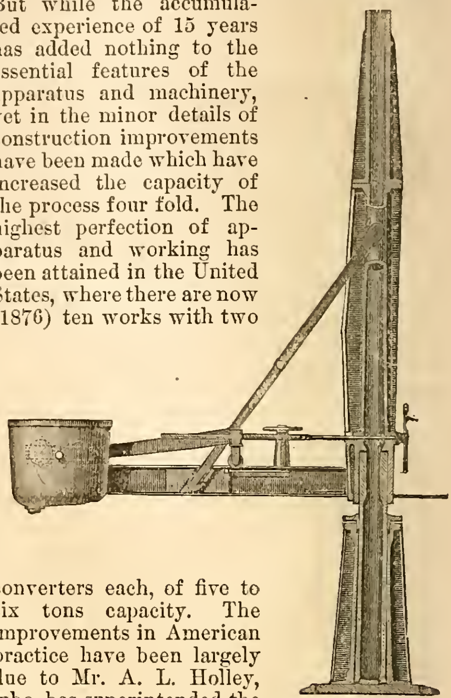

Fig. 4.

3, more roomy and convenient arrangement and distribution of the working parts and spaces; 4, filling the ingot moulds from the bottom by improved and convenient appara-

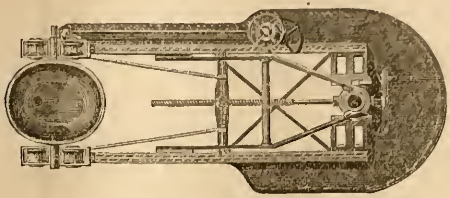

Fig. 5.

tus.—The converter, after being lined, is thoroughly dried and heated to redness, and pig iron is run into it while turned to the horizontal position. On tipping up the converter, it is necessary that the blast should be started before the metal reaches the tuyeres. This is effected automatically by a cam on one of the trunnions. When the converter has attained the upright position, the roar of the air rushing through the metal and escaping from the mouth is heard. In this stage a large part of the oxygen is absorbed by the silicon and manganese (or iron in the absence of manganese), and the flame is short and not highly luminous. The spectroscope shows at this time a continuous spectrum without lines. Soon the escaping flame increases in size and brilliancy, assuming an orange or yellow color with blue streaks and a white edge, intermingled with sparks of metal. The spectroscope now shows the sodium line, and generally those of potassium and lithium, accidental ingredients of the metal or lining. This constitutes the first period of the conversion, and is known as the slag or cinder-forming period. The action now becomes more violent, and the flame more intensely luminous, and large masses of iron or cinder are often ejected from the vessel, probably from the energetic action of the oxide of iron in the cinder on the carbon of the metal. The spectroscope now shows bands of dark lines in the green, which have been proved to be produced by manganese, though their appearance is dependent on the oxidation of the carbon. This violent stage of the process passes gradually into the third and more peaceful period, in which the flame increases in heat and brilliancy and assumes a purple or violet tint. At this high temperature the carbon appears to be directly oxidized by the blast. When the carbon is all removed the flame suddenly drops, which is the indication for tipping over the converter and stopping the blast. Coincident with the dropping of the flame is the disappearance of the dark bands from the spectrum. The length of the process up to this point may vary from 5 to 45 minutes, according to the heat of the metal, the amount of silicon and manganese, and the amount of pressure of blast. A "blow" usually lasts 15 to 20 minutes, of which the first or slag-forming period generally occupies one half. Pig irons with little silicon often pass directly into the second period. The metal in the converter after complete decarburization contains considerable oxide of iron in suspension or solution, and in that condition is worthless, since it breaks up under the hammer. There is added to it, therefore, metallic manganese, as before explained, which combines with the oxygen and passes into the cinder. Spiegeleisen is generally used for this purpose. At the end of the blow the converter is tipped over, and the spiegeleisen, previously melted, is run in. An energetic action at once manifests itself by the escape of abundant gas and flame. About 7 to 10 per cent. of the weight of the charge is used, according to the hardness of steel desired. Spiegeleisen contains about 4 to 5 per cent. of carbon, and the amount that can be used is therefore limited, for the carbon, taking but little part in the reaction, enters into combination with the metal. This has been an obstacle to the preparation of extra soft metal by the Bessemer process. Ferro-manganese, a combination of manganese and iron with a little carbon, containing 50 per cent. more or less of manganese, was early used with success in the process, but its manufacture was abandoned owing to its expense. It has recently been revived and its use resumed in the Bessemer, but more particularly in the Martin process, under analogous conditions, for the preparation of steel or homogeneous iron containing phosphorus. The employment of ferro-manganese is also becoming general for making soft iron of fine quality for construction of ships, bridges, &c. The addition of spiegeleisen or ferro-manganese is not universally practised. Where the pig iron contains considerable manganese, the process may be interrupted at the desired stage of decarburization, and even metal very low in carbon, which is not red-short from oxide of iron, may be successfully cast. This method is followed in Sweden and some parts of Germany. The loss of weight in the conversion of pig iron by the Bessemer process, including scrap, is from 10 to 15 per cent. The heat produced in the process, formerly supposed to be mainly caused by the oxidation of the carbon, is now known to be mainly due to the oxidation of silicon and manganese, and also of the iron. Silicious pig iron is therefore generally demanded for the process. From $1\frac{1}{2}$ to 2 per cent. of silicon is the amount generally desired, but pig irons with more and less are often used. The use of more silicious pigs is disadvantageous owing to a lengthening of the

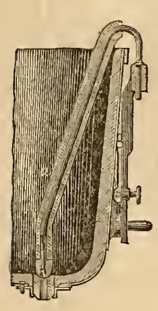

Fig. 6.

process, and also to the large amount of silicon remaining in the steel. When highly manganiferous pig is used, the silicon may sink below 1 per cent., and the resulting steel is of a much finer quality. Much of the Swedish Bessemer steel, celebrated for its purity and strength, is made from pig iron of this character.—The heavy ingots of Bessemer steel intended for rails are either hammered or rolled (bloomed), becoming thereby condensed and elongated, and then cut into lengths suitable for rolling into rails. Blooming is now generally conceded to make the best and most uniform product. The American blooming train consists of three rolls 30 in. in diameter and 5 ft. in length, which are adjustable in housings by means of steel screws. Ingots 12¼ in. square are reduced by four grooves and 17 passes to 6 or 7 in. square in four minutes. Special appliances for manipulating these heavy masses of metal by machinery are attached to the rolls and greatly facilitate the operation, which in some cases is nearly automatic. The rail trains are ordinarily three high rolls. (See Iron Manufacture.) A 21-inch train for rolling 7-inch ingots into rails in 13 passes is divided into three lengths. The product of a steel rail mill, working on 7-inch blooms, is about 1,000 tons of rails a week. The consolidation of steel usually accomplished by hammering or rolling may also be effected by the application of a heavy, steady pressure. This latter method is applicable not only to the forging of masses of steel, but also to the compression of the metal while in the molten state. Bessemer embodied this idea in one of his earlier patents. Originally practised in France, the compression of liquid steel has attained its greatest development in England, where Sir Joseph Whitworth has an extensive plant for this purpose, which includes four hydraulic presses capable of exerting a pressure of 2,000 to 8,000 tons. The pressure usually applied is six tons to the square inch, by which an ingot is reduced one eighth in length. To small castings a pressure of 20 tons to the square inch is sometimes applied. Mild steels treated by this process have shown a tensile strength of 40 tons to the square inch, with an elongation of 30 per cent. A tube of this compressed steel 26 in. long and 7·83 in. in diameter, with a bore of 2·56 in. (being that of a nine-pound field gun), sustained 48 explosions of 1½ lb. of powder with the bore closed by a screw plug, the only escape for the gases being through the touch hole, $\frac{1}{10}$ in. in diameter. The expansion of the bore increases at every explosion, but without rupture. Forging steel by means of hydraulic pressure was first introduced by Haswell in Vienna in 1861. Heavy ingots are forged by this method more effectually than by hammering, and smaller articles of irregular or intricate outline, up to 150 lbs. or more, may be directly formed by pressure of the white-hot metal into moulds. 2*d. The Bérard Process.* The conversion of pig iron into steel or soft iron by means of oxidizing and reducing gases, in this process, is carried out on the hearth of a reverberatory furnace heated by gas. The pig iron is decarburized by means of air in connection with hydro-carbon gases, which are expected to remove the sulphur and phosphorus. The resulting iron is recarburized by the reducing gases. This process has not yet proved a commercial success.—3. *Steel from Wrought Iron.* The above described processes under the second division of the classification, to which many others of minor importance might be added, all use pig iron as the principal material for the preparation of steel; and as it is a substance of complex and variable composition, the quality of the steel derived from it will depend on the composition of the pig iron used. In none of the processes using pig iron is there a complete elimination of all the substances associated with the iron; hence only the purer varieties can be used where a good product is desired. In the third division wrought iron is the principal material used, and as this may be made in a state of great purity even from moderately pure pig irons, the steel made from it is as a rule superior to that made from pig iron. Wrought iron when imperfectly worked contains considerable cinder, which holds the greater part of the phosphorus originally in the pig iron; and when steel is made from such wrought iron by fusion, the phosphorus enters the steel. 3*a. The Martin Process.* The principle of manufacturing steel by the reaction of wrought iron upon melted pig has long been known. Rinmann, Vanaccio, and even Agricola (about 1550) describe processes of this kind. Réaumur (1722), Chulut, and Clouet (1778) published experiments in which steel was produced by the simultaneous fusion of cast and wrought iron, or of cast iron and iron oxide. But these experiments, and many others of subsequent date, were successful only so far as the manufacture in crucibles was concerned. It was only in closed vessels, heated from without, that the necessary high temperature, combined with exclusion of air, could be maintained. Vitreous fluxes were early used, to protect the surface of the molten metals; and the idea of employing a reverberatory furnace is found in the work of Hassenfratz (1812). Several English and French patents of the early part of this century show that metallurgists were actively engaged with this problem. The most important historically, though at the time without commercial results, was that of Heath (1845), which indicated the fusion of material in a hearth, the maintenance of an extremely high temperature, and the employment of gaseous fuel. In a former patent (1839) Heath had claimed the addition of carburet of manganese. The oxides of manganese had been previously used in metallurgy; but the introduction of metallic manganese, alloyed with carbon, was an important novelty, which prefaced the employment by Mushet, Bessemer,
